PREFACE

Computers are an integral part of our economic, social, professional, governmental, and military infrastructures. They have become necessities in virtually every area of modern life, but their vulnerability is of increasing concern. Computer-based systems are constantly under threats of inadvertent error and acts of nature, as well as those attributable to unethical, immoral, and criminal activities. It is the purpose of *The Computer Security Handbook* to provide guidance in recognizing these threats, eliminating them where possible and, if not, then reducing any losses attributable to them.

The Handbook will be most valuable to those directly responsible for computer, network, or information security, as well as those who must design, install, and maintain secure systems. It will be equally important to those managers whose operating functions can be affected by breaches in security and to those executives who are responsible for protecting the assets that have been entrusted to them.

With the advent of desktop, laptop, and handheld computers, and with the vast international networks that interconnect them, the nature and extent of threats to computer security have grown almost beyond measure. In order to encompass this unprecedented expansion, *The Computer Security Handbook* has grown apace.

When the first edition of the *Handbook* was published, its entire focus was on main-frame computers, the only type then in widespread use. The second edition recognized the advent of small computers, while the third edition placed increased emphasis on PCs and networks.

Edition	Publication Date	Chapters	Text Pages
First	1973	12	162
Second	1988	19	383
Third	1995	23	571
Fourth	2002	54	1,184
Fifth	2009	77	2,040
Sixth	2014	75	2,224

The fourth edition of *The Computer Security Handbook* gave almost equal attention to mainframes and microcomputers, requiring more than twice the number of chapters and pages as the third.

xii PREFACE

The fifth edition was as great a step forward as the fourth. With 77 chapters and the work of 86 authors, we increased coverage in both breadth and depth. In this sixth edition, we updated all chapters while continuing to cover all 10 domains of the Common Body of Knowledge, as defined by the International Information Systems Security Certification Consortium (ISC)²:

1. Security Management Practices: Chapters 10, 12, 13, 14, 15, 19, 31, 43, 44, 45, 46, 47, 48, 49, 50, 51, 54, 55, 62, 63, 64, 65, 66, 67, 68, 74, 75
2. Security Architecture and Models: Chapters 1, 2, 3, 8, 9, 24, 26, 27, 51
3. Access Control Systems and Methodology: Chapters 15, 19, 28, 29, 32
4. Application Development Security: Chapters 13, 19, 21, 30, 38, 39, 52, 53
5. Operations Security: Chapters 13, 14, 15, 19, 21, 24, 36, 40, 47, 53, 57
6. Physical Security: Chapters 4, 13, 15, 19, 22, 23, 28, 29
7. Cryptography: Chapters 7, 32, 37, 42
8. Telecomm, Networks, and Internet Security: Chapters 4, 5, 6, 13, 14, 15, 16, 17, 18, 20, 21, 24, 25, 26, 27, 30, 31, 32, 33, 34, 35, 41, 48
9. Business Continuity Planning: Chapters 22, 23, 56, 57, 58, 59, 60
10. Law, Investigations, and Ethics: Chapters 11, 12, 13, 31, 42, 61

We have continued our practice from the fourth and fifth editions of inviting a security luminary to write the final chapter, “The Future of Information Assurance.” We are pleased to include this stellar contribution from Jeremy A. Hansen.

ACKNOWLEDGMENTS

Seymour Bosworth, Editor-in-Chief. I would like to give grateful recognition to Arthur Hutt and Douglas Hoyt, my coeditors of the first, second, and third editions of this *Handbook*. Although both Art and Doug are deceased, their commitment and their competence remain as constant reminders that nothing less than excellence is acceptable. Mich Kabay, my coeditor from the fourth and fifth editions, and Eric Whyne, our fellow editor from the fifth and now sixth editions, continue in that tradition. I would not have wanted to undertake this project without them.

Thanks are also due to our colleagues at John Wiley & Sons: Tim Burgard as former Acquisitions Editor, Helen Cho as Editorial Program Coordinator, Sheck Cho as Executive Editor, Kimberly Kappmeyer as Production Editor, Natasha Andrews as Senior Production Editor, and Darice Moore as Copyeditor. All have performed their duties in an exemplary manner and with unfailing kindness, courtesy, and professionalism.

M. E. Kabay, Technical Editor. I want to thank my beloved wife, Deborah Black, light of my life, for her support and understanding over the years that this project has taken away from our time together. I am also grateful to the authors who have selflessly contributed so much to updating the material presented in this text.

Eric Whyne, Administrative Editor. An undertaking as big as pulling together this handbook would not be possible without my wife Lindsay and the love and support she gives to me and to our son Colton. I'd also like to thank the friends and mentors that have helped me most in my career: Mich and Sy, Tom Aldrich, Tom Payne, Frank Vanecek, and my parents Len and Terri. Any successful undertakings I've had, including this book, have been from listening to the advice they've given and aspiring to internalize the virtues that they exemplify. The authors who have contributed to this book also deserve many thanks for sharing their experience and wisdom. It is something for which I, myself, and the readers are extremely grateful.

ABOUT THE EDITORS

Seymour Bosworth, M.S., CDP (email: sybosworth55@gmail.com) is president of S. Bosworth & Associates, Plainview, New York, a management consulting firm specializing in computing applications for banking, commerce, and industry. Since 1972, he has been a contributing editor for all six editions of the *Computer Security Handbook*, and for several editions has been Editor-in-Chief. He has written many articles and lectured extensively about computer security and other technical and managerial subjects. He has been responsible for the design and manufacture, systems analysis, programming, and operations, of both digital and analog computers. For his technical contributions, including an error-computing calibrator, a programming aid, and an analog-to-digital converter, he has been granted a number of patents, and is working on several others.

Bosworth is a former president and CEO of Computer Corporation of America, manufacturers of computers for scientific and engineering applications; president of Abbey Electronics Corporation, manufacturers of precision electronic instruments and digital devices; and president of Alpha Data Processing Corporation, a general-purpose computer service bureau. As a vice president at Bankers Trust Company, he had overall responsibility for computer operations, including security concerns.

For more than 20 years, Bosworth was an adjunct associate professor of management at the Information Technologies Institute of New York University, where he lectured on computer security and related disciplines. He has conducted many seminars and training sessions for the Battelle Institute, New York University, the Negotiation Institute, the American Management Association, and other prestigious organizations. For many years he served as arbitrator, chief arbitrator, and panelist for the American Arbitration Association. He holds a master's degree from the Graduate School of Business of Columbia University and a Certificate in Data Processing from the Data Processing Management Association.

M. E. Kabay, Ph.D., CISSP-ISSMP (email: mekabay@gmail.com) has been programming since 1966. In 1976, he received his Ph.D. from Dartmouth College in applied statistics and invertebrate zoology. After joining a compiler and relational database team in 1979, he worked for Hewlett-Packard (Canada) Ltd. from 1980 through 1983 as an HP3000 operating system performance specialist and then ran operations at a large service bureau in Montréal in the mid-1980s before founding his own operations management consultancy. From 1986 to 1996, he was an adjunct instructor in the John Abbott College professional programs in programming and in technical support. He was director of education for the National Computer Security Association from 1991 to the end of 1999 and was security leader for the INFOSEC Group of AtomicTangerine, Inc., from January 2000 to June 2001. In July 2001, he joined the

faculty at Norwich University as associate professor of computer information systems in the School of Business and Management. In January 2002, he took on additional duties as the director of the graduate program in information assurance in the School of Graduate and Continuing Studies at Norwich, where he was also chief technical officer for several years. He returned to full-time teaching in the School of Business and Management in 2009 and was promoted to professor of computer information systems in 2011. He serves as associate director of the Norwich University Center for Advanced Computing and Digital Forensics.

Kabay was inducted into the Information Systems Security Association Hall of Fame in 2004. He has published more than 1,500 articles in operations management and security in several trade journals since 1986. He wrote two columns a week for *Network World Security Strategies* between 2000 and 2011; archives are at www.mekabay.com/nwss. For the last three editions, Kabay has been Technical Editor of the *Computer Security Handbook*. He also has a Website with freely available teaching materials and papers at www.mekabay.com.

Eric Whyne (email: ericwhyne@gmail.com), administrative editor of the *Computer Security Handbook*, is a technical manager and engineer at Data Tactics Corporation where he develops solutions that benefit national security, currently managing and working on several DARPA-funded big data and data science projects. Prior to this position, he was employed by Exelis Corp. and managed the Joint Improvised Explosive Device Defeat Organization (JIEDDO) Counter-IED Operations Integration Center (COIC) Systems Integration Laboratory (SIL), which consisted of engineers and analysts tasked to develop, deploy, and maintain global software and systems designed to provide intelligence to help predict and prevent explosive devices in Iraq and Afghanistan. Previously, he worked as an engineer with Pennsylvania State University Applied Research Labs (PSU ARL) researching the development and use of immersive visualization systems, geospatial information systems, visual data mining, and deploying touch interfaces in operational environments.

Prior to his industry experience, Whyne spent nine years on active duty in the United States Marine Corps (USMC) in ground combat units, starting as enlisted and attaining the rank of captain. His accomplishments in the Marine Corps include two meritorious promotions and a Navy Commendation Medal with Valor distinction for actions in combat. During his time in the military, he worked in the fields of signals intelligence and communications and served as an advisor to the Iraqi Army. Since 2005, he has been the coordinating editor for the 5th and 6th editions of the *Computer Security Handbook*. He contributes to several open source projects, serves as an invited technical expert in the W3C HTML5 working group, and is a member of the AFCEA Technology Committee.

Whyne attended Norwich University and graduated magna cum laude with a B.S. in computer science and minor degrees in mathematics, information assurance, and engineering.

ABOUT THE CONTRIBUTORS

Wendy Adams Carr currently works for the U.S. Army Corps of Engineers as a member of the Computer Incident Response Team (CIRT). Prior to this she performed as an Information Assurance Security Engineer with Booz Allen & Hamilton, where she supported a Department of Defense client in developing and maintaining DITSCAP and DIACAP-based certification and accreditation of complex, large-scale Information Systems. She is retired from the U.S. Army. She is also an active member of Infragard.

Mani Akella, a director (technology), has been actively working with information-security architectures and identity protection for Consultantgurus and its clients. An industry professional for 20 years, he has worked with hardware, software, networking, and all the associated technologies that service information in all of its incarnations and aspects. Over the years, he has developed a particular affinity for international data law and understanding people and why they do what they do (or do not). He firmly believes that the best law and policy is that which understands and accounts for cross-cultural differences, and works with an understanding of culture and societal influences. To that end, he has been actively working with all his clients and business acquaintances to improve security policies and make them more people-friendly: His experience has been that the best policy is that which works with, instead of being antagonistic to, the end user.

Rebecca Gurley Bace is the president/CEO of Infidel, Inc., a strategic consulting practice headquartered in Scotts Valley, California. She is also a venture consultant for Palo Alto-based Trident Capital, where she is credited with building Trident's investment portfolio of security product and service firms. Her areas of expertise include intrusion detection and prevention, vulnerability analysis and mitigation, and the technical transfer of information-security research results to the commercial product realm. Prior to transitioning to the commercial world, she worked in the public sector, first at the National Security Agency, where she led the Intrusion Detection research program, then at the Computing Division of the Los Alamos National Laboratory, where she served as deputy security officer. Her publishing credits include two books, an NIST Special Publication on intrusion detection and prevention, and numerous articles on information-security technology topics.

Susan Baumes, MS, CISSP, is an information-security professional working in the financial services industry. In her current role, she works across the enterprise to develop information-security awareness and is responsible for application security. Her role also extends to policy development, compliance, and audit. She has 11 years'

experience in application development, systems and network administration, database management, and information security. Previously, she worked in a number of different sectors, including government (federal and state), academia, and retail.

Kurt Baumgarten, CISA, is vice president of information security and a partner at Peritus Security Partners, LLC, a leader in providing compliance-driven information security solutions. He is also a lecturer, consultant, and the developer of the DDIPS intrusion prevention technology as well as a pioneer in using best practices frameworks for the improvement of information technology security programs and management systems. He has authored multiple articles about the business benefits of sound information technology and information assurance practices, and assists businesses and government agencies in defining strategic plans that enhance IT and IA as positive value chain modifiers. He holds both a master's of science in information assurance and an M.B.A. with a concentration in e-commerce, and serves as an adjunct professor of information assurance. He has more than 20 years of experience in IT infrastructure and information security and is an active member of ISSA, ISACA, ISSSP, and the MIT Enterprise Forum. He periodically acts as an interim Director within external organizations in order to facilitate strategic operational changes in IT and information security.

Kevin Beets has been a research scientist with McAfee for over nine years. His work has concentrated on vulnerability, exploit and malware analysis, and documentation for the Foundstone and McAfee Labs teams. Prior to working with McAfee, he architected private LANS as well as built, monitored, and supported CheckPoint and PIX firewalls and RealSecure IDS systems.

Matt Bishop is a professor in the Department of Computer Science at the University of California at Davis and a codirector of the Computer Security Laboratory. His main research area is the analysis of vulnerabilities in computer systems, especially their origin, detection, and remediation. He also studies network security, policy modeling, and electronic voting. His textbook, *Computer Security: Art and Science*, is used widely in advanced undergraduate and graduate courses. He received his Ph.D. in computer science from Purdue University, where he specialized in computer security, in 1984.

Kip Boyle is the chief information-security officer of PEMCO Insurance, a \$350 million property, casualty, and life insurance company serving the Pacific Northwest. Prior to joining PEMCO Insurance, he held such positions as chief security officer for a \$50 million national credit card transaction processor and technology service provider; authentication and encryption product manager for Cable & Wireless America; senior security architect for Digital Island, Inc.; and a senior consultant in the Information Security Group at Stanford Research Institute (SRI) Consulting. He has also held director-level positions in information systems and network security for the U.S. Air Force. He is a Certified Information System Security Professional and Certified Information Security Manager. He holds a bachelor's of science in computer information systems from the University of Tampa (where he was an Air Force ROTC Distinguished Graduate) and a master's of science in management from Troy State University.

Jennifer Bradley is a member of the first Master of Science in Information Assurance graduating class at Norwich University. She is the primary Systems and Security Consultant for Indiana Networking in Lafayette, Indiana, and has served as both a

network and systems administrator in higher education and private consulting. She has almost 15 years' experience as a programmer and instructor of Web technologies, with additional interests in data backup, virtualization, authentication/identification, monitoring, desktop and server deployment, and incident response. At present she serves as an independent consultant. She has previously worked as a tester for quality and performance projects for Google, Inc., and as a collegiate adjunct instructor in computer technologies. She received a bachelor's of science in Industrial and Computer Technology from Purdue University.

Timothy Braithwaite has more than 30 years of hands-on experience in all aspects of automated information processing and communications. He is currently the deputy director of strategic programs at the Center for Information Assurance of Titan Corporation. Before joining Titan, he managed most aspects of information technology, including data and communications centers, software development projects, strategic planning and budget organizations, system security programs, and quality improvement initiatives. His pioneering work in computer systems and communications security while with the Department of Defense resulted in his selection to be the first systems security officer for the Social Security Administration (SSA) in 1980. After developing security policy and establishing a nationwide network of regional security officers, he directed the risk assessment of all payment systems for the agency. In 1982, he assumed the duties of deputy director, systems planning and control of the SSA, where he performed substantive reviews of all major acquisitions for the associate commissioner for systems and, through a facilitation process, personally led the development of the first Strategic Systems Plan for the administration. In 1984, he became director of information and communication services for the Bureau of Alcohol, Tobacco, and Firearms at the Department of Treasury. In the private sector, he worked in senior technical and business development positions for SAGE Federal Systems, a software development company; Validity Corporation, a testing and independent validation and verification company; and J.G. Van Dyke & Associates, where he was director, Y2K testing services. He was recruited to join Titan Corporation in December 1999 to assist in establishing and growing the company's Information Assurance practice.

Dr. Paul Brusil founded Strategic Management Directions, a security and enterprise management consultancy in Beverly, Massachusetts. He has been working with various industry and government sectors, including healthcare, telecommunications, and middleware to improve the specification, implementation, and use of trustworthy, quality, security-related products and systems. He supported strategic planning that led to the National Information Assurance Partnership and other industry forums created to understand, promote, and use the Common Criteria to develop security and assurance requirements and to evaluate products. He has organized, convened, and chaired several national workshops, conferences, and international symposia pertinent to management and security. Through these and other efforts to stimulate awareness and cooperation among competing market forces, he spearheaded industry's development of the initial open, secure, convergent, standards-based network and enterprise management solutions. While at the MITRE Corp, he led research and development critical to the commercialization of the world's first LAN solutions. Earlier, at Harvard, he pioneered research leading to noninvasive diagnosis of cardiopulmonary dysfunction. He is a Senior Member of the IEEE, a member of the Editorial Advisory Board of the *Journal of Network and Systems Management* (JNSM), has been senior technical editor for JNSM, is the guest editor for all JNSM's Special Issues on Security and Management,

xx ABOUT THE CONTRIBUTORS

and is a lead instructor for the adjunct faculty supporting the master's of science in information assurance degree program at Norwich University. He has authored over 100 papers and book chapters. He graduated from Harvard University with a joint degree in Engineering and Medicine.

Michael Buglewicz is employed at National Security Technologies as a section manager whose team provides technology and communications solutions to various government agencies. He spent 17 years at Microsoft in various roles in services and business management. Prior to Microsoft, he was involved with building some of the first Internet ecommerce and banking solutions while at First Data Corporation; he also spent ten years in law enforcement. In addition to his contributions to *The Computer Security Handbook*, he was a contributing author to *The Encyclopedia of Information Assurance* and, most recently, contributed to the book *Cloud Migration* by Tobias Hollwarth.

Dr. Joseph R. Bumblis is currently a research specialist with the Institute of Electrical and Electronic Engineers (IEEE) Twin Cities (TC) Section's Phoenix Project, where he conducts research and engineering projects in the areas of sensors, signal processing, and embedded systems design. His expertise includes computer networks, embedded systems with FPGA and SoC codesign, IT systems security, and software engineering methodologies. As an Associate Professor of Computer Engineering at the University of Wisconsin-Stout (UW-Stout), he developed computer engineering curriculum and taught courses in digital design, solid-state devices, embedded systems design, and Verilog programming. Prior to joining UW-Stout, he served as an IT systems architect at BAE Systems and held several adjunct professor positions where he taught software engineering and computer networking courses.

Q. Campbell has worked in the information-security field for over six years. He specializes in information-security threat analysis and education.

Santosh Chokhani is the founder and president of CygnaCom Solutions, Inc., an Entrust company specializing in PKI. He has made numerous contributions to PKI technology and related standards, including trust models, security, and policy and revocation processing. He is the inventor of the PKI Certificate Policy and Certification Practices Statement Framework. His pioneering work in this area led to the Internet RFC that is used as the standard for CP and CPS by governments and industry throughout the world. Before starting CygnaCom, he worked for The MITRE Corporation from 1978 to 1994. At MITRE, he was senior technical manager and managed a variety of technology research, development, and engineering projects in the areas of PKI, computer security, expert systems, image processing, and computer graphics. Chokhani obtained his master's (1971) and Ph.D. (1975) in electrical engineering/computer science from Rutgers University, where he was a Louis Bevier Fellow from 1971 to 1973.

Christopher Christian is a first lieutenant and an aviator in the United States Army. He received a bachelor's degree in Computer Information Systems at Norwich University class of 2005. His primary focus of study was Information Assurance and Security. He worked as an intern for an engineering consulting company for three years. He developed cost/analysis worksheets and floor-plan layouts to maximize workspace efficiency for companies in various industries. He graduated flight school at Fort Rucker, Alabama, where he trained on the H-60 Blackhawk. He serves as a flight

platoon leader in an air assault battalion. He is currently serving in Iraq in support of Operation Iraqi Freedom 08–09.

Chey Cobb, CISSP, began her career in information security while at the National Computer Security Association (now known as TruSecure/ICSA Labs). During her tenure as the NCSA award-winning Webmaster, she realized that Web servers often created security holes in networks and became an outspoken advocate of systems security. Later, while developing secure networks for the Air Force in Florida, her work captured the attention of the U.S. intelligence agencies. She moved to Virginia and began working for the government as the senior technical security advisor on highly classified projects. Ultimately, she went on to manage the security program at an overseas site. Now semiretired, she writes books and articles on computer security and is a frequent speaker at security conferences.

Stephen Cobb, CISSP, is an independent information-security consultant and an adjunct professor of information assurance at Norwich University, Vermont. A graduate of the University of Leeds, his areas of expertise include risk assessment, computer fraud, data privacy, business continuity management, and security awareness and education. A frequent speaker and seminar leader at industry conferences around the world, he is the author of numerous books on security and privacy as well as hundreds of articles. He cofounded several security companies whose products expanded the range of security solutions available to enterprises and government agencies. As a consultant, he has advised some of the world's largest companies on how to maximize the benefits of information technology by minimizing IT risks.

Caleb S. Coggins, MSIA, GSNA, CISSP, CISA, currently works for Sylint in the area of network forensics. Prior to Sylint, he operated in an internal audit and advisory services capacity for a healthcare IT company in Tennessee that focused on revenue and payment cycle management. Previous to that, he served in IT, security, and audit functions at Bridgestone Americas and its subsidiaries for over eight years. During his time working in the Americas and West Africa, he has enjoyed collaborating with management and teammates in identifying practical and effective solutions, while reducing risk to business operations. Prior to Bridgestone, he was the information manager for a private company as well as an information-security consultant to business clients. He holds a B.A. from Willamette University and an M.S. in information assurance from Norwich University.

Bernie Cowens, CISSP, CISA, is chief information-security officer at a Fortune 500 company in the financial services industry. He is an information risk, privacy, and security expert with more than 20 years' experience in industries including defense, high technology, healthcare, financial, and Big Four professional services. He has created, trained, and led a number of computer emergency, forensic investigation, and incident response teams over the years. He has real-world experience responding to attacks, disasters, and failures resulting from a variety of sources, including malicious attackers, criminals, and foreign governments. He has served as an advisor to and a member of national-level panels charged with analyzing cybersystem threats to critical infrastructures, assessing associated risks, and recommending both technical and nontechnical mitigation policies and procedures. He holds a master's degree in management information systems along with undergraduate degrees and certificates in systems management and information processing.

xxii ABOUT THE CONTRIBUTORS

Tim Crothers is an IT manager at 3M IT.

Rob Cryan is chief information-security officer for MAPFRE USA, consisting of seven property and casualty insurance companies in the United States. He has corporate responsibility for all aspects of information security and business continuity. He has worked in both the corporate and the consulting fields, managing and delivering security solutions. His current areas of focus include managing risk in cloud computing and delivering cost-effective risk management derived from larger, often cumbersome models to apply uniform controls across multiple compliance disciplines. He received his B.S. in business administration management from the University of Maine. He is currently pursuing his M.S. in information systems and technology management with a concentration in information assurance and security.

Christopher Dantos is a senior architectural specialist with Computer Science Corporation's Global Security Solutions Group. His areas of expertise include 802.11, VoIP, and Web application security. Prior to joining CSC, he spent 10 years as a security architect with Motorola Inc., including five years in the Motorola Labs Wireless Access Research Center of Excellence. He holds a master's of science degree in information assurance from Norwich University and a bachelor's of science degree in marine engineering from the Maine Maritime Academy.

Scott L. David is executive director of the Law, Technology, and Arts Group at the University of Washington School of Law.

Chris Davis, MBA, CISA, CISSP, CCNP, finds that his role as a cloud security and compliance product manager at VCE enables him to apply his past experiences to the latest in data center computing. He has trained and presented in information security, audit, forensic analysis, hardware security design, auditing, and systems engineering for government, corporate, and university requirements. He has written or contributed to nine books covering multiple security disciplines and teaches as an adjunct professor at Southern Methodist University covering graduate courses in Information Security and Risk Management (EMIS7380) and IT Controls (EMIS7382). His professional career has taken him through Texas Instruments followed by several startup and consulting roles. He holds a bachelor's degree in nuclear engineering technologies from Thomas Edison State College and a master's in business from the University of Texas McCombs School of Business at Austin. He served eight years in the U.S. Naval Submarine Fleet onboard the special projects Submarine NR-1 and the ballistic missile submarine USS Nebraska.

Seth Finkelstein is a professional programmer with degrees in Mathematics and in Physics from MIT. He cofounded the Censorware Project, an anti-censorware advocacy group. In 1998, his efforts evaluating the sites blocked by the library's Internet policy in Loudoun County, Virginia, helped the American Civil Liberties Union win a federal lawsuit challenging the policy. In 2001, he received a Pioneer of the Electronic Frontier Award from the Electronic Frontier Foundation for his groundbreaking work in analyzing content-blocking software. In 2003, he was primarily responsible for winning a temporary exemption in the Digital Millennium Copyright Act allowing for the analysis of censorware.

Eric Fisher is a systems architecture and network security engineer for Penn State University's Applied Research Laboratories and is currently a master's candidate

in the field of information security and forensics. Eric has extensive experience designing and implementing high performance and redundant compute systems for the Department of Defense and the IC at large. His areas of expertise are designing and implementing secure and scalable information systems, and the networks that connect them. Before joining Penn State, he worked for the Raytheon Corporation as a *nix/Windows/Network administrator where he managed large-scale high-availability clusters.

Robert Gezelter, CDP, has over 33 years of experience in computing, starting with programming scientific/technical problems. Shortly thereafter, his focus shifted to operating systems, networks, security, and related matters, where he has 32 years of experience in systems architecture, programming, and management. He has worked extensively in systems architecture, security, internals, and networks, ranging from high-level strategic issues to the low-level specification, design, and implementation of device protocols and embedded firmware. He is an alumnus of the IEEE Computer Society's Distinguished Visitor Program for North America, having been appointed to a three-year term in 2004. His appointment included many presentations at Computer Society chapters throughout North America. He has published numerous articles, appearing in *Hardcopy*, *Computer Purchasing Update*, *Network Computing*, *Open Systems Today*, *Digital Systems Journal*, and *Network World*. He is a frequent presenter at conference sessions on operating systems, languages, security, networks, and related topics at local, regional, national, and international conferences, speaking for DECUS, Encompass, IEEE, ISSA, ISACA, and others. He previously authored the mobile code and Internet-related chapters for the 4th edition of this *Handbook* (2002) as well as the "Internet Security" chapters of the 3rd edition (1995) and its supplement (1997). He is a graduate of New York University with B.A. (1981) and M.S. (1983) degrees in computer science. He founded his consulting practice in 1978, working with clients both locally and internationally. He maintains his offices in Flushing, New York. He may be contacted via his firm's Website at www.rlgsc.com.

Dr. Anup K. Ghosh is president and chief executive of Secure Command, LLC, a security software start-up developing next-generation Internet security products for corporate networks. He also holds a position as research professor at George Mason University. He was previously senior scientist and program Manager in the Advanced Technology Office of the Defense Advanced Research Projects Agency (DARPA), where he managed an extensive portfolio of information assurance and information operations programs. He previously served in executive management as Vice President of Research at Cigital, Inc. He has served as principal investigator on contracts from DARPA, NSA, and NIST's Advanced Technology Program and has written more than 40 peer-reviewed conference and journal articles. He is also author of three books on computer network defense, serves on the editorial board of *IEEE Security and Privacy Magazine*, and has been guest editor for *IEEE Software* and *IEEE Journal on Selected Areas in Communications*. He is a Senior Member of the IEEE. For his contributions to the Department of Defense's information assurance, he was awarded the Frank B. Rowlett Trophy for Individual Contributions by the National Security Agency in November 2005, a federal government-wide award. He was also awarded the Office of the Secretary of Defense Medal for Exceptional Public Service for his contributions while at DARPA. In 2005, Worcester Polytechnic Institute awarded him its Hobart Newell Award for Outstanding Contributions to the Electrical and Computer Engineering Profession. He has previously been awarded the IEEE's Millennium Medal for Outstanding Contributions to E-Commerce Security. He completed his Ph.D. and

master's of science in electrical engineering at the University of Virginia and his bachelor's of science in electrical engineering at Worcester Polytechnic Institute.

Donald Glass, CISA, CISSP, has over 15 years of experience in the IT Auditing and Information Security fields. He is the current director of IT audit for Kerzner International. Author of several information security and IT audit articles, he is recognized as a leader in the IT audit field and information security.

Robert Guess, CISSP, NSA-IAM, NSA-IEM, is a senior security engineer at a Fortune 500 organization and an Associate Professor of Information Systems Technology. He possesses an M.S. in information assurance and has over a dozen industry certifications, including the Certified Information Systems Security Practitioner (CISSP), National Security Agency INFOSEC Assessment Methodologist (NSA-IAM), and National Security Agency INFOSEC Evaluation Methodologist (NSA-IEM). In addition to his academic experience, his professional experience includes work within the air, space, and defense sectors, serving as primary subject matter expert on a National Science Foundation cybersecurity grant, the development of workforce certification standards for information assurance professionals (DOD 8570.01-m), and periodic work as both an editor and author (e.g., the 5th and 6th editions of *The Computer Security Handbook*, etc.). His work in recent years has focused on penetration testing, incident response, the forensic analysis of digital evidence, virtualization, and cloud computing.

David Gursky, CISA, CISM, CISSP, is an information assurance manager and researcher at Raytheon Integrated Defense Systems working in Crystal City, Virginia. He is principal investigator for behavior-based intrusion detection systems, attribute-based access control, and resource-efficient authentication techniques. He held several senior positions as a Department of Defense contractor supporting information assurance programs and has over 30 years' experience in information technology and information security. He has conducted numerous security audits for PriceWaterhouse and Coopers. He has a bachelor's of science degree in business management from Southern New Hampshire University, a master's of science degree from Norwich University, and an M.B.A. from Northeastern University. In addition, he holds a CISA, CISM, and CISSP certifications. He lives in Northern Virginia and is an active member of (ISC)² and ISACA.

Jennifer Hadley is a member of the first master's of science in information assurance graduating class at Norwich University. She is the primary systems and security consultant for Indiana Networking in Lafayette, Indiana, and has served as both a network and systems administrator in higher education and private consulting. She has almost 10 years' experience as a programmer and instructor of Web technologies with additional interests in data backup, virtualization, authentication/identification, monitoring, desktop and server deployment, and incident response. At present, she serves as a technology consultant for Axcell Technologies, Inc. Previously she worked as a tester for quality and performance projects for Google, Inc., and as a collegiate adjunct instructor in computer technologies. She received a bachelor's of science degree in industrial and computer technology from Purdue University.

Carl Hallberg, CISSP, has been a UNIX systems administrator for years as well as an information-security consultant. He has also written training courses for subjects including firewalls, VPNs, and home network security. He has a bachelor's degree in

psychology. Currently, he is a senior member of an incident response team for a major U.S. financial institution.

Jeremy A. Hansen is an information-security and cryptography educator and researcher.

David Harley, CITP, FBCS, CISSP, is CEO of Small Blue-Green World, COO of AVIEN, and ESET Senior Research Fellow, specializing in antimalware research and security/technical authoring and editing in a number of areas. His books include *Viruses Revealed* and *The AVIEN Malware Defense Guide*. Previously, he managed the UK National Health Service's Threat Assessment Centre, and before that he served as security analyst for the Imperial Cancer Research Fund (now Cancer Research UK). His academic background is in social sciences and computer science, and he is a fellow of the BCS Institute (formerly the British Computer Society).

Benjamin S. Hayes is an IT specialist at Travis Software.

Kevin Henry has been involved in computers since 1976, when he was an operator on the largest minicomputer system in Canada. He has since worked in many areas of information technology, including computer programming, systems analysis, and information technology audit. He was asked to become director of security based on the evidence of his audits and involvement in promoting secure IT operations. Following 20 years in the telecommunications field, he moved to a senior auditor position with the State of Oregon, where he was a member of the Governor's IT Security Subcommittee and performed audits on courts and court-related IT systems. He has extensive experience in risk management and business continuity and disaster recovery planning. He frequently presents papers at industry events and conferences and is on the preferred speakers list for nearly every major security conference. Since joining (ISC)² as their first full-time program manager in 2002, he has been responsible for research and development of new certifications, courseware, and development of educational programs and instructors. He has also been providing support services and consulting for organizations that require in-depth risk analysis and assistance with specific security-related challenges. This has led to numerous consulting engagements in the Middle East and Asia for large telecommunications firms, government departments, and commercial enterprises.

Don Holden, CISSP, ISSMP, is a principal consultant with Concordant specializing in information security. He has more than 20 years of management experience in information systems, security, encryption, business continuity, and disaster recovery planning in both industry and government. Previously he was a technology leader for RedSiren Technologies (formerly SRI Consulting). His achievements include leading a cyberinsurance joint venture project, developing privacy and encryption policies for major financial institutions, and recommending standards-based information technology security policies for a federal financial regulator. Holden is an adjunct professor for the Norwich University's master's of science in information assurance. He received an M.B.A. from Wharton and is a Certified Information System Security Professional and Information System Security Management Professional.

Dr. John D. Howard is a former Air Force engineer and test pilot who currently works in the Security and Networking Research Group at the Sandia National Laboratories, Livermore, California. His projects include development of the SecureLink software for

automatic encryption of network connections. He has extensive experience in systems development, including an aircraft–ground collision avoidance system for which he holds a patent. He is a graduate of the Air Force Academy, has master’s degrees in both aeronautical engineering and political science, and has a Ph.D. in engineering and public policy from Carnegie Mellon University.

Arthur E. Hutt, CCEP. The late Arthur E. Hutt was an information systems consultant with extensive experience in banking, industry, and government. He served as a contributing editor to the 1st, 2nd, and 3rd editions of *The Computer Security Handbook*. He was a principal of PAGE Assured Systems, Inc., a consulting group specializing in security and control of information systems and contingency/disaster recovery planning. He was a senior information systems executive for several major banks active in domestic and international banking. His innovative and pioneering development of online banking systems received international recognition. He was also noted for his contributions to computer security and to information systems planning for municipal government. He was on the faculty of the City University of New York and served as a consultant to CUNY on curriculum and on data processing management. He also served on the mayor’s technical advisory panel for the City of New York. He was active in development of national and international technical standards, via ANSI and ISO, for the banking industry.

John B. Ippolito, CISSP, PMP, is director of information assurance services for the Allied Technology Group, Inc. He has more than 35 years of IT experience including “hands-on” experience with legacy mainframes, PCs, and virtual systems. He has supported government-wide standards efforts and coauthored NIST IT security training guidelines. He has a broad range of IT experience and is currently supporting federal agencies in the development of information assurance and privacy programs and the secure introduction of new technologies such as cloud-based systems and “bring your own device” into the business environment.

Robert V. Jacobson, CPP, CISSP. The late Robert V. Jacobson was the president of International Security Technology, Inc., a New York City–based risk-management consulting firm. He founded IST in 1978 to develop and apply superior risk-management systems. Current and past government and industry clients are located in the United States, Europe, Africa, Asia, and the Middle East. He pioneered many of the basic computer security concepts now in general use. He served as the first information system security officer at Chemical Bank, now known as J P Morgan Chase. He was a frequent lecturer and had written numerous technical articles. He held B.S. and M.S. degrees from Yale University, and was a Certified Information Systems Security Professional. He was also a Certified Protection Professional of the American Society for Industrial Security. He was a member of the National Fire Protection Association and the Information Systems Security Association. In 1991, he received the Fitzgerald Memorial Award for Excellence in Security from the New York Chapter of the ISSA.

David J. Johnson is an information-security architect with a Fortune 500 financial services company where he provides enterprise guidance and solutions on topics such as cloud computing security, data protection technologies, and biometric authentication. His prior experience includes information-security analysis, advising business and IT management and staff on security risk, and development of policies and

procedures for a Fortune 1000 company. He also has experience designing, developing, and maintaining electronic commerce (EC/EDI) infrastructure and data transfers for a national financial services company. He holds a B.S. in business administration from Oregon State University, an M.S. in information assurance from Norwich University, and multiple information-security certifications from (ISC)², ISACA, and the Cloud Security Alliance.

Henry L. Judy is of counsel to Kirkpatrick & Lockhart, a national U.S. law firm. He advises clients on a wide range of corporate and financial law matters as well as federal and state securities, legislative and regulatory matters, with a particular emphasis on financial institutions, housing finance, and technology law. He is recognized for his work on the jurisdiction and dispute resolution issues of electronic commerce. He is a graduate of Georgetown University (J.D. and A.B.).

Sean Kelley is the vice president of technology services at Evolvent Technologies in Herndon, Virginia. He is a retired Naval Officer with over 15 years of information assurance experience. Sean Kelley has received an M.A. in computer resource and information management from Webster University and an M.S. in information technology management (information assurance core competency) from the Naval Postgraduate School (NPS) in Monterey, California. He concentrated his studies on computer and network security by taking classes through the NPS Center for INFOSEC Studies and Research (NPS CISR), the world's foremost center for military research and education in information assurance (IA), defensive information warfare, and computer and network security. During his tenure at NPS, he received several certifications from the Committee of National Security Systems (CNSS), which operates under NSA. He is a Certified Information Systems Security Professional (CISSP), and is also a Project Management Professional (PMP). He has been responsible for information systems at several high-level offices in Washington, DC, and in the operational setting.

David M. Kennedy, CISSP, is TruSecure Corporation's chief of research. He directs the Research Group to provide expert services to TruSecure Corporation members, clients, and staff. He supervises the Information Security Reconnaissance (IS/R) team, which collects security-relevant information, both above- and underground in TruSecure Corporation's IS/R data collection. IS/R provides biweekly and special topic reports to IS/R subscribers. He is a retired U.S. Army Military Police officer. In his last tour of duty, he was responsible for enterprise security of five LANs with Internet access and over 3,000 personal computers and workstations. He holds a B.S. in forensic science.

Dr. Gary C. Kessler, CISSP, CCE, is an associate professor of Homeland Security at Embry-Riddle Aeronautical University in Daytona Beach, Florida, specializing in cybersecurity. He is a member of the North Florida Internet Crimes against Children (ICAC) Task Force and an adjunct faculty member at Edith Cowan University in Perth, Western Australia. From 2011 to 2012, he was the program director of the M.S. in Information Assurance program at Norwich University in Northfield, Vermont; from 2000 to 2010, he was an associate professor at Champlain College in Burlington, Vermont, where he designed and directed undergraduate and graduate programs related to information security and digital forensics. He is a Certified Information Systems Security Professional (CISSP), Certified Computer Examiner (CCE), and on the board of directors of the Consortium of Digital Forensic Specialists (CDFS). He holds a B.A.

in mathematics, an M.S. in computer science, and a Ph.D. in computing technology in education. He is the coauthor of two professional texts and over 70 articles and papers, a frequent speaker at industry events, and immediate past editor-in-chief of the *Journal of Digital Forensics, Security, and Law*. More information about him can be found at www.garykessler.net.

Dr. Minjeong Kim is associate professor of Journalism and Technical Communication at the Colorado State University. Her areas of expertise include communication law and policy, copyright law, and digital media. Her research has been published in scholarly journals, including *Communication Law and Policy*, the *Journal of the Copyright Society of the U.S.A.*, the *Journal of Computer-Mediated Communication*, and *Telecommunications Policy*. She completed her M.A. and Ph.D. from the School of Journalism and Mass Communication at the University of North Carolina at Chapel Hill. Before joining the CSU faculty in Fall 2008, she was an assistant professor at Hawaii Pacific University in Honolulu.

David A. Land served in the U.S. Army as a Counterintelligence Special Agent. With David Christie, he developed and hosted the first Department of Defense Computer Crimes Conference. Since then he has investigated espionage cases for both the Army and the Department of Energy. He serves as the information technology coordinator for Anniston City Schools in Alabama and as an adjunct professor for Norwich University, his alma mater.

David T. Lang joined the U.S. Civil Service on August 15, 2011. He has more than 30 years of experience in technical program management, counterespionage, anti-terrorism, security, training, risk management, and law enforcement in private industry and the military. Before assuming his current position as director of the DCIN-TS PMO, he was the chief of enterprise architecture and security for the DCIN-TS PMO. His industry positions included director of federal security, director of information assurance and forensics, director of digital forensics, and director of external training. His military assignments included nearly a decade as a Special Agent for the Air Force Office of Special Investigations (AFOSI) and over a decade in special weapons.

Dr. David R. Lease is the Chief Solution Architect at Computer Sciences Corporation. He has over 30 years of technical and management experience in the information technology, security, telecommunications, and consulting industries. His recent projects include a \$2 billion security architecture redesign for a federal law enforcement agency and the design and implementation of a secure financial management system for an organization operating in 85 countries. He is a writer and frequent speaker at conferences for organizations in the intelligence community, Department of Defense, civilian federal agencies, as well as commercial and academic organizations. He is also a peer reviewer of technical research for the IEEE Computer Society. Additionally, he is on the faculty of Norwich University and the University of Fairfax, where he teaches graduate-level information assurance courses and supervises doctoral-level research.

Corinne Lefrançois is an information assurance analyst at the National Security Agency. She graduated from Norwich University with a bachelor's of science in business administration and accounting in 2004 and is a current student in Norwich University's master's of science in information assurance program.

Dr. Diane E. Levine, DBA, CISSP, CFE, FBCI, CPS, is an internationally sought after security expert with Strategic Systems Management Ltd, a leader in the computer security field for 25 years. She is one of the initial developers of the Certification for Information System Professionals (CISSP) who contributed to the creation, acceptance, and expansion of both the program and the written examinations. Besides teaching both the CISSP and CISA review courses for many years, as an adjunct professor, she created the popular graduate program in Computer Security at New York University, a program that became the model for computer security university programs throughout the world. A prominent consultant, author, and teacher, she has had a notable career developing and implementing risk management, business continuity, and enterprise security systems in corporate, nonprofit, and government institutions and organizations throughout the world. She is widely published in trade and academic press and contributed numerous chapters to the 3rd, 4th, and 5th editions of *The Computer Security Handbook*. A sought-after public speaker and member of technical panels, she served on the board of directors for numerous professional education and certification organizations (i.e., Information System Security Professionals [ISSP], Association of Certified Fraud Examiners [ACFE], Business Continuity Institute [BCI], Contingency Planning Exchange [CPE], and the Information Security, Auditing and Control Association [ISACA]). She has published regularly in print and online at *Information Week*, *Information Security*, *Executive Security*, *Internet Week*, *The TechWriter*, *EarthWeb*, *Planet IT*, *Security, Technology & Design*, *internet.com*, *Smart Computing*, *Labmice.techtarget.net*, *Auerbach Publications*, *Journal for the EDP Auditors*, and many other prominent publications. Both through teaching and publishing, much of her professional career has been devoted to developing and expanding the specialty of computer security and mentoring others. As of 2011, she has been presented with numerous awards for excellence in and her contribution to the computer security and business continuity fields. A former high-ranking corporate executive, she currently works with corporations, organizations, and governments throughout the world and is actively involved with law enforcement agencies in the apprehension and conviction of computer security criminals and the implementation of computer security legislation. Previously published obituaries by John Wiley & Sons were never corrected and remain in print, although they are totally untrue and misleading.

Dr. James Landon Linderman is an associate professor in the Computer Information Systems department at Bentley College, Waltham, Massachusetts, where he has taught for 30 years. He is a research fellow at Bentley's Center for Business Ethics, and past vice-chair of the Faculty Senate. A resident of Fitzwilliam, New Hampshire, he is a Permanent Deacon in the Roman Catholic Diocese of Worcester, Massachusetts, and a consultant in the area of computer-assisted academic scheduling and timetable construction.

Steven Lovaas, MSIA, CISSP, is the information technology security manager for Colorado State University, where he is pursuing a Ph.D. in public communication and technology. His areas of expertise include IT security policy and architecture; communication and teaching of complex technical concepts; and security issues in both K–12 and higher education. He has taught for the M.S. program in information assurance at Norwich University, and founded OMBRA Research Associates to provide technical and security consultation for social science research. As part of his volunteer commitment to educating the next generation of scientists and engineers, he serves as the president of the Colorado Science Olympiad.

xxx ABOUT THE CONTRIBUTORS

Allysa Myers is the Director of Research for West Coast Labs. Her primary responsibilities are researching and analyzing technology and security threat trends as well as reviewing and developing test methodologies. Prior to joining West Coast Labs, she spent 10 years working in the Avert group at McAfee Security, Inc. While there, she wrote for the Avert blog and *Sage* magazine, plus several external publications. She also provided training demonstrations to new researchers within McAfee, along with other groups such as the Department of Defense and McAfee Technical Support and Anti-Spyware teams. She has been a member of various security industry groups, such as the Wildlist and the Drone Armies mailing list.

John Mason is the vice president and audit manager at PacTrust Bank, a part-time director at SSAE 16 Professionals, and an adjunct professor for Norwich University's MSIA program. He has over 20 years' combined experience in internal audit, regulatory compliance, information security, SSAE 16s/SAS 70s, enterprise risk management, investigations/loss prevention, and process reengineering. He has held senior positions such as chief internal auditor and vice president of audit and compliance in a variety of companies. At two multi-billion-dollar institutions, he was the chief information security officer (CISO) and helped establish information risk-management programs, as well as designing risk-based audit programs several years before Sarbanes-Oxley. He has routinely authored, reviewed, and researched finance control policies and procedures; performed audits for governmental agencies; and managed a full spectrum of financial, operational, SOX compliance, and data processing audits. He possesses an M.B.A., a B.A. in economics, and numerous certificates, including a CISM, CISA, CGEIT, and CFE. Currently, he resides in southern California. Aside from trying to help his students maximize their value, John's favorite tenet is "Learn from the mistakes of others, because you'll never live long enough to make them all yourself."

Peter Mell is a senior computer scientist in the computer security division at the National Institute of Standards and Technology. He is the program manager for the National Vulnerability Database as well as the Security Content Automation Protocol validation program. These programs are widely adopted within the U.S. government and used for standardizing and automating vulnerability and configuration management, measurement, and policy compliance checking. He has written the NIST publications on patching, malware, intrusion detection, common vulnerability scoring system, and the common vulnerabilities and exposures standard. His research experience includes the areas of intrusion detection systems, vulnerability scoring, and vulnerability databases.

Michael Miora has designed and assessed secure, survivable, highly robust systems for industry and government over the past 30 years. He was one of the original professionals granted the CISSP in the 1990s and the ISSMP in 2004, and was accepted as a Fellow of the Business Continuity Institute (BCI) in 2005. He founded and currently serves as president of ContingenZ Corporation (www.contingenz.com). He was educated at the University of California Los Angeles and the University of California Berkeley, earning bachelor's and master's degrees in mathematics. He is an adjunct professor at Norwich University, and a frequent speaker and consultant in the area of information assurance.

Richard O. Moore III has over 20 years of information-security experience, starting with 15 years in the Marine Corps intelligence community. After leaving the Marines

as the Regimental Intelligence Chief, he worked as a security consultant for Investor's Bank and Trust, preparing them for Sarbanes Oxley and a security review of their environment. At the end of that contract, he went to work for KPMG within their security consulting practice, where he performed security reviews, audits, and penetration testing activities. He left KPMG as an associate director in the Information Security Group managing the global penetration testing team and moved to the Royal Bank of Scotland Citizens Bank, where he created the security auditing function as the senior audit manager. He has continued with the Bank and is now the senior information security manager responsible for the Technical Services group, which consists of the Forensic, Penetration Testing, Risk Assessment, Cyber Intelligence, and Information Security Consultancy services. He has served on numerous industry boards, such as Board of Directors Massachusetts InfraGard, Norwich Editorial Board, and the ISACA Academic SubCommittee, and is a contributing author to the 5th and 6th editions of *The Computer Security Handbook*.

Scott J. Nathan, Esq., is an attorney whose practice includes litigation concerning intellectual property and technology matters, computer fraud and abuse, and environmental and insurance coverage matters involving the exchange of millions of pages of documents. In addition, he advises clients about, among other things, Internet-related risks and risk avoidance, proprietary and open source software licensing, service-level agreements, and insurance coverage. He has written and spoken extensively about such issues as online privacy, cyberspace jurisdiction, and the legal issues surrounding the use of open source software. He is admitted to practice before the United States Supreme Court, the United States Court of Appeals for the First Circuit, the Federal District Court for the District of Massachusetts, and the Courts of the Commonwealth of Massachusetts. He is a member of the American Bar Association's Litigation and Computer Litigation Committees.

Carl Ness, CISSP, is a senior security analyst for the University of Iowa. He has more than 10 years' experience in the information technology and information-security fields, mainly in the academic and healthcare sector. He is a speaker, author, and educator on information assurance, including security in the academic environment, messaging security, disaster recovery and business continuity, safe home computing, and information technology operations. He previously served as a systems administrator, network administrator, information technology director, and information-security officer. He holds an M.S. degree and also provides consulting to several security software development organizations.

Lester E. Nichols III has more than 15 years' experience in information technology, including: technology computing, cybersecurity, information assurance, and enterprise and security architecture. His experiences span the medical, nonprofit, financial, and local and federal government sectors in a variety of roles, including: application developer, network engineering, security operations manager, and information-security architect. He is a published author, contributing to major security publications such as the fifth and sixth editions of *The Computer Security Handbook*, and is a frequent contributor to the (ISC)² blog and other security-related communities and lectures. He also teaches college-level computing courses and provides computing lectures at secondary schools. Prior to joining ApplyLogic, he served in various technical, consulting, and leadership roles with both federal and commercial clients, such as the Administrative Offices of U.S. Courts, KCG, Prolific Solutions, the University of California Irvine,

and the University of Phoenix, and as a federal employee with the U.S. Department of Homeland Security, Transportation Security Administration.

Justin Opatrny currently works for a Fortune 500 company specializing in security infrastructure. He also is an adjunct instructor teaching information assurance courses and an independent consultant providing technology and security services. He holds a master's degree in information assurance from Norwich University; he holds industry certifications, including CISSP, GCFA, GSNA, and CASP; and he is an active member of the Information Systems Security Association and InfraGard.

Dr. John Orlando speaks and consults on the use of social media in disaster response, marketing, sales, business development, and training. He developed and managed the Master's of Science in Business Continuity Management program at Norwich University in Vermont, created the Social Media in Disaster Response LinkedIn Group, and has written over 20 articles on business continuity and disaster response in publications such as *Continuity Insights*, *Disaster Recovery Journal*, *Global Assurance*, *CFO*, and *The Definitive Handbook on Business Continuity Management*.

Dr. Raymond Panko is a professor of information technology management in the Shidler College of Business at the University of Hawaii. His interest in security began during lunches with Donn Parker in the 1970s at SRI International and has grown ever since. His textbook on IT security, *Corporate Computer and Network Security*, is published by Prentice-Hall. His current research focuses are security for end-user applications (especially spreadsheets), how to deal with fraud, and human and organizational controls. His main teaching focus, however, remains networking. In his networking classes and textbook, he emphasizes security throughput, pointing out the security implications of network protocols and practices.

Robert A. Parisi, Jr. is the senior vice-president and national technology, network risk and telecommunications practice leader for the FINPRO unit of Marsh USA. He has spoken at various businesses, technology, legal, and insurance forums throughout the world and has written on issues affecting professional liability, privacy, technology, telecommunications, media, intellectual property, computer security, and insurance. In 2002, he was honored by *Business Insurance* magazine as one of the Rising Stars of Insurance. Immediately prior to joining Marsh, he was the senior vice-president and chief underwriting officer of eBusiness Risk Solutions (a unit of the property and casualty companies of American International Group, Inc.). He joined the AIG group of companies in 1998 as legal counsel for its Professional Liability group and held several executive and legal positions within AIG, including the position of chief underwriting officer for professional liability and technology. While at AIG, he oversaw the creation and drafting of underwriting guidelines and policies for all lines of professional liability. Prior to joining AIG, he had been in private practice, principally as legal counsel to various Lloyds of London syndicates handling a variety of professional liability lines. He graduated cum laude from Fordham College with a B.A. in economics and received his law degree from Fordham University School of Law. He is admitted to practice in New York and the U.S. District Courts for the Eastern and Southern Districts of New York.

Donn B. Parker, CISSP, Fellow of the Association for Computing Machinery and Distinguished Fellow of the Information Systems Security Association (ISSA) is a retired (1997) senior management consultant from SRI International in Menlo Park,

California, who has specialized in information security and computer crime research for 40 of his 50 years in the computer field. He is the founder of the International Information Integrity Institute (I-4), which provides a forum for exchange of security information among 75 of the largest international enterprises. He has written numerous books, papers, articles, and reports in his specialty based on interviews of over 200 computer criminals and reviews of the security of many large enterprises. He received the ISSA 1992 Individual Outstanding Achievement Award, the 1994 National Computer Systems Security Award from the US NIST and NSA, the Aerospace Computer Security Associates 1994 Distinguished Lecturer Award, and the MIS Training Institute Infosecurity News 1996 Lifetime Achievement Award. He received the ISSA Hall of Fame award and was chosen as one of five pioneers and profiled in *Information Security Magazine* in 1999.

Padgett Peterson, P.E., CISSP, IAM/IEM, has been involved with computer security and encryption for over 40 years. Since 1979 he has been employed by different elements of a major aerospace contractor. He is also an adjunct professor in the Master's of Science in Information Assurance program at Norwich University.

Franklin Platt is the founder and president of Office Planning Services, a Wall Street consultancy for 20 years headquartered in Stark, New Hampshire, since 1990. He has worked extensively in security planning, management, and preparedness in both the private and public sectors. His academic background includes business administration and electrical engineering. He has received extensive government training in emergency management, including terrorism and weapons of mass destruction, much of which is not available to the public. He holds many security certifications and is currently vetted by the FBI and by several states. His areas of expertise include: security risk management; compliance with the latest Homeland Security procedures and other federal regulations that affect the private sector; risk identification and assessment; vulnerability analysis; cost-value studies; response planning; site security surveys and compliance auditing; briefing and training; second opinion; and due diligence.

N. Todd Pritsky is the director of e-learning courseware at Hill Associates, a telecommunications training company in Colchester, Vermont. He is a senior member of the technical staff and an instructor of online, lecture, and hands-on classes. His teaching and writing specialties include e-commerce, network security, TCP/IP, and the Internet, and he also leads courses on fast packet and network access technologies. He enjoys writing articles on network security and is a contributing author of *Telecommunications: A Beginner's Guide* (McGraw-Hill/Osborne). Previously, he managed a computer center and created multimedia training programs. He holds a B.A. in philosophy and Russian/Soviet studies from Colby College.

Karthik Raman, CISSP, is a security researcher on the Adobe Secure Software Engineering Team (ASSET) where he focuses on vulnerability analysis and technical collaboration with industry partners. Before joining Adobe, he was a research scientist at McAfee Labs where he worked on threat analysis, building automation systems, malware analysis, and developing advanced anti-malware technology. He holds an M.S. degree in computer science from the University of California Irvine and B.S. degrees in computer science and computer security from Norwich University. Karthik has spoken at Infosec Southwest, SOURCE Boston, SOURCE Seattle, LayerOne, and Kaspersky Security Analyst Summit and has delivered a Black Hat Webcast.

Bridgitt Robertson has been teaching business and technology courses for over a decade years. Her multidisciplinary approach to security awareness analyzes threats in the global enterprise and investigates how an educated workforce can mitigate risks and enhance corporate competitiveness. Prior to teaching, she worked for global companies in the areas of project management, business analysis, and consulting. She is a member of InfraGard.

Russell D. Rosco is currently program chair/professor of the Computer Information Network Technology program at Ivy Tech Community College–NorthEast. He is also a graduate student at Purdue University, where he is working on his dissertation for an Interdisciplinary Ph.D. in information assurance; combining his interests of computers, business, and psychology. He has an M.S. in information assurance from Norwich University, a B.S. in psychology, and a B.A. in business administration from Washington State University. Mr. Rosco had several years of IT work experience prior to his decade of teaching IT courses, ranging from intro to PCs to Active Directory design.

Marc Rotenberg is executive director of the Electronic Privacy Information Center in Washington, DC. He teaches information privacy law at Georgetown University Law Center. He has published many articles in legal and scientific journals. He is the coauthor of several books, including *Information Privacy Law*, *Privacy and Human Rights*, *The Privacy Law Sourcebook*, and *Litigation under the Federal Open Government Laws*. He frequently testifies before the U.S. Congress and the European Parliament on emerging privacy issues. He is a Fellow of the American Bar Foundation and the recipient of several awards, including the World Technology Award in Law.

K. Rudolph is the president and chief inspiration officer for Native Intelligence, Inc. She is a Certified Information Systems Security Professional (CISSP), a Federal IT Security Professional (FITSP-M), and holds a degree from Johns Hopkins University. Her interests include the psychology of security awareness and influence as related to learning and behavior, storytelling, and security-awareness metrics. Her publications include *System Forensics, Investigation, and Response* (2010) and the second edition of *Computer Forensics Jumpstart* (2011). She was also the technical editor for Michael Solomon's book, *Security Strategies in Windows Platforms and Applications*. She is a named contributor and participant in the group that created *NIST Special Publication 800-16, Information Technology Security Training Requirements: A Role-and Performance-Based Model*. In 2006, she was honored by the Federal Information Systems Security Educators' Association (FISSEA) as the Security Educator of the Year. She is currently a volunteer with (ISC)²'s Safe and Secure Online program.

Ravi Sandhu is cofounder and chief scientist of SingleSignOn.Net in Reston, Virginia, and professor of information technology and engineering at George Mason University in Fairfax, Virginia. An ACM and an IEEE Fellow, he is the founding editor-in-chief of *ACM's Transactions on Information and System Security*, chairman of ACM's Special Interest Group on Security, Audit and Control, and security editor for *IEEE Internet Computing*. He has published over 140 technical papers on information security. He is a popular teacher and has lectured all over the world. He has provided high-level consulting services to numerous private and government organizations.

Eric Salveggio is an information technology security professional who enjoys teaching online courses in CMIS for Liberty University and auditing for Norwich University.

He works as a trained ISO 17799, NISTISSI 4011 and 4013 consultant for Dynetics Corporation of Huntsville, Alabama, in IT Security and Auditing, and as a Private Consultant in networking, network design, and security (wired and wireless) with 10 years experience. He previously worked as the IT director for the Birmingham, Alabama, campus of Virginia College, where he opened two start-up campuses—on ground and online—and created three accredited programs (two undergrad, one graduate level) at state and federal levels in Network and Cyber Security. While in this position, he was chosen as a nominee for the 2006 Information Security Executive Award, and enjoyed being the only educational facility recognized. He was personally awarded a plaque of recognition by the Stonesoft Corporation for the same. He is a published author and photographer, and enjoys working at times as a technical editor for Pearson Education and Thomson Publishing on cyberforensics, cybersecurity, and operating systems.

Karen Scarfone is the principal consultant for Scarfone Cybersecurity. She provides cybersecurity publication consulting services to federal agencies, specializing in security automation standards and network and system security guidelines. Karen was formerly a senior computer scientist for the National Institute of Standards and Technology (NIST) and has co-authored over 50 NIST Special Publications and Interagency Reports. She holds bachelor's and master's degrees in computer science, and she has 20 years of professional experience in the IT field. Her security domains include general security engineering and administration, wired and wireless network security, host security, incident response, intrusion detection, log management, vulnerability measurement, and security automation.

Sondra Schneider is CEO and founder of Security University (SU), an information security and information assurance training and certification company. She and SU have challenged security professionals for the past 10 years, delivering hands-on tactical security classes and certifications around the world. Starting in 2008, SU set up an exam server to meet the demand for tactical security certifications. In 2005, SU refreshed the preexisting AIS security training program to the new “SU Qualified Programs,” which meet and exceed security professionals requirements for hands-on tactical security “skills” training. SU delivers the Qualified/Information Security Professional and Qualified/Information Assurance Professional certifications, which are the first of their kind that measure a candidate's tactical hands-on security skills. In 2004, she was awarded Entrepreneur of the Year for the First Annual Women of Innovation Award from the Connecticut Technology Council. In 2007, she was tech editor for the popular 2007 *CEH V5 Study Guide*, and a multiple chapter author for the 2007 *CHFI Study Guide*. She sits on three advisory boards for computer security (start-up) technology companies and is a frequent speaker at computer security and wireless industry events. She is a founding member of the NYC HTCIA and IETF chapters, works closely with (ISC)², ISSA, and ISACA chapters, and the security and wireless vendor community. She specializes in information security, intrusion detection, information assurance (PKI), wireless security, and security-awareness training.

Jason Sinchak, CISSP, is an information-security consultant for Emerging Defense, LLC and an independent researcher specializing in risk assessment and penetration testing. He possesses a broad range of experience, beginning his career in application development and systems management, to operational security monitoring, enterprise security program advisory, incident response, and penetration testing. His security

experience primarily stems from industry positions and consulting, where he has had the pleasure of serving multiple Fortune 500 clients and deeply focusing on performing technical security assessments in a multitude of industries and environments.

William Stallings has made a unique contribution to understanding the broad sweep of technical developments in computer networking and computer architecture. He has authored 17 titles and, counting revised editions, has published a total of over 40 books on various aspects of these subjects. In over 20 years in the field, he has been a technical contributor, technical manager, and an executive with several high-technology firms. Currently, he is an independent consultant whose clients have included computer and networking manufacturers and customers, software development firms, and leading-edge government research institutions. He created and maintains the Computer Science Student Resource Site at www.computersciencestudent.com. He is a member of the editorial board of *Cryptologia*, a scholarly journal devoted to all aspects of cryptology.

Dr. Peter Stephenson is a writer, researcher and lecturer on information assurance and risk, information warfare and counterterrorism, and digital investigation and forensics on large-scale computer networks. He has lectured extensively on digital investigation and security and has written or contributed to 14 books and several hundred articles in major national and international trade, technical, and scientific publications. He is the associate program director in the Master's of Science in Information Assurance program at the Norwich University School of Graduate Studies, where he teaches information assurance, cybercrime and cyberlaw, and digital investigation on both the graduate and undergraduate levels. He is senior research scientist at the Norwich University Applied Research Institutes, chair of the Department of Computing, and the chief information-security officer for the university. He has lectured or delivered consulting engagements for the past 23 years in 11 countries plus the United States and has been a technologist for over 40 years. He operated a successful consulting practice for over 20 years and has worked for such companies as Siemens, Tektronix, and QinetiQ (UK). He obtained his Ph.D. in computer science at Oxford Brookes University, Oxford, England, where his research was in the structured investigation of digital incidents in complex computing environments. He holds a master's of arts degree in diplomacy with a concentration in terrorism from Norwich University. He is on the editorial advisory boards of *International Journal of Digital Evidence* and the Norwich University *Journal of Information Assurance* among several others, and serves as technology editor for *SC Magazine* and the editor in chief for Norwich University Press. He is a Fellow of the Institute for Communications, Arbitration and Forensics in the United Kingdom and is a member of Michigan InfraGard and the International Federation of Information Processing Technical Committee 11, Working Group 11.9, Digital Forensics. He serves on the steering Committee of the Michigan Electronic Crime Task Force. His research is focused on information conflict.

Gary L. Tagg, CISSP, is a highly experienced information-security professional with over 20 years working in the financial and government sectors. The organizations he has worked with include Deutsche Bank, PA Consulting group, Clearstream, Pearl Assurance, and Lloyds TSB. He has performed a wide range of security roles including risk management, consulting, security architecture, policy and standards, project management, development, testing, and auditing. He is currently a risk consultant in Deutsche Bank's IT security Governance Group.

Nicholas Takaacs is an information-security professional and business systems director for a long-term care insurance company. He is also an adjunct professor of information assurance at Norwich University. He has expertise in the areas of security policy management, security awareness, business continuity planning, and execution. Prior to moving into the insurance industry, he spent several years in the public utility industry focusing on the areas of regulatory compliance, disaster recovery, and identity management.

James Thomas, CISSP, is a senior partner with Norwich Security Associates, a full-spectrum information assurance consultancy headquartered in Scotland. Thomas spends most of his professional time providing policy, process, and governance advice to large banking and financial organizations in the United Kingdom and Europe. He is a 2004 graduate of the Norwich University Master's of Science in Information Assurance program. Prior to focusing his efforts in the security space, he had a long career in information technology and broadcast engineering spanning the United Kingdom and the eastern United States.

Lee Tien, Esq., is a senior staff attorney with the Electronic Frontier Foundation in San Francisco, California. He specializes in free speech and surveillance law and has authored several law review articles. He received his undergraduate degree in psychology from Stanford University and his law degree from Boalt Hall School of Law, University of California Berkeley. He is also a former newspaper reporter.

Timothy Virtue, CISSP, CISA, CCE, CFE, CIPP/G, is an accomplished information assurance leader with a focus in strategic enterprise technology risk management, information security, data privacy, and regulatory compliance. He has extensive experience with publicly traded corporations, privately held businesses, government agencies, and nonprofit organizations of all sizes.

Myles Walsh is an adjunct professor at three colleges in New Jersey: Ramapo College, County College of Morris, and Passaic County Community. For the past 12 years, he has taught courses in Microsoft Office and Web page design. He also implements small Office applications and Websites. From 1966 until 1989, he worked his way up from programmer to director in several positions at CBS, CBS Records, and CBS News. His formal education includes an M.B.A. from the Baruch School of Business and a B.B.A. from St. John's University.

Karen F. Worstell, CISM, is cofounder and principal of W Risk Group, a consultancy serving clients across multiple sectors to define due diligence to a defensible standard of care for information protection. Her areas of expertise include incident detection and management, compliance, governance, secure data management, and risk management. She is coauthor of *Evaluating the Electronic Discovery Capabilities of Outside Law Firms: A Model Request for Information and Analysis* (BNA, 2006) and is a frequent speaker and contributor in risk management and information-security forums internationally. She participates in ISACA, IIA, and the ABA Science and Technology Section, Information Security Committee, and serves as president of the Puget Sound Chapter of the ISSA.

Noel Zakin is president of RANCO Consulting LLC. He has been an information technology/telecommunications industry executive for over 45 years. He has held

managerial positions at the Gartner Group, AT&T, the American Institute of CPAs, and Unisys. These positions involved strategic planning, market research, competitive analysis, business analysis, and education and training. His consulting assignments have ranged from the Fortune 500 to small start-ups and have involved data security, strategic planning, conference management, market research, and management of corporate operations. He has been active with ACM, IFIP, and AFIPS and currently with ISSA. He holds an M.B.A. from the Wharton School.

William A. Zucker, Esq., is a partner at McCarter & English, LLP's Boston office. He serves as a senior consultant for the Cutter Consortium on legal issues relating to information technology, outsourcing, and risk management, and is a member of the American Arbitration Association's National Technology Panel and a member of the CPR Institute's working group on technology business alliances and conflict management. He has also served on the faculty of Norwich University, where he taught the intellectual property aspects of computer security. He is a trial lawyer whose practice focuses on negotiation/litigation of business transactions, outsourcing/ebusiness and technology/intellectual property. Among his publications are: "The Legal Framework for Protecting Intellectual Property in the Field of Computing and Computer Software," written for *The Computer Security Handbook*, 4th edition, coauthored with Scott Nathan; and "Intellectual Property and Open Source: Copyright, Copyleft and Other Issues for the Community User."

A NOTE TO THE INSTRUCTOR

This two-volume text will serve the interests of practitioners and teachers of information assurance. The fourth edition and fifth editions of the *Handbook* were well received in academia; at least one-quarter of all copies were bought by university and college bookstores. The design of this sixth edition continues in the same vein and includes many updates to the material.

University professors looking for texts appropriate for a two-semester sequence of undergraduate courses in information assurance will find the *Handbook* most suitable. In my own work at Norwich University in Vermont, Volume I is the text for our *IS340 Introduction to Information Assurance* and Volume II is the basis for our *IS342 Management of Information Assurance* courses.

The text will also be useful as a resource in graduate courses. In the School of Graduate and Continuing Studies at Norwich University, both volumes have been used as required and supplementary reading for the 18-month, 36-credit Master's of Science in Information Security and Assurance program (MISA).

I will continue to create, update, and post PowerPoint lecture slides based on the chapters of the *Handbook* on my Website for free access by anyone applying them to noncommercial use (e.g., for self-study, for courses in academic institutions, and for unpaid industry training); the materials will be available in the IS340 and IS342 sections:

INTRODUCTION TO PART I

FOUNDATIONS OF COMPUTER SECURITY

The foundations of computer security include answers to the superficially simple question “What is this all about?” Our first part establishes a technological and historical context for information assurance so that readers will have a broad understanding of why information assurance matters in the real world. Chapters focus on principles that will underlie the rest of the text: historical perspective on the development of our field; how to conceptualize the goals of information assurance in a well-ordered schema that can be applied universally to all information systems; computer hardware and network elements underlying technical security; history and modern developments in cryptography; and how to discuss breaches of information security using a common technical language so that information can be shared, accumulated, and analyzed.

Readers also learn or review the basics of commonly used mathematical models of information-security concepts and how to interpret survey data and, in particular, the pitfalls of self-selection in sampling about crimes. Finally, the first section of the text introduces elements of law (U.S. and international) applying to information assurance. This legal framework from a layman’s viewpoint provides a basis for understanding later chapters; in particular, when examining privacy laws and management’s fiduciary responsibilities.

Chapter titles and topics in Part I include:

1. **Brief History and Mission of Information System Security.** An overview focusing primarily on developments in the second half of the twentieth century and the first decade of the twenty-first century
2. **History of Computer Crime.** A review of key computer crimes and notorious computer criminals from the 1970s to the mid-2000s
3. **Toward a New Framework for Information Security.** A systematic and thorough conceptual framework and terminology for discussing the nature and goals of securing all aspects of information, not simply the classic triad of confidentiality, integrity, and availability
4. **Hardware Elements of Security.** A review of computer and network hardware underlying discussions of computer and network security

I · 2 FOUNDATIONS OF COMPUTER SECURITY

- 5. Data Communications and Information Security.** Fundamental principles and terminology of data communications, and their implications for information assurance
- 6. Local Area Network Topologies, Protocols, and Design.** Information assurance of the communications infrastructure
- 7. Encryption.** Historical perspectives on cryptography and steganography from ancient times to today as fundamental tools in securing information

1.1 INTRODUCTION TO INFORMATION SYSTEM SECURITY. The growth of computers and of information technology has been explosive. Never before has an entirely new technology been propagated around the world with such speed and with so great a penetration of virtually every human activity. Computers have brought vast benefits to fields as diverse as human genome studies, space exploration, artificial intelligence, and a host of applications from the trivial to the most life-enhancing.

Unfortunately, there is also a dark side to computers: They are used to design and build weapons of mass destruction as well as military aircraft, nuclear submarines,

1 · 2 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

and reconnaissance space stations. The computer's role in formulating biologic and chemical weapons, and in simulating their deployment, is one of its least auspicious uses.

Of somewhat lesser concern, computers used in financial applications, such as facilitating the purchase and sales of everything from matchsticks to mansions, and transferring trillions of dollars each day in electronic funds, are irresistible to miscreants; many of them see these activities as open invitations to fraud and theft. Computer systems, and their interconnecting networks, are also prey to vandals, malicious egotists, terrorists, and an array of individuals, groups, companies, and governments intent on using them to further their own ends, with total disregard for the effects on innocent victims. Besides these intentional attacks on computer systems, there are innumerable ways in which inadvertent errors can damage or destroy a computer's ability to perform its intended functions.

Because of these security problems and because of a great many others described in this volume, the growth of information systems security has paralleled that of the computer field itself. Only by a detailed study of the potential problems, and implementation of the suggested solutions, can computers be expected to fulfill their promise, with few of the security lapses that plague less adequately protected systems. This chapter defines a few of the most important terms of information security and includes a very brief history of computers and information systems, as a prelude to the works that follow.

Security can be defined as the state of being free from danger and not exposed to damage from accidents or attack, or it can be defined as the process for achieving that desirable state. The objective of information system security¹ is to optimize the performance of an organization with respect to the risks to which it is exposed.

Risk is defined as the chance of injury, damage, or loss. Thus, risk has two elements: (1) chance—an element of uncertainty, and (2) potential loss or damage. Except for the possibility of restitution, information system security actions taken today work to reduce *future* risk losses. Because of the uncertainty about future risk losses, perfect security, which implies zero losses, would be infinitely expensive. For this reason, risk managers strive to optimize the allocation of resources by minimizing the total cost of information system security measures taken and the risk losses experienced. This optimization process is commonly referred to as *risk management*.

Risk management in this sense is a three-part process:

1. Identification of material risks
2. Selection and implementation of measures to mitigate the risks
3. Tracking and evaluating of risk losses experienced, in order to validate the first two parts of the process

The purpose of this *Handbook* is to describe information security system risks, the measures available to mitigate these risks, and techniques for managing security risks. (For a more detailed discussion of risk assessment and management, see Chapters 47 and 54.)

Risk management has been a part of business for centuries. Renaissance merchants often used several vessels simultaneously, each carrying a portion of the merchandise, so that the loss of a single ship would not result in loss of the entire lot. At almost the same time, the concept of insurance evolved, first to provide economic protection against the loss of cargo and later to provide protection against the loss of buildings

by fire. Fire insurers and municipal authorities began to require adherence to standards intended to reduce the risk of catastrophes like the Great Fire of London in 1666. The Insurance Institute was established in London one year later. With the emergence of corporations as limited liability stock companies, corporate directors have been required to use prudence and due diligence in protecting shareholders' assets. Security risks are among the threats to corporate assets that directors have an obligation to address.

Double-entry bookkeeping, another Renaissance invention, proved to be an excellent tool for measuring and controlling corporate assets. One objective was to make insider fraud more difficult to conceal. The concept of separation of duties emerged, calling for the use of processing procedures that required more than one person to complete a transaction. As the books of account became increasingly important, accounting standards were developed, and they continue to evolve to this day. These standards served to make books of account comparable and to assure outsiders that an organization's books of account presented an accurate picture of its condition and assets. These developments led, in turn, to the requirement that an outside auditor perform an independent review of the books of account and operating procedures.

The transition to automated accounting systems introduced additional security requirements. Some early safeguards, such as the rule against erasures or changes in the books of account, no longer applied. Some computerized accounting systems lacked an audit trail, and others could have the audit trail subverted as easily as actual entries.

Finally, with the advent of the Information Age, intellectual property has become an increasingly important part of corporate and governmental assets. At the same time that intellectual property has grown in importance, threats to intellectual property have become more dangerous, because of information system (IS) technology itself. When sensitive information was stored on paper and other tangible documents, and rapid copying was limited to photography, protection was relatively straightforward. Nevertheless, document control systems, information classification procedures, and need-to-know access controls were not foolproof, and information compromises occurred with dismaying regularity. Evolution of IS technology has made information control several orders of magnitude more complex. The evolution and, more importantly, the implementation of control techniques have not kept pace.

The balance of this chapter describes how the evolution of information systems has caused a parallel evolution of information system security and at the same time has increased the importance of anticipating the impact of technical changes yet to come. This overview will clarify the factors leading to today's information system security risk environment and mitigation techniques and will serve as a warning to remain alert to the implication of technical innovations as they appear. The remaining chapters of this *Handbook* discuss information system security risks, threats, and vulnerabilities, their prevention and remediation, and many related topics in considerable detail.

1.2 EVOLUTION OF INFORMATION SYSTEMS. The first electromechanical punched-card system for data processing, developed by Herman Hollerith at the end of the nineteenth century, was used to tabulate and total census field reports for the U.S. Bureau of the Census in 1890. The first digital, stored-program computers developed in the 1940s were used for military purposes, primarily cryptanalysis and the calculation and printing of artillery firing tables. At the same time, punched-card systems were already being used for accounting applications and were an obvious choice for data input to the new electronic computing machines.

1 · 4 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

1.2.1 1950s: Punched-Card Systems. In the 1950s, punched-card equipment dominated the commercial computer market.² These electromechanical devices could perform the full range of accounting and reporting functions. Because they were programmed by an intricate system of plugboards with a great many plug-in cables, and because care had to be exercised in handling and storing punched cards, only experienced persons were permitted near the equipment. Although any of these individuals could have set up the equipment for fraudulent use, or even engaged in sabotage, apparently few, if any, actually did so.

The punched-card accounting systems typically used four processing steps. As a preliminary, operators would be given a “batch” of documents, typically with an adding machine tape showing one or more “control totals.” The operator keyed the data on each document into a punched card and then added an extra card, the batch control card, which stored the batch totals. Each card consisted of 80 columns, each containing, at most, one character. A complete record of an inventory item, for example, would be contained on a single card. The card was called a unit record, and the machines that processed the cards were called either unit record or punched-card machines. It was from the necessity to squeeze as much data as possible into an 80-character card that the later Year 2000 problem arose. Compressing the year into two characters was a universally used space-saving measure; its consequences 40 years later were not foreseen.

A group of punched cards, also called a “batch,” were commonly held in a metal tray. Sometimes a batch would be rekeyed by a second operator, using a “verify-mode” rather than actually punching new holes in the cards, in order to detect keypunch errors before processing the card deck. Each batch of cards would be processed separately, so the processes were referred to as “batch jobs.”

The first step would be to run the batch of cards through a simple program, which would calculate the control totals and compare them with the totals on the batch control card. If the batch totals did not reconcile, the batch was sent back to the keypunch area for rekeying. If the totals reconciled, the deck would be sort-merged with other batches of the same transaction type, for example, the current payroll. When this step was complete, the new batch consisted of a punched card for each employee in employee-number order. The payroll program accepted this input data card deck and processed the cards one by one. Each card was matched up with the corresponding employee’s card in the payroll master deck to calculate the current net pay and itemized deductions and to punch a new payroll master card, including year-to-date totals. The final step was to use the card decks to print payroll checks and management reports. These steps were identical with those used by early, small-scale electronic computers. The only difference was in the speed at which the actual calculations were made. A complete process was still known as a batch job.

With this process, the potential for abuse was great. The machine operator could control every step of the operation. Although the data was punched into cards and verified by others, there was always a keypunch machine nearby for use by the machine operator. Theoretically, that person could punch a new payroll card and a new batch total card to match the change before printing checks and again afterward. The low incidence of reported exploits was due to the controls that discouraged such abuse, and possibly to the pride that machine operators experienced in their jobs.

1.2.2 Large-Scale Computers. While these electromechanical punched card machines were sold in large numbers, research laboratories and universities were working to design large-scale computers that would have a revolutionary effect on

the entire field. These computers, built around vacuum tubes, are known as the first generation. In March 1951, the first Universal Automatic Computer (UNIVAC) was accepted by the U.S. Census Bureau. Until then, every computer had been a one-off design, but UNIVAC was the first large-scale, mass-produced computer, with a total of 46 built. The word “universal” in its name indicated that UNIVAC was also the first computer designed for both scientific and business applications.³

UNIVAC contained 5,200 vacuum tubes, weighed 29,000 pounds, and consumed 125 kilowatts of electrical power. It dispensed with punched cards, receiving input from half-inch-wide metal tape recorded from keyboards, with output either to a similar tape or to a printer. Although not a model for future designs, its memory consisted of 1,000 72-bit words and was fabricated as a mercury delay line. Housed in a cabinet about six feet tall, two feet wide, and two feet deep was a mercury-filled coil running from top to bottom. A transducer at the top propagated slow-moving waves of energy down the coil to a receiving transducer at the bottom. There it was reconverted into electrical energy and passed on to the appropriate circuit, or recirculated if longer storage was required.

In 1956, IBM introduced the Random Access Method of Accounting and Control (RAMAC) magnetic disk system. It consisted of 50 magnetically coated metal disks, each 24 inches in diameter, mounted on a common spindle. Under servo control, two coupled read/write heads moved to span each side of the required disk and then inward to any one of 100 tracks. In one revolution of the disks, any or all of the information on those two tracks could be read out or recorded. The entire system was almost the size of a compact car and held what, for that time, was a tremendous amount of data—5 megabytes. The cost was \$10,000 per megabyte, or \$35,000 per year to lease. This compares with some of today’s magnetic hard drives that measure about 3½ inches wide by 1 inch high, store as much as 1,000 gigabytes, and cost less than \$400, or about \$0.0004 per megabyte.

Those early, massive computers were housed in large, climate-controlled rooms. Within the room, a few knowledgeable experts, looking highly professional in their white laboratory coats, attended to the operation and maintenance of their million-dollar charges. The concept of a “user” as someone outside the computer room who could interact directly with the actual machine did not exist.

Service interruptions, software errors, and hardware errors were usually not critical. If any of these caused a program to fail or abort, beginning again was a relatively simple matter. Consequently, the primary security concerns were physical protection of the scarce and expensive hardware, and measures to increase their reliability. Another issue, then as now, was human fallibility. Because the earliest computers were programmed in extremely difficult machine language, consisting solely of ones (1s) and zeros (0s), the incidence of human error was high, and the time to correct errors was excessively long. Only later were assembler and compiler languages developed to increase the number of people able to program the machines and to reduce the incidence of errors and the time to correct them.

Information system security for large-scale computers was not a significant issue then for two reasons. First, only a few programming experts were able to utilize and manipulate computers. Second, there were very few computers in use, each of which was extremely valuable, important to its owners, and consequently closely guarded.

1.2.3 Medium-Size Computers. In the 1950s, smaller computer systems were developed with a very simple configuration; punched-card master files were replaced by punched paper tape and, later, by magnetic tape, and disk storage systems. The

1 · 6 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

electromechanical calculator with its patchboard was replaced by a central processor unit (CPU) that had a small main memory, sometimes as little as 8 kilobytes,⁴ and limited processing speed and power. One or two punched-card readers could read the data and instructions stored on that medium. Later, programs and data files were stored on magnetic tape. Output data were sent to cardpunches, for printing on unit record equipment, and later to magnetic tape. There was still no wired connection to the outside world, and there were no online users because no one, besides electronic data processing (EDP) people within the computer room, could interact directly with the system. These systems had very simple operating systems and did not use multiprocessing; they could run only one program at a time.

The IBM Model 650, as an example, introduced in 1954, measured about 5 feet by 3 feet by 6 feet and weighed almost 2,000 pounds. Its power supply was mounted in a similarly sized cabinet, weighing almost 3,000 pounds. It had 2,000 (10-digit) words of magnetic drum primary memory, with a total price of \$500,000 or a rental fee of \$3,200 per month. For an additional \$1,500 per month, a much faster core memory, of 60 words, could be added. Input and output both utilized read/write punch-card machines. The typical 1950s IS hardware was installed in a separate room, often with a viewing window so that visitors could admire the computer. In an early attempt at security, visitors actually within the computer room were often greeted by a printed sign saying:

Achtung! Alles Lookenspeepers!

Das computermachine ist nicht fur gefingerpoken und mittengrabben.

Ist easy schnappen der springenwerk, blowenfusen, und poppencorken mit spitzensparken.

Ist nicht fur gewerken bei das dumbkopfen.

Das rubbernecken sightseeren keepen hans in das pockets muss. Relaxen und watch das blinkenlichten.

Since there were still no online users, there were no user IDs and passwords. Programs processed batches of data, run at a regularly scheduled time—once a day, once a week, and so on, depending on the function. If the data for a program were not available at the scheduled run time, the operators might run some other job instead and wait for the missing data. As the printed output reports became available, they were delivered by hand to their end users. End users did not expect to get a continuous flow of data from the information processing system, and delays of even a day or more were not significant, except perhaps with paycheck production.

Information system security was hardly thought of as such. The focus was on batch controls for individual programs, physical access controls, and maintaining a proper environment for the reliable operation of the hardware.

1.2.4 1960s: Small-Scale Computers. During the 1960s, before the introduction of small-scale computers, dumb⁵ terminals provided users with a keyboard to send a character stream to the computer and a video screen that could display characters transmitted to it by the computer. Initially, these terminals were used to help computer operators control and monitor the job stream, while replacing banks of switches and indicator lights on the control console. However, it was soon recognized that these terminals could replace card readers and keypunch machines as well. Now users, identified by user IDs, and authenticated with passwords, could enter input data through a CRT terminal into an edit program, which would validate the input and then store it on a hard drive until it was needed for processing. Later, it was realized that users also could directly access data stored in online master files.

1.2.5 Transistors and Core Memory. The IBM 1401, introduced in 1960 with a core memory of 4,096 characters, was the first all-transistor computer, marking the advent of the second generation. Housed in a cabinet measuring 5 feet by 3 feet, the 1401 required a similar cabinet to add an additional 12 kilobytes of main memory. Just one year later, the first integrated circuits were used in a computer, making possible all future advances in miniaturizing small-scale computers and in reducing the size of mainframes significantly.

1.2.6 Time Sharing. In 1961, the Compatible Time Sharing System (CTSS) was developed for the IBM 7090/7094. This operating system software, and its associated hardware, was the first to provide simultaneous remote access to a group of online users through multiprogramming.⁶ “Multiprogramming” means that more than one program can appear to execute at the same time. A master control program, usually called an operating system (OS), managed execution of the functional applications programs. For example, under the command of the operator, the OS would load and start application #1. After 50 milliseconds, the OS would interrupt the execution of application #1 and store its current state in memory. Then the OS would start application #2 and allow it to run for 50 milliseconds, and so on. Usually, within a second after users had entered keyboard data, the OS would give their applications a time slice to process the input. During each time slice, the computer might execute hundreds of instructions. These techniques made it appear as if the computer were entirely dedicated to each user’s program. This was true only so long as the number of simultaneous users was fairly small. After that, as the number grew, the response to each user slowed down.

1.2.7 Real-Time, Online Systems. Because of multiprogramming and the ability to store records online and accessible in random order, it became feasible to provide end users with direct access to data. For example, an airline reservation system stores a record of every seat on every flight for the next 12 months. A reservation clerk, working at a terminal, can answer a telephoned inquiry, search for an available seat on a particular flight, quote the fare, sell a ticket to the caller, and reserve the seat. Similarly, a bank officer can verify an account balance and effect money transfers. In both cases, each data record can be accessed and modified immediately, rather than having to wait for a batch to be run. Today, both the reservation clerk and the bank officer can be replaced by the customers themselves, who directly interface with the online computers.

While this advance led to a vast increase in available computing power, it also increased greatly the potential for breaches in computer security. With more complex operating systems, with many users online to sensitive programs, and with databases and other files available to them, protection had to be provided against inadvertent error and intentional abuse.

1.2.8 A Family of Computers. In 1964, IBM announced the S/360 family of computers, ranging from very small-scale to very large-scale models. All of the six models used integrated circuits, which marked the beginning of the third generation of computers. Where transistorized construction could permit up to 6,000 transistors per cubic foot, 30,000 integrated circuits could occupy the same volume. This lowered the costs substantially, and companies could buy into the family at a price within their means. Because all computers in the series used the same programming language and the same peripherals, companies could upgrade easily when necessary. The 360 family

1 · 8 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

quickly came to dominate the commercial and scientific markets. As these computers proliferated, so did the number of users, knowledgeable programmers, and technicians. Over the years, techniques and processes were developed to provide a high degree of security to these mainframe systems.

The year 1964 also saw the introduction of another computer with far-reaching influence: the Digital Equipment Corp. (DEC) PDP-8. The PDP-8 was the first mass-produced true minicomputer. Although its original application was in process control, the PDP-8 and its progeny quickly proved that commercial applications for minicomputers were virtually unlimited. Because these computers were not isolated in secure computer rooms but were distributed throughout many unguarded offices in widely dispersed locations, totally new risks arose, requiring innovative solutions.

1.2.9 1970s: Microprocessors. The foundations of all current personal computers (PCs) were laid in 1971 when Intel introduced the 4004 computer on a chip. Measuring 1/16 inch long by 1/8 inch high, the 4004 contained 2,250 transistors with a clock speed of 108 kiloHertz. The current generation of this earliest programmable microprocessor contains millions of transistors, with speeds over 1 gigaHertz, or more than 10,000 times faster. Introduction of microprocessor chips marked the fourth generation.

1.2.10 The First Personal Computers. Possibly the first personal computer was advertised in *Scientific American* in 1971. The KENBAK-1, priced at \$750, had three programming registers, five addressing modes, and 256 bytes of memory. Although not many were sold, the KENBAK-1 did increase public awareness of the possibility for home computers.

It was the MITS Altair 8800 that became the first personal computer to sell in substantial quantities. Like the KENBAK-1, the Altair 8800 had only 256 bytes of memory, but it was priced at \$375 without keyboard, display, or secondary memory. About one year later, the Apple II, designed by Steve Jobs and Steve Wozniak, was priced at \$1,298, including a CRT display and a keyboard.

Because these first personal computers were entirely stand-alone and usually under the control of a single individual, there were few security problems. However, in 1978, the VisiCalc spreadsheet program was developed. The advantages of standardized, inexpensive, widely used application programs were unquestionable, but packaged programs, as opposed to custom designs, opened the way for abuse because so many people understood their user interfaces as well as their inner workings.

1.2.11 The First Network. A national network, conceived in late 1969, was born as ARPANET⁷ (Advanced Research Projects Agency Network), a Department of Defense-sponsored effort to link a few of the country's important research universities, with two purposes: to develop experience in interconnecting computers and to increase productivity through resource sharing. This earliest connection of independent large-scale computer systems had just four nodes: the University of California at Los Angeles (UCLA), the University of California at Santa Barbara, Stanford Research Institute, and the University of Utah. Because of the inherent security in each leased-line interconnected node, and the physically protected mainframe computer rooms, there was no apparent concern for security issues. It was this simple network, with no thought of security designed in, from which evolved today's ubiquitous Internet and the World Wide Web (WWW), with their vast potential for security abuses.

1.2.12 Further Security Considerations. With the proliferation of remote terminals on commercial computers, physical control over access to the computer room was no longer sufficient. In response to the new vulnerabilities, logical access control systems were developed. An access control system maintains an online table of authorized users. A typical user record would store the user's name, telephone number, employee number, and information about the data the user was authorized to access and the programs the user was authorized to execute. A user might be allowed to view, add, modify, and delete data records in different combinations for different programs.

At the same time, system managers recognized the value of being able to recover from a disaster that destroyed hardware and data. Data centers began to make regular tape copies of online files and software for offsite storage. Data center managers also began to develop and implement offsite disaster recovery plans, often involving the use of commercial disaster-recovery facilities. Even with such a system in place, new vulnerabilities were recognized throughout the following years, and these are the subjects of much of this *Handbook*.

1.2.13 The First "Worm". A prophetic science-fiction novel, *The Shockwave Rider*, by John Brunner⁸ (1975), depicted a "worm" that grew continuously throughout a computer network. The worm eventually exceeded a billion bits in length and became impossible to kill without destroying the network. Although actual worms (e.g., the Morris Worm of 1988) later became real-and-present menaces to all networked computers, prudent computer security personnel install constantly updated antimalware programs that effectively kill viruses and worms without having to kill the network.

1.2.14 1980s: Productivity Enhancements. The decade of the 1980s might well be termed the era of productivity enhancement. The installation of millions of personal computers in commercial, industrial, and government applications enhanced efficiency and functionality of vast numbers of users. These advances, which could have been achieved in no other way, were made at costs that virtually any business could afford.

1.2.15 1980s: The Personal Computer. In 1981, IBM introduced a general-purpose small computer it called the "Personal Computer." That model and similar systems became known generically as PCs. Until then, small computers were produced by relatively unknown sources, but IBM, with its worldwide reputation, brought PCs into the mainstream. The fact that IBM had demonstrated a belief in the viability of PCs made them serious contenders for corporate use.

There were many variations on the basic Model 5100 PC, and sales expanded far beyond IBM's estimates. The basic configuration used the Intel 8088, operating at 4.77 megaHertz, with up to two floppy disk drives, each of 160 kilobytes capacity and with a disk-based operating system (DOS) in an open architecture. This open OS architecture, with its available "hooks," made possible the growth of independent software producers, the most important of which was the Microsoft Corporation, formed by Bill Gates and Paul Allen.

IBM had arranged for Gates and Allen to create the DOS operating system. Under the agreement, IBM would not reimburse Gates and Allen for their development costs; rather, all profits from the sale of DOS would accrue to them. IBM did not have an exclusive right to the operating system, and Microsoft began selling it to many other customers as MS-DOS. IBM initially included with its computer the VisiCalc

1 · 10 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

spreadsheet program, but soon sales of Lotus 1-2-3 surpassed those of VisiCalc. The open architecture not only made it possible for many developers to produce software that would run on the PC, but also enabled anyone to put together purchased components into a computer that would compete with IBM's PC. The rapid growth of compatible application programs, coupled with the ready availability of compatible hardware, soon resulted in sales of more than 1 million units. Many subsequent generations of the original hardware and software are still producing sales measured in millions every year.

Apple took a very different approach with its Macintosh computer. Where IBM's system was wide open, Apple maintained tight control over any hardware or software designed to operate on the Macintosh so as to assure compatibility and ease of installation. The most important Apple innovations were the graphical user interface (GUI) and the mouse, both of which worked together to facilitate ease of use and both of which were derived from research and development at the Stanford Research Institute and the Xerox Palo Alto Research Institute in the 1960s and 1970s. Microsoft had attempted in 1985 to build these features into the Windows operating system, but early versions were generally rejected as slow, cumbersome, and unreliable. It was not until 1990 that Windows 3.0 overcame many of its problems and provided the foundation for later versions that were almost universally accepted.

1.2.16 Local Area Networks. During the 1980s, stand-alone desktop computers began to perform word processing, financial analysis, and graphic processing. Although this arrangement was much more convenient for end users than was a centralized facility, it was more difficult to share data with others.

As more powerful PCs were developed, it became practical to interconnect them so that their users could easily share data. These arrangements were commonly referred to as local area networks (LANs) because the hardware units were physically close, usually in the same building or office area. LANs have remained important to this day. Typically, a more powerful PC with a high storage capacity fixed⁹ disk was designated as the file server. Other PCs, referred to as workstations, were connected to the file server using network interface cards installed in the workstations with cables between these cards and the file server. Special network software installed on the file server and workstations made it possible for workstations to access defined portions of the file server fixed disk just as if these portions were installed on the workstations. Furthermore, these shared files could be backed up at the file server without depending on individual users. By 1997, it was estimated that worldwide there were more than 150 million PCs operating as LAN workstations. The most common network operating systems (NOS) were Novell NetWare and later Microsoft IE (Internet Explorer).

Most LANs were implemented using the Ethernet (IEEE 802.3) protocol.¹⁰ The server and workstations could be equipped with a modem (modulator/demodulator) connected to a dedicated telephone line. The modem enabled remote users, with a matching modem, to dial into the LAN and log on. This was a great convenience to LAN users who were traveling or working away from their offices, but such remote access created yet another new security issue. For the first time, computer systems were exposed in a major way to the outside world. From then on, it was possible to interact with a computer from virtually anywhere and from locations not under the same physical control as the computers themselves.

Typical NOS logical access control software provided for user IDs and passwords and selective authority to access file server data and program files. A workstation user logged on to the LAN by executing a log-in program resident on the file server.

The program prompted the user to enter an ID and password. If the log-in program concluded that the ID and password were valid, it consulted an access-control table to determine which data and programs the user might access. Access modes were defined as read-only, execute-only, create, modify (write or append), lock, and delete, with respect to individual files and groups of files. The LAN administrator maintained the access control table using a utility program. The effectiveness of the controls depended on the care taken by the administrator, and so, in some circumstances, controls could be weak. It was essential to protect the ID and password of the LAN administrator since, if they were compromised, the entire access-control system became vulnerable. Alert information system security officers noted that control over *physical* access to LAN servers was critical in maintaining the logical access controls. Intruders who could physically access a LAN server could easily restart the server using their own version of the NOS, completely bypassing the installed logical access controls.

Superficially, a LAN appears to be the same as a 1970s mainframe with remote dumb terminals. The difference technically is that each LAN workstation user is executing programs on the workstation, not on the centralized file server, while mainframe computers use special software and hardware to run many programs concurrently, one program for each terminal. To the user at a workstation or remote terminal, the two situations appear to be the same, but from a security standpoint, there are significant differences. The mainframe program software stays on the mainframe and cannot, under normal conditions, be altered during execution. A LAN program on a workstation can be altered, for example, by a computer virus, while actually executing. As a rule, mainframe remote terminals cannot download and save files, whereas workstations usually have at least a removable disk drive. Furthermore, a malicious workstation user can easily install a rewritable CD device, which makes it much easier to copy and take away large amounts of data.

Another important difference is the character of the connection between the computer and the terminals. Each dumb terminal has a dedicated connection to its mainframe and receives only that data that is directed to it. A LAN operates more like a set of radio transmitters sharing a common frequency on which the file server and the workstations take turns “broadcasting” messages. Each message includes a “header” block that identifies the intended recipient, but every node (the file server and the workstations) on a LAN receives all messages. Under normal circumstances, each node ignores messages not addressed to it. However, it is technically feasible for a workstation to run a modified version of the NOS that allows it to capture all messages. In this way, a workstation could identify all log-in messages and record the user IDs and passwords of all other users on the LAN, giving it complete access to all of the LAN’s data and facilities.

Mainframe and LAN security also differ greatly in the operating environment. As noted, the typical mainframe is installed in a separate room and is managed by a staff of skilled technicians. The typical LAN file server, on the other hand, is installed in ordinary office space and is managed by a part-time, remotely located LAN administrator who may not be adequately trained. Consequently, the typical LAN has a higher exposure to tampering, sabotage, and theft. However, if the typical mainframe is disabled by an accident, fire, sabotage, or any other security incident, many business functions will be interrupted, whereas the loss of a LAN file server usually disrupts only a single function.

1.2.17 1990s: Interconnection. The Usenet evolved in the early 1980s as a free system for posting and retrieving news and commentary from participants—an

1 · 12 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

early form of disintermediation, since there were no controlling authorities to limit speech. Newsgroups developed on every conceivable topic, reaching tens of thousands of discussion areas within a few years. Computer enthusiasts and criminal hackers took to Usenet as an ideal channel for exchanging code, including details of hacks.

The commercial equivalents of the Usenet were the value-added networks (VANs) such as America On Line (AOL), CompuServe, and Prodigy. These services provided modems for telephone access, email, and facilities for defining discussion groups. Fees varied from hourly to monthly.

1.2.18 1990s: Total Interconnection. With the growing popularity of LANs, the technologies for interconnecting them emerged. These networks of physically interconnected local area networks were called wide area networks, or WANs. Any node on a LAN could access every node on any other interconnected LAN, and in some configurations, those nodes might also be given access to mainframe and minicomputer files and to processing capabilities.

1.2.19 Telecommuting. Once the WAN technology was in place, it became feasible to link LANs together by means of telecommunications circuits. It had been expensive to do this with the low-speed, online systems of the 1970s because all data had to be transmitted over the network. Now, since processing and most data used by a workstation were on its local LAN, a WAN network was much less expensive. Low-traffic LANs were linked using dial-up access for minimum costs, while major LANs were linked with high-speed dedicated circuits for better performance. Apart from dial-up access, all network traffic typically flowed over nonswitched private networks. Of the two methods, dial-up communications were considerably more vulnerable to security violations, and they remain so to this day.

1.2.20 Internet and the World Wide Web. The Internet, which began life in 1969 as the Advanced Research Projects Agency Network (ARPANET), slowly emerged onto the general computing scene during the 1980s. Initially, access to the Internet was restricted to U.S. Government agencies and their contractors. ARPANET users introduced the concept of email as a convenient way to communicate and exchange documents. Then, in 1989–1990, Sir Tim Berners-Lee conceived of the World Wide Web and the Web browser. This one concept produced a profound change in the Internet, greatly expanding its utility and creating an irresistible demand for access. During the 1990s, the U.S. Government relinquished its control, and the Internet became the gigantic, no-one-is-in-charge network of networks it is today. The explosive growth in participation in the global Internet is generally viewed as having started with the opening up of the .COM top-level domain to general use in 1993.

The Internet offers several important advantages: The cost is relatively low, connections are available locally in most industrialized countries, and by adopting the Internet protocol, TCP/IP, any computer becomes instantly compatible with all other Internet users.

The World Wide Web technology made it easy for anyone to access remote data. Almost overnight, the Internet became the key to global networking. Internet service providers (ISPs) operate Internet-compatible computers with both dial-up and dedicated access. A computer may access an ISP directly as a stand-alone ISP client or via a gateway from a LAN or WAN. A large ISP may offer dial-up access at many locations, sometimes called points of presence or POPs, interconnected by its own network. ISPs establish links with one another through the national access points (NAPs) initially set

up by the National Science Foundation. With this “backbone” in place, any node with access can communicate with another node, connected to a different ISP, located half way around the globe, without making prior arrangements.

The unrestricted access provided by the Internet created new opportunities for organizations to communicate with clients. A company can implement a Web server with a full-time connection to an ISP and open the Web server, and the WWW pages it hosts, to the public. A potential customer can access a Website, download product information and software updates, ask questions, and even order products. Commercial Websites, as they evolved from static “brochure-ware” to online shopping centers, stock brokerages, and travel agencies, to name just a few of the uses, became known as e-businesses.

1.2.21 Virtualization and the Cloud. As far back as the late 1960s, software was available to create encapsulated versions of an operating system on mainframe computers. Users interacted with what appeared to be their own, private mainframe environment. By the late 1980s, vendors created simulations of operating environments that could run under different operating systems (e.g., one could run DOS programs on UNIX machines). The trend continued throughout the succeeding years so that it is commonplace now to run programs under hypervisors that simulate complete or functionally limited versions of required operating systems on shared hardware.¹¹

Today it is possible to provide users with instances of an operating environment on shared hardware, often at a distance, so that incremental increases in requirements can be satisfied at modest costs instead of having to purchase large-scale improvements in the hardware infrastructure. The situation is similar to what service bureaus offered in the decades when mainframe time-sharing was popular.

Another development in the last decade has been the availability of cloud computing, which refers to computer services, including storage (see Chapters 36 and 68), software as a service (SAAS), and infrastructure or platform as a service (IAAS and PAAS). See Chapter 68 for more details of managing and securing cloud computing.

1.2.22 Supervisory Control and Data Acquisition. The use of computers to control production of goods and services through supervisory control and data acquisition (SCADA) software and hardware has been growing throughout the four decades since this *Handbook* was first published in 1973. SCADA systems for critical infrastructure have been of great concern because contrary to initial design specifications, many of them have been connected to the general Internet, opening the systems they govern to subversion. For more about SCADA in information warfare, see Chapter 14 in this *Handbook*.

1.3 GOVERNMENT RECOGNITION OF INFORMATION ASSURANCE.

Certain major events in the history of information assurance (IA) center on government initiatives. In particular, IA has been strongly influenced by the development of security standards starting in the 1980s, by the publication of the landmark publication *Computers and Risk* in 1991, and by the establishment of the InfraGard program in the late 1990s for protection of the U.S. critical infrastructure.

1.3.1 IA Standards. In the late 1970s, the U.S. Department of Defense “established a Computer Security Initiative to foster the wide-spread availability of trusted

1 · 14 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

computer systems.”¹² The author of the initial report that later became the *Trusted Computer Systems Evaluation Criteria* (TCSEC), DoD Standard 5200.28, wrote,

Trusted computer systems are operating systems capable of preventing users from accessing more information than that to which they are authorized. Such systems are in great demand as more processing is entrusted to computers, while less information should be shared by all the system’s users. With this demand comes a need to ascertain the integrity of computer systems on the market ...

The TCSEC was issued with a bright orange cover and became known as the “Orange Book.” Under the direction of National Computer Security Center (NCSC) director Patrick Gallagher and others, the National Security Agency (NSA) issued a “Rainbow Series” of books that profoundly affected the direction of IA in the USA and globally.¹³

The Rainbow Series led to similar efforts in other countries, culminating in the Common Criteria Evaluation and Validation Scheme (CCEVS), which has become the international standard for defining security levels for systems and software and for determining acceptable methods for testing and certifying system compliance with such standards.¹⁴

For details of the evolution of security standards, see Chapter 51 in this *Handbook*.

1.3.2 Computers at Risk.¹⁵ In 1988, the Defense Advanced Research Projects Agency (DARPA) asked the Computer Science and Technology Board (renamed the Computer Science and Telecommunications Board of the NRC in 1990) for a study of computer and communications security issues affecting U.S. Government and industry. The NRC’s System Security Study Committee published its results in a readable and informative book, *Computers at Risk: Safe Computing in the Information Age*.¹⁶

The Committee included experts with impeccable credentials, including executives from major computer vendors such as HP, DEC, and IBM; from high-technology companies such as Shearson, Lehman, Hutton Inc., and Rockwell International; universities such as Harvard and MIT; and think tanks like the RAND Corporation.

A public misconception is the supposed divergence in focus of the military and of commerce: The military is usually described as concerned with external threats and the problem of disclosure, whereas businesses are said to worry more about insider threats to data integrity. On the contrary, the military and commerce need to protect data in similar ways. The differences arise primarily from (1) the sophistication and resources available to governments that try to crack foreign military systems; (2) the relatively strong military emphasis on prevention compared with commercial need for proof that can be used in legal proceedings; and (3) the availability to the military of deep background checks on personnel, contrasted with the limits imposed on the invasion of privacy in the commercial sector.

Some of the more interesting points raised by the NRC Committee assert that:

- Because of the rapid and discontinuous pace of innovation in the computer field, “with respect to computer security, the past is not a good predictor of the future”;
- Embedded systems (those where the microprocessor is not accessible to reprogramming by the user; e.g., medical imaging systems) open us to greater risks from inadequate quality assurance (e.g., a software bug in a Therac 25 linear accelerator killed three patients by irradiating them with more than 100 times the intended radiation dosage);

- Networking makes it possible to harm many more systems: “Interconnection gives an almost ecological flavor to security; it creates dependencies that can harm as well as benefit the community ...”

The Committee proposed major recommendations, summarized as follows:

1. Push for implementation of generally accepted system security principles including:

- Quality assurance standards that address security considerations;
- Access control for operations as well as data (e.g., any of the menu systems which preclude access to the operating system);
- Unambiguous user identification (ID) and authentication (e.g., personal profiles and hand-held password generators)
- Protection of executable code (e.g., flags to show that certain object modules are “production” or “installed” and thus apply strict access control that would prevent unauthorized modification—as found in configuration control systems);
- Security logging (e.g., logging failed file-open attempts and logon password violations);
- Assigning a security administrator to each enterprise;
- Data encryption;
- Operational support tools for verifying the state and effectiveness of security measures (e.g., audit tools);
- Independent audits of system security by people not directly involved in programming or system management of the audited system;
- Hazard analysis evaluating threats to safety from different malfunctions and breaches of security (e.g., consequences of tampering with patient data in hospitals).

2. Take specific short-term actions now:

- Develop security policies for your organization before there’s a problem;
- Form and train computer emergency response teams before a crisis to respond to security violations or attacks;
- Use the Orange Book’s (TCSEC, from the National Computer Security Center’s Rainbow series) C2 and B1 criteria to define guidelines on security;
- Improve software systems development by applying better quality-assurance methods;
- Contribute to voluntary industry groups developing modern security standards and implement those standards in commercial software;
- Make effective security the default in software and hardware (make the user explicitly disable security instead of having to enable it).

3. Learn and teach about security:

- Build a repository of incident data;
- Foster education in engineering secure systems, both by encouraging universities to provide postgraduate training in security and by urging industry to include security training as part of software engineering projects;

1 · 16 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

- Teach beginners about security and ethics in computer usage and programming (e.g., the NCSA is working on a research and development project to study beliefs, attitudes, and behavior about ethical issues in computing in grade and high schools, colleges, and universities).
- 4. Clarify export control criteria and set up a forum for arbitration (hardware and software vendors have been complaining for years that the arbitrary imposition of severe export restrictions hampers American competitiveness in overseas markets without materially helping national security).
- 5. Fund and pursue needed research in such areas as:
 - Security modularity: the effects on security of combining modules with known security properties;
 - Security policy models: more subtle requirements like integrity and availability are still not easily represented by control structures;
 - Cost estimation: there should be better ways of measuring the costs and benefits of security mechanisms in particular applications;
 - New technology: networking, in particular, leads to greater complexity (e.g., how to connect “mutually suspicious organizations”);
 - Quality assurance for security: how to measure effectiveness;
 - Modeling tools: standards for graphical representations of security relationships analogous to the diagrams used in functional decomposition and object-oriented methodologies for program design;
 - Automated procedures: audit and monitoring tools for the data center management team;
 - Nonrepudiation: combining the need for detailed records of user actions with the values of privacy;
 - Resource control: how to ensure that proprietary software and data are used legitimately (e.g., preventing more than the licensed number of users from accessing a system, preventing software theft);
 - Security perimeters: how to reconcile the desire for network interconnection with limitations due to security requirements (“If, for example, a network permits mail but not directory services ... less mail may be sent because no capability exists to look up the address of a recipient”).

Chapter 2 of the NRC report, *Concepts of Information Security*, is a 25-page primer on information systems security that could be handed to any manager who needs to be filled in on why you propose to spend so much money protecting the computer systems. The authors cover the fundamental aspects of information security (confidentiality, integrity, and availability); management controls (individual accountability, auditing, and separation of duties); risks (probabilities of attack or damage) and vulnerabilities (weak points); and privacy issues. In Appendix 2.2, the authors report an informal survey in April 1989 of 30 private companies in a variety of fields. The consensus among those polled included the following basic standards for information systems security (show these to your upper management if necessary):

- Unique IDs, block access after a maximum number of incorrect logon attempts, show last successful access at logon time, make passwords and IDs expire;

- Disallow embedded passwords during logon, make passwords invisible during entry, force minimum length (6), store passwords encrypted, scan proposed passwords to eliminate easy words;
- Permit strict control over file access;
- Detect and interdict viruses, certify software as virus-free, provide data encryption, overwrite deleted files to prevent recovery, force tight binding of production data to production programs;
- Automated time-out for inactive sessions, unique identification of terminals and workstations during logon;
- Network security monitoring, modem locking, callback, automatic data encryption during transmission;
- Audit trails, including security violations;
- Generally applicable security standards that could be used by vendors and users to evaluate different equipment and software for specific environments.

Twenty years later, focus among information assurance experts has shifted beyond the technical to emphasize organizational controls. For example, the 2003 survey of members of the Information Systems Security Association included these information security function practices among the respondents:

- Access controls: 73%
- Written information security policy: 72%
- Compliance with existing laws and regulations: 66%
- Creation of organization and process to implement policy: 59%
- Awareness and training program: 57%
- Regular monitoring, reviewing, and auditing: 57%
- Business continuity planning: 57%
- Risk assessment and risk management: 56%

In 2007, Gary S. Miliefsky proposed the following seven priorities for corporate information security:

1. Policies
2. Awareness and training
3. Information security self-assessments
4. Regulatory compliance self-assessments
5. Corporate-wide encryption
6. Manage all corporate assets
7. Test Business Continuity Planning (BCP) and Disaster Recovery Planning (DRP)¹⁷

The Computer Security Division of the Information Technology Laboratory at the National Institute of Standards and Technology issued a draft reference model that

1 · 18 BRIEF HISTORY AND MISSION OF INFORMATION SYSTEM SECURITY

included the following “programmatic, integration, and system security activities that are typically a part of an information security program”:

- Program Security Activities
 - Annual and Quarterly Review and Reporting of Information Security Program
 - Asset Inventory
 - Awareness and Specialized Security Training
 - Continuity of Operations
 - Incident Response
 - Periodic Testing and Evaluation
 - Plan of Action and Milestones
 - Policies and Procedures
 - Risk Management
- Integration Activities
 - Business Risk
 - Capital Planning and Investment Control (CPIC)
 - Configuration Management
 - Enterprise Architecture (EA)
 - Environmental Protection
 - Human Resources
 - Personnel Security
 - Physical Security
 - Privacy
 - Records Management
 - Strategic Plan
 - System Development Life Cycle (SDLC)
- System Security Activities
 - Categorize the Information System
 - Select Security Controls
 - Supplement Security Controls
 - Document Security Controls
 - Implement Security Controls
 - Assess Security Controls
 - Authorize the Information System
 - Monitor Security Controls

1.3.3 InfraGard.¹⁸ InfraGard is a nationwide program in the United States that brings together representatives from information technology departments in industry and academia for information sharing and analysis, especially to help protect critical infrastructure against cyberattacks and also to support the FBI in its cybercrime investigations and education projects.¹⁹

The organization started in the Cleveland Field Office of the FBI in 1996 and expanded rapidly until there are now over 11,000 members in over 40 chapters. Joining InfraGard is easy and free for U.S. citizens residing in the United States. Using the Website (www.infragard.org), you can locate a nearby local chapter (“Find Chapters”) and contact your chapter officers. You can get application forms online and then send them in to the FBI liaison officer for that chapter to be vetted for admission. The FBI conducts a background check to ensure that all members are likely to be trustworthy to participate in confidential discussions of threats and vulnerabilities. Chapters usually conduct regular local meetings and organize list-servers for exchange of information among members. Many have newsletters as well.

1.4 RECENT DEVELOPMENTS. In recent years, a key development has been the dramatic increase in availability of inexpensive portable data storage devices. At the time of writing (2013), flash drives the size of a lipstick or even of an antacid pill are available with capacities in the dozens of gigabytes for a few dollars. Such devices are available in a wide range of concealable formats such as pens, music players, watches, and (no joke) sushi. Pocket-sized hard disks and solid-state drives with capacities in the hundreds of gigabytes to terabytes are available for less than US\$100. Digital cameras use storage cards that can be used for data transfers; mobile phones include cameras and recording capabilities. A 64 GB micro SD card for a phone costs about \$50 and can hold 6,000 songs from iTunes—or the entire customer database being stolen by a disaffected soon-to-be-fired employee. Controlling data leakage through unauthorized connection of such devices has become a significant problem for security managers. Systems for restricting connection of devices and controlling data transfers to such storage media (data-loss prevention or DLP) are spreading through government and corporate environments (see Chapter 13 in this *Handbook* for a detailed discussion of DLP).

Another issue that increasingly concerns security managers is the protection of personally identifiable information (PII) from customers or data subjects. Many organizations including government agencies, banks, and universities have suffered serious damage from loss of control over PII and the risks of identity theft resulting from exposure of such sensitive data. Legislators are responding to public concern by increasing legal requirements for protection of PII. The use of encryption on mobile data systems such as laptop computers, personal digital assistants (PDAs), mobile phones, and integrated systems that combine many functions (e.g., BlackBerries) has become a necessity. See Chapter 69 in this *Handbook* for extensive discussion of protection of PII.

A consequence of the growing interconnectivity of storage and communications devices is that corporate networks are no longer insulated from less-secure systems. Users who connect poorly protected laptops (or other devices) to public networks such as hotel-supplied ISPs or wireless access points in coffee shops may return to their home offices with malware-infected systems that contaminate the entire network. Security managers are increasingly turning to integrated systems for controlling connectivity via virtual private networks and supervisory software that monitors and restricts unauthorized connections, software installations, and downloads.

Another growing issue is the increasing speed and persistence of attacks on systems and networks by state-sponsored and criminal organizations engaged in industrial espionage and fraud. See Chapters 2, 14, 15, and 46, among many others in this *Handbook*, for further discussion of the changing threat profile for today’s information systems.

1.5 ONGOING MISSION FOR INFORMATION SYSTEM SECURITY.

There is no end in sight to the continuing proliferation of Internet nodes, to the variety of applications, to the number and value of online transactions, and, in fact, to the rapid integration of computers into virtually every facet of our existence. Nor will there be any restrictions as to time or place. With 24/7/365, always-on operation, and with global expansion even to relatively undeveloped lands, both the beneficial effects and the security violations can be expected to grow apace.

Convergence, which implies computers, televisions, cell phones, and other means of communication combined in one unit, together with continued growth of information technology, will lead to unexpected security risks. Distributed denial-of-service (DDoS) attacks, copyright infringement, child pornography, fraud, theft of identity, and industrial espionage are all ongoing security threats. So far, no perfect defensive measures have been developed.

The situation is currently (2013) changing from identifying vulnerabilities and preventing penetrations to identifying compromises and minimizing damage from long-lasting subversion of protection mechanisms. Situational awareness and rapid response are becoming an increasingly important element in long-term defenses of our information.

This *Handbook* provides a foundation for understanding and blunting both the existing vulnerabilities and those new threats that will inevitably arise in the future. Certainly, no one but the perpetrators could have foreseen the use of human-guided missiles to attack the World Trade Center. Besides its symbolic significance, the great concentration of resources within the WTC increased its attractiveness as a target. After 9/11, the importance of physical safety of personnel has become the dominant security issue, with disaster recovery of secondary, but still great, concern. This *Handbook* cannot foresee all possible future emergencies, but it does prescribe some preventative measures, and it does recommend procedures and resources for mitigation and remediation.

1.6 NOTES

1. Many technical specialists tend to use the term “security” to refer to logical access controls. A glance at the contents pages of this volume shows the much broader scope of information system security.
2. For further details, see, for example, www.cs.uiowa.edu/~jones/cards.
3. See <http://ei.cs.uiowa.edu/~history/UNIVAC.Weston.html> and inventors.about.com/library/weekly/aa062398.htm
4. It is notable that the IBM 1401 computer was so named because the initial model had 1,400 bytes of main memory. It was not long before memory size was raised to 8 kilobytes and then later to as much as 32 kilobytes. In 1980, the Series III minicomputer from Hewlett-Packard doubled its maximum memory from 1 megabyte to 2 megabytes at a cost of \$64,000 (about \$200,000 in 2008 dollars). This compares with today’s personal computers, typically equipped with no less than 512 megabytes and often a gigabyte or more.
5. The term “dumb” was used because the terminal had no internal storage or processing capability. It could only receive and display characters and accept and transmit keystrokes. Both the received characters and the transmitted ones were displayed on a cathode ray tube (CRT) much like a pre-color television screen. Consequently, these were also called “glass” terminals.

6. “Multiprocessing,” “multiprogramming,” and “multitasking” are terms that are used almost interchangeably today. Originally, multitasking implied that several modules or subroutines of a single program could execute together. Multiprogramming was designed to execute several different programs, and their subroutines, concurrently. Multiprocessing most often meant that two or more computers worked together to speed program execution by providing more resources.

2.1 WHY STUDY HISTORICAL RECORDS? Every field of study and expertise develops a common body of knowledge that distinguishes professionals from amateurs. One element of that body of knowledge is a shared history of significant events that have shaped the development of the field. Newcomers to the field benefit from learning the names and significant events associated with their field so that they can understand references from more senior people in the profession, and so that they can put new events and patterns into perspective. This chapter provides a brief overview of some of the more famous (or notorious) cases of computer crime (including those targeting computers and those mediated through computers) of the last four decades.¹

2.2 OVERVIEW. This chapter illustrates several general trends from the 1960s through mid-2013:

- In the early decades of modern information technology (IT), computer crimes were largely committed by individual disgruntled and dishonest employees.
- Physical damage to computer systems was a prominent threat until the 1980s.
- Criminals often used authorized access to subvert security systems as they modified data for financial gain or destroyed data for revenge.
- Early attacks on telecommunications systems in the 1960s led to subversion of the long-distance phone systems for amusement and for theft of services.
- As telecommunications technology spread throughout the IT world, hobbyists with criminal tendencies learned to penetrate systems and networks.
- Programmers in the 1980s began writing malicious software, including self-replicating programs, to interfere with personal computers.
- As the Internet increased access to increasing numbers of systems worldwide, criminals used unauthorized access to poorly protected systems for vandalism, political action, and financial gain.
- As the 1990s progressed, financial crime using penetration and subversion of computer systems increased.
- The types of malware shifted during the 1990s, taking advantage of new vulnerabilities and dying out as operating systems were strengthened, only to succumb to new attack vectors.

- Illegitimate applications of email grew rapidly from the mid-1990s onward, generating torrents of unsolicited commercial and fraudulent email.
- Organized crime became increasingly involved in systematic penetration of financial systems and targeted fraud.
- Chinese government-supported civilian and military agents increasingly used computer-based industrial espionage to gain significant economic advantages over industry and commerce in North America and Europe.

2.3 1960s AND 1970s: SABOTAGE. Early computer crimes often involved physical damage to computer systems and subversion of the long-distance telephone networks.

2.3.1 Direct Damage to Computer Centers. In February 1969, the largest student riot in Canada was set off when police were called in to put an end to a student occupation of several floors of the Hall Building. The students had been protesting against a professor accused of racism, and when the police came in, a fire broke out and computer data and university property were destroyed. The damages totaled \$2 million, and 97 people were arrested.²

Thomas Whiteside cataloged a litany of early physical attacks on computer systems in the 1960s and 1970s³:

1968	Olympia, WA: An IBM 1401 in the state is shot twice by a pistol-toting intruder
1970	University of Wisconsin: Bomb kills one and injures three people and destroys \$16 million of computer data stored on site
1970	Fresno State College: Molotov cocktail causes \$1 million damage to computer system
1970	New York University: Radical students place fire-bombs on top of Atomic Energy Commission computer in attempt to free a jailed Black Panther
1972	Johannesburg, South Africa: Municipal computer is dented by four bullets fired through a window
1972	New York: Magnetic core in Honeywell computer attacked by someone with a sharp instrument, causing \$589,000 of damage
1973	Melbourne, Australia: Antiwar protesters shoot American firm's computer with double-barreled shotgun
1974	Charlotte, NC: Charlotte Liberty Mutual Life Insurance Company computer is shot by a frustrated operator
1974	Dayton, OH: Wright Patterson Air Force Base: Four attempts are made to sabotage computers, including by magnets, loosened wires, and gouges in equipment
1977	Rome, Italy: Four terrorists pour gasoline on university computer and burn it to cinders
1978	Lompoc, CA: Vandenberg Air Force Base: A peace activist destroys an unused IBM 3031 using a hammer, a crowbar, a bolt cutter, and a cordless power drill as a protest against the NAVSTAR satellite navigation system, claiming it gives the United States a first-strike capability

The incidents of physical abuse of computer systems did not stop as other forms of computer crime increased. For example, in 2001, *NewsScan* editors⁴ summarized a report from *Wired Magazine*:

A survey by British PC maker Novatech, intended to take a lighthearted look at techno-glitches, instead revealed the darker side of computing. One in every four computers has been physically assaulted by its owner, according to the 4,200 respondents.⁵

2 · 4 HISTORY OF COMPUTER CRIME

In April 2003, the National Information Protection Center and Department of Homeland Security reported:

Nothing brings a network to a halt more easily and quickly than physical damage. Yet as data transmission becomes the lifeblood of Corporate America, most big companies haven't performed due diligence to determine how damage-proof their data lifelines really are. Only 20 percent of midsize and large companies have seriously sussed out what happens to their data connections after they go beyond the company firewall, says Peter Salus of MatrixNetSystems, a network-optimization company based in Austin, TX.⁶

By the mid-2000s, concerns over the physical security of electronic voting systems had risen to public awareness. For example:

A cart of Diebold electronic voting machines was delivered today to the common room of this Berkeley, CA, boarding house, which will be a polling place on Tuesday's primary election. The machines are on a cart which is wrapped in plastic wrap (the same as the stuff we use in the kitchen). A few cable locks (bicycle locks, it seems) provide the appearance of physical security, but they aren't threaded through each machine. Moreover, someone fiddling with the cable locks, I am told, announced after less than a minute of fiddling that he had found the three-digit combination to be the same small integer repeated three times.⁷

2.3.2 1970–1972: Albert the Saboteur. One of the most instructive early cases of computer sabotage occurred at the National Farmers Union Service Corporation of Denver, where a Burroughs B3500 computer suffered 56 disk head crashes in the two years from 1970 to 1972. Downtime was as long as 24 hours per crash, with an average of 8 hours per incident. Burroughs experts were flown in from all over the United States at one time or another, and concluded that the crashes must be due to power fluctuations.

By the time all the equipment had been repaired and new wiring, motor generators, circuit breakers, and power-line monitors had been installed in the computer room, total expenditures for hardware and construction were over \$500,000 (in 1970 dollars). Total expenses related to down time and lost business opportunities because of delays in providing management with timely information are not included in this figure. In any case, after all this expense, the crashes continued sporadically as before.

By this time, the experts were beginning to wonder about their analysis. For one thing, all the crashes had occurred at night. Could it be sabotage? Surely not! Old Albert, the night-shift operator, had been so helpful over all these years; he had unfailingly called in the crashes at once, gone out for coffee and donuts for the repair crews, and been meticulous in noting the exact times and conditions of each crash. However, all the crashes had in fact occurred on his shift.

Management installed a closed-circuit television (CCTV) camera in the computer room—without informing Albert. For some days, nothing happened. Then one night another crash occurred. On the CCTV monitor, security guards saw good ol' Albert open up a disk cabinet and poke his car key into the read/write head solenoid, shorting it out and causing the 57th head crash.

The next morning, management confronted Albert with the film of his actions and asked for an explanation. Albert broke down in mingled shame and relief. He confessed to an overpowering urge to shut the computer down. Psychological investigation determined that Albert, who had been allowed to work night shifts for years without a change, had simply become lonely. He arrived just as everyone else was leaving; he left as everyone else was arriving. Hours and days would go by without the slightest human

interaction. He never took courses, never participated in committees, never felt involved with others in his company. When the first head crashes occurred—spontaneously—he had been surprised and excited by the arrival of the repair crew. He had felt useful, bustling about, telling them what had happened. When the crashes had become less frequent, he had involuntarily, and almost unconsciously, re-created the friendly atmosphere of a crisis team. He had destroyed disk drives because he needed company.⁸

2.4 IMPERSONATION. Using the insignia and specialized language of officials as part of social engineering has a long history in crime; a dramatization of these techniques is in the popular movie *Catch Me If You Can*⁹ about Frank William Abagnale Jr., the teenage scammer and counterfeiter who pretended to be a pilot, a doctor, and a prosecutor before eventually becoming a major contributor to the U.S. Government's anticounterfeiting efforts and then founding a major security firm.¹⁰

Several criminals involved in computer-mediated or computer-oriented crime became notorious for using impersonation.

2.4.1 1970: Jerry Neal Schneider. A notorious computer-related crime started in 1970, when teenager Jerry Neal Schneider used Dumpster[®] diving to retrieve printouts from the Pacific Telephone and Telegraph (PT&T) company in Los Angeles. After years of collection, he had enough knowledge of procedures that he was able to impersonate company personnel on the phone. He collected yet more detailed information on procedures. Posing as a freelance magazine writer, he even got a tour of the computerized warehouse and information about ordering procedures. In June 1971, he ordered \$30,000 of equipment to be sent to a normal PT&T dropoff point—and promptly stole it and sold it. He eventually had a 6,000-square-foot warehouse and 10 employees. He stole over \$1 million of equipment—and sold some of it back to PT&T. He was finally denounced by one of his own disgruntled employees and became a computer security consultant after his prison term.¹¹

2.4.2 1980–2003: Kevin Mitnick. Born in 1963, Kevin Mitnick became involved in crime early, using a special punch for bus transfers to get free rides anywhere in the San Fernando Valley in California by the time he was a young teenager. His own autobiographical comments show him to have been involved in phone phreaking, malicious pranks, and breaking into computers at the Digital Equipment Corporation (DEC) using social engineering.¹²

In 1981, he and his friend Lewis De Payne used social engineering to gain unauthorized access to an operations center for Pacific Bell; “the juvenile court ordered a diagnostic psychological study of Mitnick and sentenced him to a year’s probation.”¹³ In 1987, he was arrested for breaking into the computers of the Santa Cruz Operation, makers of SCO UNIX, and sentenced to three years’ probation.

In the summer of 1988, Mitnick and his accomplice and friend Lenny DiCicco cracked the University of Southern California computers again and misappropriated hundreds of Mb of disk space (a lot at the time) to store VAX VMS source files stolen from Digital Equipment Corporation (DEC). Mitnick was arrested by the Federal Bureau of Investigation (FBI) for having stolen the VAX VMS source code. During his trial, he was described as suffering from an impulse-control disorder. In July 1989, he was sentenced to a year in jail and six months’ rehabilitation. He later tried to become a private investigator and security specialist. He was generally treated with hostility by the established information security community.

2 · 6 HISTORY OF COMPUTER CRIME

In November 1992, Mitnick went underground again when the FBI got a warrant for his arrest on charges of stealing computer time from a phone company. He was located two years later when he made the mistake of leaving insulting messages on the computer and voicemail systems of a physicist and Internet security expert Tsutomu Shimomura. Shimomura was so irritated that he helped law enforcement authorities track the fugitive to North Carolina, where Mitnick was arrested in February 1995 and imprisoned pending trial.

Mitnick was convicted in federal court for the Central District of California on August 9, 1999, and sentenced to 46 months imprisonment for “four counts of wire fraud, two counts of computer fraud, and one count of illegally intercepting a wire communication.”¹⁴ Mitnick was previously sentenced by Judge Pfaelzer to an additional 22 months in prison, this for possessing cloned cellular phones when he was arrested in North Carolina in 1995, and for violating terms of his supervised release imposed after being convicted of an unrelated computer fraud in 1989. He admitted to violating the terms of supervised release by hacking into PacBell voicemail and other systems, and to associating with known computer hackers, in this case codefendant Louis De Payne. Following his release from prison in September 2000, Mitnick was to be on three years’ parole, during which his access to computers was restricted¹⁵ and his profits from writing or speaking about his criminal career were to be turned over to reimburse his victims.

Mitnick earned a living on the talk circuit and eventually founded his own security consulting firm. In the years since his release from prison, he has collaborated in writing several books on social engineering.¹⁶

Perhaps his most significant position in the history of computer crime is that he became an icon in the criminal underground. “FREE KEVIN” was a popular component of Web vandalism for many years, and Eric Corley, the longtime editor of the criminal-hacking publication *2600: The Hacker Quarterly*, even made a movie, *Freedom Downtime*, about what the criminal underground describes as the grossly unfair treatment of Mitnick by the federal government and the news media.¹⁷

2.4.3 Credit Card Fraud. Credit at local businesses dates back into the undocumented past.¹⁸ In the United States, credit cards appeared in the mid-1920s when gasoline companies began issuing cards that were recognized at stations across the country.¹⁹ In 1950, Frank X. McNamara started the Diners Club, the first credit card company serving multiple types of businesses; the company began the practice of charging a percentage fee for each transaction and also charged its clients a membership fee.²⁰ The VISA card evolved from the 1951 BankAmericard from the Bank of America, and a consortium of California banks established MasterCard shortly thereafter. American Express started its card program in 1958.

Card use rose and, unsurprisingly, credit card fraud was rampant. Mail theft also became widespread as unscrupulous individuals discovered that envelopes containing credit cards were just like envelopes full of cash. And there was little to stop card companies from sending out cards that customers had never asked for, were not expecting, and could not have known had been stolen, until the issuing company began demanding payment for the charges that had been run up. These crimes and other problems stemming from the relentless card-pushing by banks led directly to the passage of the Fair Credit Billing Act of 1974²¹ as well as many other laws²² designed to protect the consumer.²³

By the mid-1990s, credit card fraud was a rapidly growing problem for consumers and for law enforcement. A 1997 FBI report stated:

Around the world, bank card fraud losses to Visa and Master-Card alone have increased from \$110 million in 1980 to an estimated \$1.63 billion in 1995 The United States has suffered the bulk of these losses—approximately \$875 million for 1995 alone. This is not surprising because 71 percent of all worldwide revolving credit cards in circulation were issued in this country Law enforcement authorities continually confront new and complex schemes involving credit card frauds committed against financial institutions and bank card companies. Perpetrators run the gamut from individuals with easy access to credit card information—such as credit agency officials, airline baggage handlers, and mail carriers, both public and private, to organized groups, usually from similar ethnic backgrounds, involved in large-scale card theft, manipulation, and counterfeiting activities. Although current bank card fraud operations are numerous and varied, several schemes account for the majority of the industry's losses by taking advantage of dated technology, customer negligence, and laws peculiar to the industry.²⁴

2.4.4 Identity Theft Rises. By the late 1990s and in the decade following the year 2000, credit card fraud was subsumed into the broader category of *identity theft*. Instead of limiting their depredations to running up bills on stolen or forged credit card accounts, thieves, often in organized rings, created entire bogus parallel identities, initiating unpaid bank loans, buying cars with other people's credit, and wreaking havoc with innocent victims' credit ratings, financial situations, and even their daily life. Victims of extreme cases lost their ability to obtain mortgages, buy new homes, and accept new jobs. Worse, the burden of proof of innocence fell on the victims, in a bitter reversal of the assumption of innocence underlying British common law and its offshoot in the commonwealth and the United States.

In August 2008, the U.S. Department of Justice announced²⁵ the single largest and most complex case of identity theft ever charged in this country. It involved eleven people from five different countries, including two from the United States and two from the People's Republic of China, who had stolen more than 40,000,000 credit card records from a major U.S. retailer. They drove by, or loitered at, buildings in which wireless networks were housed, and installed sniffers that recorded passwords, card numbers, and account data. Unless adequate preventative measures are installed quickly, more such horrendous events will be sure to occur. For more on wireless network security, see Chapter 33 in this *Handbook*.

The 2011 report from the U.S. Bureau of Justice Statistics, *Identity Theft Reported by Households, 2005–2010* provides additional details. The abstract includes these highlights:

- In 2010, 7.0 percent of households in the United States, or about 8.6 million households, had at least one member age 12 or older who experienced one or more types of identity theft victimization.
- Among households in which at least one member experienced one or more types of identity theft, 64.1 percent experienced the misuse or attempted misuse of an existing credit card account in 2010.
- From 2005 to 2010, the percentage of all households with one or more type of identity theft that suffered no direct financial loss increased from 18.5 percent to 23.7 percent.²⁶

2 · 8 HISTORY OF COMPUTER CRIME

A report from Javelin Strategy & Research covering identity fraud in 2012 included the following observation in the overview: “Identity fraud incidence increased in 2012 for the second consecutive year, affecting 5.26% of U.S. adults. This increase was driven by dramatic jumps in the two most severe fraud types, new account fraud (NAF) and account takeover fraud (ATF).”²⁷

2.5 PHONE PHREAKING. Even in the earliest days of telephony, teenage boys played with the new technology to cause havoc. In the late 1870s, the new AT&T system in America had to stop using teenagers as switchboard operators:

The boys were openly rude to customers. They talked back to subscribers, saucing off, uttering facetious remarks, and generally giving lip. The rascals took Saint Patrick’s Day off without permission. And worst of all they played clever tricks with the switchboard plugs: disconnecting calls, crossing lines so that customers found themselves talking to strangers, and so forth.

This combination of power, technical mastery, and effective anonymity seemed to act like catnip on teenage boys.²⁸

2.5.1 2600 Hz. In the late 1950s, AT&T began switching its telephone networks to direct-dial long distance, using specific frequency tones to communicate among its switches. Around 1957, a blind seven-year-old child named Josef Engressia with perfect pitch and an emotional fixation on telephones learned to whistle the 2600-Hz pitch that interrupted long-distance telephone calls and allowed him to place a free long-distance call to anywhere in the world.²⁹ This emotionally disturbed person eventually renamed himself “Joybubbles” and is often described as the founder of phone phreaking—the manipulation of the phone system for unauthorized access to services.

John Draper was in the U.S. Air Force in 1964 when he began helping his colleagues place free phone calls. At the suggestion of Joybubbles, he used the whistles in Cap’n Crunch cereal boxes to generate the 2600-Hz tone and then, calling himself Captain Crunch, went on to create electronic tone synthesizers called *blue boxes*.³⁰ In the 1970s, Apple founders Steve Wozniak and Steve Jobs built blue boxes and, using the devices, perpetrated such pranks as calling the Vatican while pretending to be Henry Kissinger.³¹

A significant contributor to the growth of phreaking in the 1970s was the publication in 1971 of an article about phreaking in *Esquire Magazine*, which attracted the attention of many young technophiles.³²

2.5.2 1982–1991: Kevin Poulsen. As the phone system shifted to greater reliance on computers, the border between phreaking and hacking began to blur. One of the important names from the 1980s period of fascination with everything phone-related was Kevin Poulsen.

Kevin Poulsen’s autobiographical sketch is shown next.

Kevin Poulsen first gained notoriety in 1982, when the Los Angeles County District Attorney’s Office raided him for gaining unauthorized access to a dozen computers on the ARPANET, the forerunner of the modern Internet. Seventeen years old at the time, he was not charged, and went on to work as a programmer and computer security supervisor for SRI International in Menlo Park, California, then as a network administrator at Sun Microsystems.

In 1987, Pacific Bell security agents discovered that Poulsen and his friends had been penetrating telephone company computers and buildings. After learning that Poulsen had also worked for a defense contractor where he’d held a SECRET level security clearance, the FBI began building an espionage case against the hacker.

Confronted with the prospect of being held without bail, Poulsen became a fugitive. While on the run, he obtained information on the FBI's electronic surveillance methods, and supported himself by hacking into Pacific Bell computers to cheat at radio-station phone-in contests, winning a vacation to Hawaii and a Porsche 944-S2 Cabriolet in the process.

After surviving two appearances on NBC's *Unsolved Mysteries*, Poulsen was finally captured on April 10th, 1991, in a Van Nuys grocery store, by a Pacific Bell security agent acting on an informant's tip. On December 4th, 1992, Poulsen became the first hacker to be indicted under U.S. espionage laws when the Justice Department charged him with stealing classified information. (18 U.S.C. 793).

Poulsen was held without bail while he vigorously fought the espionage charge. The charge was dismissed on March 18th, 1996.

Poulsen served five years, two months, on a 71-month sentence for the crimes he committed as a fugitive, and the phone hacking that began his case. He was freed June 4th, 1996, and began a three-year period of supervised release, barred from owning a computer for the first year, and banned from the Internet for the next year and a half.

Since his release, Poulsen has appeared on MSNBC, and on ABC's Nightline, and he was the subject of Jon Littman's flawed book, "The Watchman—the Twisted Life and Crimes of Serial Hacker Kevin Poulsen." His case has earned mention in several computer security and infowar tracts—most of which still report that he broke into military computers and stole classified documents.³³

After his release from prison, Kevin Poulsen turned to journalism. He became an editor for *SecurityFocus* and then was hired as a senior editor at *Wired News*. He is a serious investigative reporter (e.g., he broke the story of sexual predators in MySpace)³⁴ and a frequent contributor to the "Threat Level" blog.³⁵

2.6 DATA DIDDLE. One of the most common forms of computer crime since the start of electronic data processing is *data diddling*—illegal or unauthorized data alteration. These changes can occur before and during data input, or before output. Data-diddling cases have included bank records, payrolls, inventory data, credit records, school transcripts, telephone switch configurations, and virtually all other applications of data processing.

2.6.1 Equity Funding Fraud (1964–1973). One of the classic early data-diddling frauds was the Equity Funding case, which began with computer problems at the Equity Funding Corporation of America, a publicly traded and highly successful firm with a bright idea. The idea was that investors would buy insurance policies from the company and also invest in mutual funds at the same time, with profits to be redistributed to clients and to stockholders. Through the late 1960s, Equity's shares rose dizzyingly in price, and there were news magazine stories about this wunderkind of the Los Angeles business community.

The computer problems occurred just before the close of the financial year in 1964. An annual report was about to be printed, yet the final figures simply could not be extracted from the mainframe. In despair, the head of data processing told the president the bad news; the report would have to be delayed. Nonsense, said the president expansively (in the movie, anyway); simply make up the bottom line to show about \$10 million in profits and calculate the other figures so it would come out that way. With trepidation, the DP chief obliged. He seemed to rationalize it with the thought that it was just a temporary expedient, and could be put to rights later in the real financial books.

2 · 10 HISTORY OF COMPUTER CRIME

The expected profit did not materialize, and some months later, it occurred to the executives at Equity that they could keep the stock price high by manufacturing false insurance policies that would make the company look good to investors. They therefore began inserting false information about nonexistent policyholders into the computerized records used to calculate the financial health of Equity.

In time, Equity's corporate staff got even greedier. Not content with jacking up the price of their stock, they decided to sell the policies to other insurance companies via the redistribution system known as reinsurance. Reinsurance companies pay money for policies they buy and spread the risk by selling parts of the liability to other insurance companies. At the end of the first year, the issuing insurance companies have to pay the reinsurers part of the premiums paid in by the policyholders. So in the first year, selling imaginary policies to the reinsurers brought in large amounts of real cash. However, when the premiums came due, the Equity crew "killed" imaginary policyholders with heart attacks, car accidents, and, in one memorable case, cancer of the uterus—in a male imaginary policyholder.

By late 1972, the head of DP calculated that by the end of the decade, at this rate, Equity Funding would have insured the entire population of the world. Its assets would surpass the gross national product of the planet. The president merely insisted that this showed how well the company was doing.

The scheme fell apart when an angry operator who had to work overtime told the authorities about shenanigans at Equity. Rumors spread throughout Wall Street and the insurance industry. Within days, the Securities and Exchange Commission had informed the California Insurance Department that they had received information about the ultimate form of data diddling: Tapes were being erased. The officers of the company were arrested, tried, and condemned to prison terms.³⁶

2.6.2 1994: Vladimir Levin and the Citibank Heist. In February 1998, Vladimir Levin was sentenced to three years in prison by a court in New York City. Levin masterminded a major conspiracy in 1994 in which the gang illegally transferred \$12 million in assets from Citibank to a number of international bank accounts. The crime was spotted after the first \$400,000 was stolen in July 1994, and Citibank cooperated with the FBI and Interpol to track down the criminals. Levin was ordered to pay back \$240,000, the amount he actually managed to withdraw before he was arrested.³⁷ The incident led to Citibank's hiring of Stephen R. Katz as the banking industry's first chief information security officer (CISO).

2.7 SALAMI FRAUD. In the salami technique, criminals steal money or resources a bit at a time. Two different etymologies are circulating about the origins of this term. One school of security specialists claim that it refers to slicing the data thin—like a salami. Others argue that it means building up a significant object or amount from tiny scraps—like a salami.

There were documented cases of salami frauds in the 1970s and 1980s, but one of the more striking incidents came to light in January 1993, when four executives of a Value Rent-a-Car franchise in Florida were charged with defrauding at least 47,000 customers using a salami technique. The federal grand jury in Fort Lauderdale claimed that the defendants modified a computer billing program to add five extra gallons to the actual gas tank capacity of their vehicles. From 1988 through 1991, every customer who returned a car without topping it off ended up paying inflated rates for an inflated

total of gasoline. The thefts ranged from \$2 to \$15 per customer—rather thick slices of salami but nonetheless difficult for the victims to detect.

Unfortunately, salami attacks are *designed* to be difficult to detect. The only hope is that random audits, especially of financial data, will pick up a pattern of discrepancies and lead to discovery. As any accountant will warn, even a tiny error must be tracked down, since it may indicate a much larger problem. For example, Cliff Stoll's famous adventures tracking down spies in the Internet began with an unexplained \$0.75 discrepancy between two different resource accounting systems on UNIX computers at the Keck Observatory of the Lawrence Berkeley Laboratories. Stoll's determination to understand how the problem could have occurred revealed an unknown user; investigation led to the discovery that resource-accounting records were being modified to remove evidence of system use. The rest of the story is told in Clifford Stoll's book *The Cuckoo's Egg*.

2.8 LOGIC BOMBS. A logic bomb is a program that has deliberately been written or modified to produce results when certain conditions are met that are unexpected and unauthorized by legitimate users or owners of the software. Logic bombs may be within standalone programs, or they may be part of worms (programs that hide their existence and spread copies of themselves within a computer systems and through networks) or viruses (programs or code segments which hide within other programs and spread copies of themselves).

Time bombs are a subclass of logic bombs that “explode” at a certain time.

According to a National Security Council employee, the United States Government authorized insertion of a time bomb in software to control the Trans-Siberian natural gas pipeline that they knew would be stolen from U.S. sources by the Soviet government. “The result was the most monumental non-nuclear explosion and fire ever seen from space,” said Thomas C. Reed.³⁸

The infamous Jerusalem virus (also known as the Friday the 13th virus) of 1988 was a time bomb. It duplicated itself every Friday and on the thirteenth of the month, causing system slowdown; on every Friday the 13th after May 13, 1988, it also corrupted all available disks on the infected systems.

Other examples of notorious time bombs include:

- A common PC virus from the 1980s, *Cascade*, made all the characters fall to the last row of the display during the last three months of every year.
- The Michelangelo virus of 1992 was designed to damage hard disk directories on the sixth of March every year.
- In 1992, computer programmer Michael Lauffenburger was fined \$5,000 for leaving a logic bomb at General Dynamics. His intention was to return after his program had erased critical data and be paid to fix the problem.³⁹

The most famous time bomb of recent years was the Y2K (year 2000) problem. In brief, old programs used two-digit year codes that were based on the assumption that they applied to the twentieth century. As the twenty-first century approached, analysts warned of catastrophic consequences if the programs were not corrected to use four-digit years or otherwise adapt to the change of century.⁴⁰ In the event, the corrective measures worked and there were no disasters. Later analysis showed a positive correlation between investments in Y2K remediation and later profitability.⁴¹

2 · 12 HISTORY OF COMPUTER CRIME

2.9 EXTORTION. Computer data can be held for ransom. For example, according to Whiteside, in 1971, two reels of magnetic tape belonging to a branch of the Bank of America were stolen at Los Angeles International Airport. The thieves demanded money for their return. The owners ignored the threat of destruction because they had adequate backup copies.

Other early cases of extortion involving computers:

- In 1973, a West German computer operator stole 22 tapes and received \$200,000 for their return. The victim did not have adequate backups.
- In 1977, a programmer in the Rotterdam offices of Imperial Chemical Industries, Ltd. (ICI) stole all his employer's tapes, including backups. Luckily, ICI informed Interpol of the extortion attempt. As a result of the company's forthrightness, the thief and an accomplice were arrested in London by officers from Scotland Yard.

In the 1990s, one of the most notorious cases of extortion was the 1999 theft of 300,000 records of customer credit cards from the CD Universe Web site by "Maxus," a 19-year-old Russian. He sent an extortion note that read: "Pay me \$100,000 and I'll fix your bugs and forget about your shop forever ... or I'll sell your cards [customer credit data] and tell about this incident in news." Refused by CD Universe owners, he promptly released 25,000 credit card numbers via a Web site that became so popular with criminals that Maxus had to limit access to one stolen number per visit.

2.10 TROJAN HORSES. Trojans are programs that pretend to be useful but that also contain harmful code or are just plain harmful.

2.10.1 1988 Flu-Shot Hoax. One of the nastiest tricks played on the shell-shocked world of early microcomputer users was the FLU-SHOT-4 incident of March 1988. With the publicity given to damage caused by destructive, self-replicating virus programs distributed through electronic bulletin board systems (BBSs), it seemed natural that public-spirited programmers would rise to the challenge and provide protective screening.

Flu-Shot-3 was a useful program for detecting viruses. Flu-Shot-4 appeared on BBSs and looked just like version 3; however, it actually destroyed critical areas of hard disks and any floppies present when the program was run. The instructions that caused the damage were not present in the program file until it was running; this self-modifying code technique makes it especially difficult to identify Trojans by simple inspection of the assembler-level code.

2.10.2 Scrambler, 12-Tricks, and PC Cyborg. Other early and notorious PC Trojans from the late 1980s that are still remembered in the industry included:

- The Scrambler (also known as the KEYBGR Trojan), which pretended to be a keyboard driver (KEYBGR.COM), but actually made a smiley face move randomly around the screen

- The 12-Tricks Trojan, which masqueraded as CORETEST.COM, a program for testing the speed of a hard disk, but actually caused 12 different kinds of damage (e.g., garbling printer output, slowing screen displays, and formatting the hard disk).
- The PC Cyborg Trojan (or “AIDS Trojan”), which claimed to be an AIDS information program but actually encrypted all directory entries, filled up the entire C disk, and simulated COMMAND.COM, but produced an error message in response to nearly all commands.

2.10.3 1994: Datacomp Hardware Trojan. On November 8, 1994, a correspondent reported to the *RISKS Forum Digest* that he had been victimized by a curious kind of Trojan:

I recently purchased an Apple Macintosh computer at a “computer superstore,” as separate components—the Apple CPU, and Apple monitor, and a third-party keyboard billed as coming from a company called Sicon.

This past weekend, while trying to get some text-editing work done, I had to leave the computer alone for a while. Upon returning, I found to my horror that the text “welcome datacomp” had been inserted into the text I was editing. I was certain that I hadn’t typed it, and my wife verified that she hadn’t, either. A quick survey showed that the “clipboard” (the repository for information being manipulated via cut/paste operations) wasn’t the source of the offending text.

As usual, the initial reaction was to suspect a virus. Disinfectant, a leading anti-viral application for Macintoshes, gave the system a clean bill of health; furthermore, its descriptions of the known viruses (as of Disinfectant version 3.5, the latest release) did not mention any symptoms similar to my experiences.

I restarted the system in a fully minimal configuration, launched an editor, and waited. Sure enough, after a (rather long) wait, the text “welcome datacomp” once again appeared, all at once, on its own.

Further investigation revealed that someone had put unauthorized code in the ROM chip used in several brands of keyboard. The only solution was to replace the keyboard. Readers will understand the possible consequences of a keyboard that inserts unauthorized text into, say, source code. Winn Schwartau, the renowned computer security expert, has coined the word “chipping” to refer to such unauthorized modification of firmware.

2.10.4 Keylogger Trojans. By the mid-2000s, software and hardware Trojans designed to capture logs of keystrokes and sometimes to transmit those logs via covert Internet connections had become a well-known tool of industrial espionage. The United States Department of Homeland Security issued a warning in December 2005 that included this overview:

According to industry security experts, the biggest security vulnerability facing computer users and networks is email with concealed Trojan Horse software—destructive programs that masquerade as benign applications and embedded links to ostensibly innocent websites that download malicious code. While firewall architecture blocks direct attacks, email provides a vulnerable route into an organization’s internal network through which attackers can destroy or steal information.

Attackers try to circumvent technical blocks to the installation of malicious code by using social engineering—getting computer users to unwittingly take actions that allow the code to be installed and organization data to be compromised.

2 · 14 HISTORY OF COMPUTER CRIME

The techniques attackers use to install Trojan Horse programs through email are widely available, and include forging sender identification, using deceptive subject lines, and embedding malicious code in email attachments.

Developments in thumb-sized portable storage devices and the emergence of sophisticated keystroke logging software and devices make it easy for attackers to discover and steal massive amounts of information surreptitiously.⁴²

2.10.5 Haephtrati Trojan. A case that made the news in the mid-2000s began when Israeli author Amon Jackont was upset to find parts of the manuscript on which he was working posted on the Internet. Then someone tried to steal money from his bank account. Suspicion fell on his stepdaughter's ex-husband, Michael Haephtrati. Police discovered a keystroke logger on Jackont's computer. It turned out that Haephtrati had also sold spy software to clients; the Trojan was concealed in what appeared to be confidential email. Once installed on the victims' computers, the software sent surveillance data to a server in London, England.

Haephtrati was detained by U.K. police and investigations began in Germany and Israel. Twelve people were detailed in Israel; eight others were under house arrest. Suspects included private investigators and top executives from industrial firms. Victims included Hewlett-Packard, Ace hardware stores, and a cable-communications company.

Michael and Ruth Haephtrati were extradited from Britain for trial in Israel on January 31, 2006. They were accused of installing the Trojan horse program that activated a key logger with remote-reporting capabilities.⁴³

In March 2006, the couple were indicted in Tel Aviv for corporate espionage.⁴⁴ They pleaded guilty to the charges⁴⁵ and were sentenced to four and two years of jail, respectively, as well as punished with fines.⁴⁶

The story did not end there, however. Two years later, "Four members of the Israeli Modi'in Ezrahi private investigation firm were sentenced on Monday after they were found guilty of using Trojan malware to steal commercially sensitive information from their clients' competitors."⁴⁷ The report continues:

Asaf Zlotovsky, a manager at the Modi'in Ezrahi detective firm, was jailed for 19 months. Two other employees, Haim Zissman and Ron Barhoum, were sent to prison for 18 and nine months respectively. The firm's former chief exec, Yitzhak Rett, the victim of an apparent accident when he fell down a stairwell during a break in police questioning back in 2005, escaped a jail sentence under a plea bargaining agreement. Rett was fined 250,000 Israeli Shekels (£36,500) and ordered to serve ten months' probation over his involvement in the scam.

However, an article in April 2008 reported that Michael Haephtrati "claimed that there was no jail time, and that he was completely free. As a matter of fact he was going to continue to offer his Trojan Horse service but this time he would only work with 'law enforcement agencies.'"⁴⁸

2.10.6 Hardware Trojans and Information Warfare. In the late 2000s, a flurry of news stories discussed the dangers of growing reliance on Chinese-manufactured computing components.

U.S. Defense Department sources say privately that the level of Chinese cyberattacks obliges them to avoid Chinese-origin hardware and software in all classified systems and as many unclassified systems as fiscally possible. The high threat of Chinese cyberpenetrations into U.S. defense networks will be magnified as the Pentagon increasingly loses domestic sources of "trusted and classified" microchips.⁴⁹

The discovery of counterfeit Cisco routers worsened concerns about the reliability of Chinese-manufactured network equipment.⁵⁰ The FBI, Immigration and Customs Enforcement (ICE), Customs and Border Protection (CBP), and the Royal Canadian Mounted Police (RCMP) worked together to track a massive pattern of counterfeit network hardware including Cisco routers; these investigations and seizures raised questions about the reliability and trustworthiness of such equipment, much of which was manufactured in the People's Republic of China. Although Cisco scientists examined some of the counterfeit equipment and found no back doors, concern was serious enough that government agencies created test chips to challenge quality assurance processes at military contractors:

In April [2008], the Defense Advanced Research Projects Agency, part of the Defense Department, began distributing chips with hidden Trojan horse circuitry to military contractors participating in an agency program, Trusted Integrated Circuits. The goal is to test forensic techniques for finding hidden electronic trap doors, which can be maddeningly elusive. The agency is not yet ready to announce the results of the test, said Jan Walker, a spokeswoman for the agency.⁵¹

A 2011 report on hearings before the U.S. House Oversight and Government Reform Committee about the issue of Trojan backdoors in imported software and hardware included this assertion with references for each topic:

... [E]mbedded malware lurking in consumer tech is not a new development. Since it's been happening for years and is hardly a national security secret, it's unclear why Schaffer hesitated so long before answering. There have been many incidents of malware-infected products being shipped to consumers, from hardware, to software, and even tainted peripheral devices. Malware has been sent pre-loaded in products like USBs, microchips, cameras, battery chargers, digital photo frames, webcams, printers, cell phones, motherboards or system boards, and hard drives.⁵²

2.11 NOTORIOUS WORMS AND VIRUSES. The next sections briefly describe some of the outstanding incidents that are often mentioned in discussions of the history of malware.⁵³

2.11.1 1970–1990: Early Malware Outbreaks. The ARPANET was the precursor of the Internet.⁵⁴ According to several reports:

Sometime in the early 1970s, the Creeper virus was detected on ARPANET, a US military computer network which was the forerunner of the modern Internet. Written for the then-popular Tenex operating system, this program was able to gain access independently through a modem and copy itself to the remote system. Infected systems displayed the message, "I'M THE CREEPER: CATCH ME IF YOU CAN."

Shortly thereafter, the Reaper program was anonymously created to delete Creeper. Reaper was a virus: it spread to networked machines and if it located a Creeper virus, Reaper would delete it. Even the participants are unable to say whether Reaper was a response to Creeper, or if it was created by the same person or persons who created Creeper in order to correct their mistake.⁵⁵

By 1981, the Apple II computer was a popular system among hobbyists; the Elk Cloner virus spread via infected floppy disks and is regarded as "the first large-scale computer virus outbreak in history."⁵⁶

2 · 16 HISTORY OF COMPUTER CRIME

In 1986, the Brain boot-sector virus was the first IBM-PCs malware to spread around the world. It was created by two brothers from Lahore, Pakistan, and included this text:

Welcome to the Dungeon (c) 1986 Brain & Amjads (pvt) Ltd VIRUS.SHOE RECORD V9.0
Dedicated to the dynamic memories of millions of viruses who are no longer with us today -
Thanks GOODNESS!! BEWARE OF THE er...VIRUS: this program is catching program
follows after these messages....\$#@%@!!

The Lehigh Virus appeared at Lehigh University in Pennsylvania in 1987 and damaged the files of several professors and students. This early program-infector targeted only *command.com* and was therefore extremely limited in its spread.

In 1988, the Jerusalem virus, a file infector that reproduced by inserting its code into EXE and COM files, caused a global PC epidemic.

Another noteworthy infection of 1988 came from the self-encrypting Cascade virus of 1988, which confused many naive users who interpreted the falling symbols on their screen as part of an unexpected screen saver. This virus was one of the earliest examples of the attempts to counter signature-based antivirus products.

2.11.2 December 1987: Christmas Tree Worm. In December 1987, users of IBM mainframe computers connected to the European Academic Research Network (EARN), BITNET, and the IBM company VNET were flooded with email bearing a character-based representation of a Christmas tree. A student at Technische Universität Clausthal⁵⁷ in Germany launched “a worm, written in an IBM-specific language called REXX.”⁵⁸ The worm used the victim’s list of correspondents to send copies of itself to everyone on the list.⁵⁹

2.11.3 November 2, 1988: Morris Worm. On November 2, 1988, the Internet was rocked by the explosive appearance of unauthorized code on systems all over the world. At 17:00 EST on November 2, 1988, Robert T. Morris, a student at Cornell University in Ithaca, New York, released a worm into the Internet. By midnight, it had attacked VAX computers running 4 BSD UNIX and SUN Microsystems Sun 3 computers throughout the United States. One of the most interesting aspects of the worm’s progress through the Internet was the almost complete independence of its path from normal geographical constraints. It sometimes leaped from coast to coast faster than it reached physically neighboring computer systems. The worm graphically demonstrated that cyberspace has its own geography.

The worm often superinfected its hosts, leading to slowdowns in overall processing speed. The first Internet warning (“We are under attack”) was posted at 02:38 on November 3 to the TCP-IP list by a scientist at University of California at Berkeley. At 03:34, Andy Sudduth, a friend of Morris’s at Harvard, posted a warning message (“There may be a virus loose on the internet”) anonymously and included a few comments on how to stop the worm. Unfortunately, Spafford writes, the Internet was so severely impeded by the worm that this message was not widely distributed for over 24 hours.

By 6:00 on the morning of November 3, messages were creeping through the Internet with details of how the worm worked. The news spread via news groups such as the TCP-IP list, Usenix 4bsd-ucb-fixes, and the Usenet news.announce.important group. Spafford and his friends and colleagues on the Internet collaborated feverishly on providing patches against the worm.

Meanwhile, as word spread of the attack, some systems administrators began cutting their networks out of the Internet. The Defense Communications Agency isolated its Milnet and Arpanet networks from each other around 11:30 on November 3. At noon, machines in the science and technology center at the Stanford Research Institute were shut down.

By late on November 4, a comprehensive set of patches was posted on the Internet to defend systems against the worm. That evening, a *New York Times* reporter told Spafford that the author of the worm had been found.

By November 8, the Internet seemed to be back to normal. A group of concerned computer scientists met at the National Computer Security Center to study the incident and think about preventing recurrences of such attacks. Spafford put the incident into perspective with the comment that the affected systems were no more than 5 percent of the hosts on the Internet. It would be foolish to dismiss Morris's electronic vandalism as a prank or to claim that the worm alerted managers to weak security on their systems. Nonetheless, it is true that the incident contributed to the establishment of the Computer Emergency Response Team at the Software Engineering Institute of Carnegie-Mellon University. For these blessings, however, we owe no gratitude to Robert T. Morris.

In 1990, Morris was found guilty under the Computer Fraud and Abuse Act of 1986. The maximum penalties included five years in prison, a \$250,000 fine, and restitution costs. Morris was ordered to perform 400 hours of community service, sentenced to three years probation, and required to pay \$10,000 in fines. He was expelled from Cornell University.

His lawyers appealed the conviction to the Supreme Court of the United States. Their arguments included lack of evil intent (he did not mean to cause harm, honest—even though his worm took extraordinary precautions to conceal itself) and they deplored the scandalous behavior of Cornell University authorities, who had the temerity to search their own electronic mail message system to locate evidence that incriminated Morris. The lawyers also argued that sending a mail message might become a crime if Morris's conviction were upheld.

The Supreme Court upheld the decision by declining to hear the appeal.⁶⁰

Robert T. Morris eventually became an associate professor in the Electrical Engineering and Computer Science Department of the Massachusetts Institute of Technology and a member of the Computer Science and Artificial Intelligence Laboratory.⁶¹

2.11.4 Malware in the 1990s. The most significant malware development of the 1990s was the release in July 1995 of the world's first widely distributed macro-language virus. The *macro.concept* virus made its appearance in MS-Word for Windows documents. It demonstrated how to use the macro programming language, common to many Microsoft products, to generate self-reproducing macros that spread from document to document. Within a few months, clearly destructive versions of this demonstration virus appeared.

Macro viruses were a dangerous new development. As explained in a recent history of viruses and antiviruses:

- Putting self-reproducing code in easily and frequently exchanged files, such as documents, greatly increased the infectiousness of the viruses.
- Virus writers shifted their attention to a much easier programming language than assembly.

2 · 18 HISTORY OF COMPUTER CRIME

- Email exchanges of infected documents were a far more effective mechanism for virus infection than exchanges of infected programs or disks.
- “[M]acro viruses were neither platform-specific, nor OS-specific. They were application-based.”⁶²

In the latter half of the 1990s, macro viruses replaced boot sector viruses and file infector viruses as a major type of malicious self-reproducing malware; during that period, additional types of script-based, network worms also increased.

Exhibit 2.1 shows the rise and fall of prevalence of macro viruses over the decade from discovery to extinction using data from the WildList archives. The WildList shows malware identified on user systems by at least two virus researchers.⁶³

Roger Thompson summarizes the developments in malware in the 1990s in this way:

By around 2000, macro viruses ceased to be a problem because the new version of MS-Office 2000 included features that blocked macro viruses. The next step in the evolution of malware was the mass mailers like the ILOVEYOU worm and then the network worms. These were easy to write and easy to obfuscate by varying the text contents, thus defeating signature scanners. These worms spread very quickly until the release of Windows XP Service Pack 2, which forced the Windows Firewall to be on by default. After that extinction-level event, criminals moved onward to creating mass mailers and bots which could spread malware and spam or cause distributed denial-of-service through communication via the trusted Web sites accessed through browsers that created a tunnel through the firewall.⁶⁴

2.11.5 March 1999: Melissa. On Friday, March 26, 1999, the CERT/CC received initial reports of a fast-spreading new MS-Word macro virus. “Melissa” was written to infect such documents; once loaded, it uses the victim’s MAPI-standard email address book to send copies of itself to the first 50 people on the list. The virus attaches an infected document to an email message with subject line “Subject: Important Message From <name>” where <name> is that of the inadvertent sender. The email message reads: “Here is that document you asked for ... don’t show anyone else;-)” and includes a MS-Word file as an infected attachment. The original infected document, “list.doc,” was a compilation of URLs for pornographic Websites. However, as the virus spread, it was capable of sending any other infected document created by the victim.

Because of this high replication rate, the virus spread faster than any previous virus in history. On many corporate systems, the rapid rate of internal replication saturated email servers with outbound automated junk email. Initial estimates were in the range of 100,000 downed systems. Antivirus companies rallied immediately, and updates for all the standard products were available within hours of the first notices from CERT/CC.

The search for the originator of the Melissa email computer virus/worm began immediately after the outbreak. Initial findings traced the virus to Access Orlando, a Florida Internet Service Provider (ISP), whose servers were shut down by order of the FBI for forensic examination; the systems were then confiscated. That occurrence was then traced back to Source of Kaos, a free-speech Website where the virus may have lain dormant for months in a closed but not deleted virus-distributor’s pages. Investigators discovered a serial number in the vector document, written with MS-Word; the undocumented serial number helped law enforcement when investigators circulated it on the Net to help track down the perpetrator.

The next steps turned to the value-added network AOL, where the virus was released to the public. The giant ISP’s information helped to identify a possible suspect and

by April 2, the FBI arrested David L. Smith (age 30) of Aberdeen, New Jersey. Smith apparently panicked when he heard the FBI was on the trail of the Melissa spawner and he threw away his computer—stupidly, into the trash at his own apartment building.

Smith was charged with second-degree offenses of interruption of public communication, conspiracy to commit the offense and attempt to commit the offense, third-degree theft of computer service, and third-degree damage or wrongful access to computer systems. If convicted, Smith faced a maximum penalty of \$480,000 in fines and 40 years in prison. On December 10, 1999, Smith pleaded guilty to all federal charges and agreed to every particular of the indictment, including the estimates by the International Computer Security Association of at least \$80 million of consequential damages due to the Melissa infections.⁶⁵

2 · 20 HISTORY OF COMPUTER CRIME

2.11.6 May 2000: I Love You. Starting around May 4, 2000, email users opened messages from familiar correspondents with the subject line “I love you”; many then opened the attachment, LOVE-LETTER-FOR-YOU.txt.vbs, which infected the user’s email address book and initiated mass mailing of itself to all the contacts. The “Love Bug” was the fastest-spreading worm to that time, infecting computers all over the world, starting in Asia, then Europe.⁶⁶

On May 11, Filipino computer science student Onel de Guzman of AMA Computer College in Manila admitted to authorities that he may “accidentally have launched the destructive Love Bug virus out of youthful exuberance.” He did not admit that he had created the malware himself; however, the name GRAMMERSoft appeared in the computer code of the virus, and that was the name of a computer group to which the 23-year-old de Guzman belonged.⁶⁷

In September 2000, de Guzman participated in a live chat hosted by CNN.com; he vigorously defended virus-writing and blamed the creators of vulnerable systems for releasing poorly designed software. He refused to take responsibility for writing the worm.⁶⁸

Philippine authorities tried to prosecute de Guzman but had to drop their attempts in August 2000 for lack of sufficient evidence. Due to the lack of computer crime laws at the time, it was impossible for other countries such as the United States to extradite the suspect: International principles of dual criminality require equivalent laws in both jurisdictions before extradition can proceed.

By October 2000, de Guzman had refused to take responsibility for writing the worm and publicly stated, “I admit I create viruses, but I don’t know if it’s one of mine.... If the source code was given to me, I could look at it and see. Maybe it is somebody else’s, or maybe it was stolen from me.”⁶⁹

The “I Love You” case was a wake-up call for the international community to think about standardizing computer crime laws around the globe.⁷⁰

2.11.7 July 2010 Stuxnet. In July 2010, reports surfaced of a zero-day threat to SCADA systems using Siemens AG’s Simatic WinCC and PCS 7 software. Analysts found that the Stuxnet worm was designed for industrial espionage; however, the same techniques could have been used for sabotage. Experts expressed concern that the worm was signed using valid digital certificates from Taiwanese companies and that the complex code implied considerable knowledge of the SCADA software.⁷¹ Further analysis of the malware code suggested that the software was developed by the United States and Israel and used at least as early as November 2007.⁷²

2.12 SPAM. Chapter 20 in this *Handbook* includes a detailed history of unsolicited commercial email and the reason it is called *spam*. This section looks solely at a seminal abuse of the USENET in 1994 and trends in spam over the next decade.

2.12.1 1994: Green Card Lottery Spam. On April 2, 1994, Laurence A. Canter and Marthas S. Siegel posted an advertisement for legal services connected to the U.S. Government’s Green Card Lottery to over 6,000 USENET groups. Instead of cross-posting their commercial message, they used a script to post a copy of the message separately to every group. The former method would have shown the message to USENET users once; Canter and Siegel’s abuse of the USENET made their ad show up in every affected group to which users subscribed.⁷³

Reaction worldwide was massive. Automated cancelbots trolled the USENET deleting the unwanted messages; the attorneys' ISP was so overloaded with email complaints that its servers crashed. Canter and Siegel were reviled in postings and newspaper articles.⁷⁴ Their unsavory backgrounds were posted in discussion groups, including details of disciplinary hearings before the Florida Bar and accusations of dishonesty and unprofessional behavior.⁷⁵

Unfazed, the couple published a book about how to abuse the Internet using spam and defended their actions in interviews as an expression of freedom of speech; they dismissed critics as “wild-eyed zealots” or as commercial interests intent on controlling the Internet for their own gain.⁷⁶

Canter was eventually disbarred in Tennessee, in part for his spamming.⁷⁷ He remained unrepentant; in 2002, he spammed 50,000 K–12 teachers with an advertisement for a book whose title he liked so he could harvest payments for referrals from Amazon.⁷⁸

2.12.2 Spam Goes Global. Over the next decade, the incidence of spam grew explosively. By 2007, spam watchers and anti-spam companies reported that around 88 percent of all email traffic on the Internet was spam. Spammers caused so much irritation that companies developed software and hardware solutions for filtering email by content. Spammers responded by increasing the number of images in their spam, making content filtering more difficult. At one point, the amount of spam grew 17 percent between one day and the next as spammers began pumping PDF files into spam pipelines.⁷⁹

Botnets spawned through infected zombie machines established rogue SMTP nodes using innocent (and ignorant) PC users' computers and persistent high-speed Internet connections.⁸⁰ Spam currently provides a major vector for fraud by deceit, including in particular 4-1-9 advance fee fraud and phishing attacks.⁸¹ Advance-fee fraud usually consists of enticements to participate in the theft of ill-gotten gains such as bank deposits belonging to dead people or stolen from poor countries; the dupes who agree to participate in such illegality are promised millions of dollars—only to be told that they suddenly have to send cash for unexpected bribes or fees. If they do so, they are asked for more ... and more ... and more. Phishing involves sending email messages that are supposed to look like official, usually alarming, warnings from banks and other institutions; victims click on links that look like one thing but actually go to the criminals' Websites. There the victims cheerfully type in their user identification, passwords, bank account numbers, and all manner of other confidential information useful for identity theft.⁸² Advance-fee fraud and phishing are discussed in Chapter 20 in this *Handbook*.

2.13 DENIAL OF SERVICE. Denial of service results from exhaustion or destruction of necessary resources and is thoroughly discussed in Chapter 18. However, a couple of denial-of-service attackers stand out among all the others in the last two decades: the Unamailer and Mafiaboy.

2.13.1 1996: Unamailer. In August 1996, someone using the pseudonym “johnny [x]chaotic” claimed the blame for a massive mail-bombing run based on fraudulently subscribing dozens of victims to hundreds of mailing lists. The denial of service was the result in part of the naïveté of list managers who accepted subscriptions for any email address from any other email address. In a rambling and incoherent letter posted on the Net, (s)he made rude remarks about famous and not-so-famous

2 · 22 HISTORY OF COMPUTER CRIME

people, whose capacity to receive meaningful email was then obliterated by up to thousands of unwanted messages a day.⁸³ “The first attack, in August, targeted more than 40 individuals, including Bill Clinton and Newt Gingrich and brought a torrent of complaints from the people who found their names sent as subscribers to some 3,000 E-mail lists.”⁸⁴

Someone claiming to be the same “Unamailer” (as the news media labeled him or her in reference to the Unabomber) launched a similar mass-subscription mail-bombing run in late December.

This attack is estimated to involve 10,139 listservs groups, 3 times greater than the one that took place in the summer, also at xchaotic’s instigation. If each mailing list in this attack sent the targeted individuals just a modest 10 letters to the subscribers’ computers those individuals would receive more than 100,000 messages. If each listing system sent 100 messages—and many do—then the total messages could tally 1,000,000.⁸⁵

In December, the attacker(s) sneered at list administrators for failing to use authentication before allowing subscriptions and wrote that they would continue their attacks until practices changed.⁸⁶

Partly as a result of the Unamailer’s depredations, list administrators did in fact change their practices—not that anyone thanked Johnny [x]chaotic for his method of persuasion.

2.13.2 2000: MafiaBoy. On February 8, 2000, Yahoo.com suffered a three-hour flood from a distributed denial-of-service (DDoS) attack and lost its capacity to serve Web pages to visitors. The next day, the same technique was extended to Amazon.com, eBay.com, Buy.com, and CNN.com.⁸⁷ Later information also showed that Charles Schwab, the online stock brokerage, had been seriously impeded in serving its customers because of the DDoS. Buy.com managers were particularly disturbed because the attack occurred on the day of their initial public offering. As a result of the attacks, a number of firms formed a consortium to fight DDoS attacks.⁸⁸

Investigation by the RCMP and the FBI located a 15-year-old child in west-end Montreal who used a modem to control zombies in his DDoS escapade:

On April 15, 2000, the RCMP arrested a Canadian juvenile known as Mafiaboy for the February 8th DDoS attack on CNN in Atlanta, Georgia. On August 3, 2000, Mafiaboy was charged with 64 additional counts. On January 18, 2001, Mafiaboy appeared before the Montreal Youth Court in Canada and pleaded guilty to 56 counts. These counts included mischief to property in excess of \$5,000 against Internet sites, including CNN.com, in relation to the February 2000 attacks. The other counts related to unauthorized access to several other Internet sites, including those of several US universities. On September 12, 2001, Mafiaboy appeared before the Montreal Youth Court in Canada and was sentenced to eight months “open custody,” one year probation, and restricted use of the Internet.⁸⁹

MafiaBoy’s name was not released by Canadian authorities because of Canadian laws protecting juveniles, although several U.S. reporters distributed his identity in their publications. His chief contribution to the history of computer crime was to demonstrate asymmetric warfare in cyberspace.⁹⁰ His actions showed that even an ignorant child with little knowledge of computing could use low-tech hardware and tools available to anyone on the Internet to cripple major organizations.

2.14 HACKER UNDERGROUND. Newcomers to the field of information assurance will encounter references to the computer underground in texts, articles, and

discussions. The sections that follow provide thumbnail sketches of some of the key groups and events in the shadowy world of criminal hacking (known as *black hats*, in contrast to *white hats*, who are law enforcement and establishment security experts), and the intermediate range of well-intentioned rebels who use unorthodox means to challenge corporations and governments over what they see as security failings (these people are often called *gray hats*).

2.14.1 1981: Chaos Computer Club. On September 12, 1981, a group of German computer enthusiasts with a strong radical political orientation formed the Chaos Computer Club (CCC) in Hamburg.⁹¹ One of their first achievements was to demonstrate a serious problem in the Bundespost's (German post office) new Bildschirmtext (BTX) interactive videotext service in 1984, not long after the service was announced.⁹² The CCC used security flaws in BTX to transfer a sizable amount of money into their own bank account through a script that ran overnight as a demonstration to the press (returning the money publicly).

After the Legion of Underground (LoU) announced on January 1, 1999, that they would attack and disable the computer systems of the People's Republic of China and of Iraq, a coalition of hacker organizations including the CCC announced opposition to the move. "We strongly oppose any attempt to use the power of hacking to threaten or destroy the information infrastructure of a country, for any reason," the coalition said. "Declaring war against a country is the most irresponsible thing a hacker group could do. This has nothing to do with hacktivism or hacker ethics and is nothing a hacker could be proud of," the coalition said in the statement.

The CCC has, in general, challenged the general view that "hacker" necessarily means "criminal hacker."⁹³ Their annual Chaos Communications Conferences have proven to be a site of technology exchange and serious discussion of information security issues. Their continued commitment to the rule of law (except where their own activities are concerned), and their willingness to engage authorities in the courts when necessary has gained them an unusual degree of credibility and acceptance in the information security community as relatively pale-gray hats.⁹⁴

2.14.2 1982: The 414s. One morning in June 1982, a system administrator for a DEC VAX 11/780 minicomputer at the Memorial Sloan-Kettering Cancer Center in Manhattan found his system down. Investigation led to the discovery that his and dozens of other systems around the country were being hacked by Milwaukee-area teenagers and others aged 15 to 22. The youths called themselves the 414s after the Milwaukee area code.

Using home computers connected to ordinary telephone lines, they had been breaking into computers across the U.S. and Canada, including one at a bank in Los Angeles, another at a cement company in Montreal and, ominously, an unclassified computer at a nuclear weapons laboratory in Los Alamos, [New Mexico].⁹⁵

In March 1984, "two members of Milwaukee's 414 Gang ... pleaded guilty to misdemeanor charges of making obscene or harassing phone calls. Maximum sentence for each charge: six months in jail and a \$500 fine."⁹⁶

2.14.3 1984: Cult of the Dead Cow. Another influential criminal-hacker group is the Cult of the Dead Cow (cDc), which used to sport amusing (although intentionally offensive to some) cartoons such as that of a crucified cow.⁹⁷ The cDc

2 · 24 HISTORY OF COMPUTER CRIME

was noted for its consistent use of humor and parody; for example, “Swamp Rat’s” 1985 article on building “The infamous ... GERBIL FEED BOMB” included instructions such as “Light the fuse if you put one in. If you dropped a match into it, then go to the nearest phone, dial ‘911’ and tell the nice people that you have a large number of glass shards embedded in your lower body. An ambulance should be there soon.”⁹⁸

The cDc became important proponents of hactivism in the 1990s—the use of criminal hacking techniques for political purposes. They also released a number of hacking tools, of which Back Orifice (BO) and especially Back Orifice 2000 (BO2K) were notorious examples. BO2K was ostensibly a remote administration tool but was in fact a Trojan that ran in stealth mode and allowed remote control of infected machines.⁹⁹ Some observers felt that presenting BO2K as a legitimate tool was another instance of cDc’s satirical bent: The idea that anyone would consider software written by criminal hackers as a trustworthy administration tool struck them as ludicrous.

2.14.4 1984: 2600: *The Hacker Quarterly*. Eric Corley founded *2600: The Hacker Quarterly* in 1984. This publication has become a standard-bearer for proponents of criminal hacking. The magazine has published a steady stream of explanations of how to exploit specific vulnerabilities in a wide range of operating systems and application environments. In addition, the editor’s political philosophy has influenced more than one generation of black-hat and gray-hat hackers:

In the worldview of *2600*, the tiny band of technocrat brothers (rarely, sisters) are a besieged vanguard of the truly free and honest. The rest of the world is a maelstrom of corporate crime and high-level governmental corruption, occasionally tempered with well-meaning ignorance. To read a few issues in a row is to enter a nightmare akin to Solzhenitsyn’s, somewhat tempered by the fact that *2600* is often extremely funny.¹⁰⁰

2.14.5 1984: Legion of Doom. The DC Comics empire created an animated cartoon series called *Super Friends* that appeared in 1973; it starred various DC Comics heroes, such as Superman, Aquaman, Wonder Woman, and Batman.¹⁰¹ In a follow-up series called *Challenge of the Super Friends* that ran from 1978 through 1979, the archenemies of these heroes were a group known as the *Legion of Doom*, which included Lex Luthor, archenemy of Superman.¹⁰² A group of phone phreakers who later turned to criminal hacking called themselves the Legion of Doom (LOD); their founder called himself “Lex Luthor.” Another major member was Loyd Blankenship (“The Mentor”).

Bruce Sterling describes the LOD as an influential hacker underground group of the 1980s and one of the earliest to capitalize on regular publication of their findings of vulnerabilities and exploits in the phone system and then in computer networks:

LOD members seemed to have an instinctive understanding that the way to real power in the underground lay through covert publicity. LOD were flagrant. Not only was it one of the earliest groups, but the members took pains to widely distribute their illicit knowledge. Some LOD members, like “The Mentor,” were close to evangelical about it. *Legion of Doom Technical Journal* began to show up on boards throughout the underground.

LOD Technical Journal was named in cruel parody of the ancient and honored *AT&T Technical Journal*. The material in these two publications was quite similar—much of it, adopted from public journals and discussions in the telco community. And yet, the predatory attitude of LOD made even its most innocuous data seem deeply sinister; an outrage; a clear and present danger.¹⁰³

In the later 1980s, the LOD actually helped law enforcement on occasion by restraining malicious hackers.

One of the best-known members was Chris Goggans, whose handle was “Erik Bloodaxe”; he was also an editor of *Phrack* and later became part of the Masters of Deception (MOD), which was involved in a conflict with LOD in 1990 and 1991 known in hacker circles as “The Great Hacker War.”¹⁰⁴

Another well-known hacker who started in LOD and moved to MOD was Mark Abene (“Phiber Optik”), who was eventually imprisoned for a year after pleading guilty in federal court to conspiracy and unauthorized access to federal-interest computers (a violation of 18 USC 1030(a), the Computer Fraud and Abuse Act of 1986).¹⁰⁵ Abene’s punishment was the subject of much protest in the hacker community and elsewhere.¹⁰⁶

2.14.6 1985: *Phrack*. *Phrack* began publishing in November 1985. With a new issue every month or two at first, the electronic magazine continued uninterrupted distribution of technical information and rants. The uncensored commentary provided a fascinating glimpse of some of the personalities and worldviews of its contributors and editors, including Taran King and Craig Neidorf (later to become famous as “Knight Lightning” and for his involvement in an abortive prosecution involving Bell-South documents). For example, *Phrack* published what became known as the “Hacker Manifesto”—held up by criminal hackers as a light unto the nations (“Written almost 15 years ago by The Mentor, this should be taped up next to everyone’s monitor to remind them who we are, this rang true with Hackers, but it now rings truth to the internet generation.”¹⁰⁷), but viewed with skepticism by security professionals. It read in part:

This is our world now ... the world of the electron and the switch, the beauty of the baud. We make use of a service already existing without paying for what could be dirt-cheap if it wasn’t run by profiteering gluttons, and you call us criminals. We explore ... and you call us criminals. We seek after knowledge ... and you call us criminals. We exist without skin color, without nationality, without religious bias ... and you call us criminals. You build atomic bombs, you wage wars, you murder, cheat, and lie to us and try to make us believe it’s for our own good, yet we’re the criminals.

Yes, I am a criminal. My crime is that of curiosity. My crime is that of judging people by what they say and think, not what they look like. My crime is that of outsmarting you, something that you will never forgive me for.

I am a hacker, and this is my manifesto. You may stop this individual, but you can’t stop us all ... after all, we’re all alike.¹⁰⁸

In the 1990s, publication frequency faltered, falling to once every three to six months until the editors announced the final issue, #63, for August 2005. However, publication resumed under new editorial leadership in May 2007 with issue 64; given that issue 65 did not come out until April 2008, the magazine’s heyday is presumably past.

2.14.7 1989: Masters of Deception. The Masters of Deception (MOD) were a New York hacker group active from about 1989 through 1992.¹⁰⁹ Among the most notorious criminal hackers in the group was “Phiber Optik” (Mark Abene, born in 1972), who was unusually visible in the media:

Phiber Optik in particular was to seize the day in 1990. A devotee of the 2600 circle and stalwart of the New York hackers’ group “Masters of Deception,” Phiber Optik was a splendid exemplar of the computer intruder as committed dissident. The eighteen-year-old Optik, a high-school dropout and part-time computer repairman, was young, smart, and ruthlessly obsessive, a sharp-dressing, sharp-talking digital dude who was utterly and airily contemptuous of anyone’s rules

2 · 26 HISTORY OF COMPUTER CRIME

but his own. By late 1991, Phiber Optik had appeared in *Harper's*, *Esquire*, the *New York Times*, in countless public debates and conventions, even on a television show hosted by Geraldo Rivera.¹¹⁰

2.14.8 1990: Operation Sundevil. After two years of investigation, on May 7, 8, and 9, 1990, 150 FBI agents, aided by state and local authorities, raided presumed criminal-hacker organizations allegedly involved in credit-card abuse and theft of telephone services. They seized 42 computers and 23,000 disks from locations in 14 cities. Targets were principally sites running discussion boards, some of which were classified as “hacker boards.” However, two years after the raid, there were only three indictments (resulting in three guilty pleas). Evidence began to accumulate that much of the evidence seized in the raids was useless.¹¹¹ Bruce Sterling spent a year and a half researching the operation and concluded that it was largely a propaganda effort:

... An unprecedented action of great ambition and size, Sundevil's motives can only be described as political. It was a public-relations effort, meant to pass certain messages, meant to make certain situations clear: both in the mind of the general public, and in the minds of various constituencies of the electronic community.

First—and this motivation was vital—a “message” would be sent from law enforcement to the digital underground. This very message was recited in so many words by Garry M. Jenkins, the Assistant Director of the US Secret Service, at the Sundevil press conference in Phoenix on May 9, 1990, immediately after the raids. In brief, hackers were mistaken in their foolish belief that they could hide behind the “relative anonymity of their computer terminals.” On the contrary, they should fully understand that state and federal cops were actively patrolling the beat in cyberspace—that they were on the watch everywhere, even in those sleazy and secretive dens of cybernetic vice, the underground boards.¹¹²

2.14.9 1990: Steve Jackson Games. Two months before the Operation Sundevil raids, but (contrary to popular conflation of the two) in a completely separate operation, a role-playing game company called Steve Jackson Games in Austin, Texas, was raided on March 1, 1990. The Secret Service seized computers and disks at the company's offices and also at the home of one of their employees, Loyd Blankenship—“The Mentor,” formerly of the LOD. Blankenship was writing a role-playing game called GURPS Cyberpunk, which the agents interpreted as “a handbook for computer crime.” Some of the equipment seized in the raid was returned four weeks later; most but not all was returned four months later. The company nearly went bankrupt as a result of the sequestration of critical resources.¹¹³

Outrage in the computing community spread beyond the underground. Mitch Kapor, John Barlow, and John Gilmore founded the Electronic Frontier Foundation in part because of their outrage over the treatment of Steve Jackson Games:

... We got the attorneys involved, and then we asked them to look into what was going on with a variety of government investigations and prosecutions. We identified a couple of particular legal situations, like Craig Neidorf in Chicago and Steve Jackson Games, where there seemed to us to have been a substantial overstepping of bounds by the government and an infringement on rights of free speech and freedom of the press. We were in the process of deciding how to intervene when we also realized very clearly that we didn't want to be a legal defense fund as that was too narrow. What was really needed was to somehow improve the discourse about how technology is going to be used by society; we need to do things in the area of public education and policy development.¹¹⁴

Steve Jackson Games sued the Secret Service for damages and were awarded \$50,000 in damages and more than \$25,000 in attorney's fees.¹¹⁵ The case had a lasting effect

on how law enforcement officials carried investigations of computer crimes and seizure of electronic evidence.

2.14.10 1992: L0pht Heavy Industries. In 1992, a group of computer enthusiasts arranged to store their spare equipment in some rented space in Boston. They collaborated on analysis of vulnerabilities, especially Microsoft product vulnerabilities, and gained a reputation for contributing serious research to the field and for appearing at security conferences. Their “L0phtCrack” program was adopted by many system administrators for testing password files to locate easy-to-guess passwords; members even testified before a Senate Subcommittee on Government Cybersecurity in 1998 (saying they could take down the Internet in half an hour).¹¹⁶ Famous handles from the group included “Brian Oblivion,” “Kingpin,” “Mudge,” “Space Rogue,” “Stefan von Neumann,” “Tan,” and “Weld Pond.”¹¹⁷

The group caused ripples in both the underground and aboveground security communities when their company, L0pht Heavy Industries, was purchased by security services firm @stake, Inc. in 2000. @stake was eventually bought by Symantec in 1994.¹¹⁸

2.14.11 2004: Shadowcrew. Stealing physical credit cards and creating fake ones are part of the criminal technique called “carding.” One of the significant successful investigations and prosecutions of an international credit card fraud ring of the 2000 decade began with the U.S. Secret Service’s *Operation Firewall* in late 2004. The investigators discovered a network of more than 4,000 members communicating through the Internet and conspiring to use phishing, spamming, forged identity documents (e.g., fake driver’s licenses), creation of fake plastic credit cards, resale of gift cards bought with fake credit cards, fencing of stolen goods via eBay, and interstate or international funds transfers using electronic money such as E-Gold and Web Money.

In October 2004, the Department of Justice indicted 19 of the leaders of Shadowcrew.¹¹⁹ By November 2005, 12 of these people had already pleaded guilty to charges of conspiracy and trafficking in stolen credit card numbers with losses of more than \$4 million.¹²⁰

In February 2006, Shadowcrew leader Kenneth J. Flury, 41, of Cleveland Ohio, was sentenced to 32 months in prison with three years of supervised release and \$300,000 in restitution to Citibank.¹²¹ In June 2006, cofounder Andrew Mantovani, 24, of Scottsdale, Arizona, was fined \$5,000 and also received 32 months of prison with three years of supervised release. Five other indicted Shadowcrew criminals were sentenced with him. By that time, a total of 18 of 28 indicted suspects had already pleaded guilty.¹²²

2.14.12 Late 2000s: Russian Business Network (RBN). The Russian Business Network (RBN) may have originated as a legitimate Web hosting company in 2006:

According to internet security company Verisign, which in June published an extensive investigation into the Russian outfit (tinyurl.com/ywvpgp), RBN was registered as an internet site in 2006.

Initially, much of its activity was legitimate. But apparently the founders soon discovered that it was more profitable to host illegitimate activities and started hiring its services to criminals. Verisign says simply that it is now “entirely illegal.” Since then its activities have been monitored by a number of organisations, including the London-based anti-spam group Spamhaus. “RBN is among the world’s worst spammer, child-pornography, malware, phishing

2 · 28 HISTORY OF COMPUTER CRIME

and cybercrime hosting networks,” says a spokesman. “It provides ‘bulletproof’ hosting, but is probably involved in the crime too.”¹²³

A researcher for the Internet Storm Center, “David Bizeul, spent the past three months researching the Russian Business Network (RBN). The RBN is a virtual safe house for Russian criminals responsible for malicious code attacks, phishing attacks, child pornography, and other illicit operations ...” Bizeul’s study is a 70-page report with extensive documentation about the criminal activities of the RBN.¹²⁴ The group has supported malware diffusion, spam, phishing, denial of service, distribution of cyberattack tools, pornography, and child pornography.

A 2011 report by David Goldman included the following useful insights:

“It’s not like the Mafia, it is a Mafia running these operations,” said Karim Hijazi, CEO of botnet monitoring company Unveillance. “The Russian Mafia are the most prolific cybercriminals in the world.”

Organized cybercrime is a truly international affair, but the most advanced attacks tend to stem from Russia. The Russian mob is incredibly talented for a reason: After the Iron Curtain lifted in the 1990s, a number of ex-KGB cyberspies realized they could use their expert skills and training to make money off of the hacked information they had previously been retrieving for government espionage purposes.

Former spies grouped together to form the Russian Business Network, a criminal enterprise that is capable of some truly scary attacks. It’s just one of many organized cybercriminal organizations, but it’s one of the oldest and the largest.

“The Russians have everyone nailed cold in terms of technical ability,” said Greg Hoglund, CEO of cybersecurity company HBGary. “The Russian crime guys have a ridiculous toolkit. They’re targeting end users in many cases, so they have to be sophisticated.”¹²⁵

2.14.13 Anonymous. In 2003, political activists with a penchant for computer skills formed a loose association calling itself *Anonymous* for collaboration in a range of cyberattacks on targets its members disliked. The philosophy of the group explicitly rejects any centralized controls; anyone can claim to be a member of Anonymous.

In 2008, self-identified members of the movement labeling their efforts *Chanology*¹²⁶ attacked the Church of Scientology (readers interested in following the reference provided in the end note should be aware that the site is loaded with pornographic advertisements for pornography sites). Members also harassed organizations attempting to strengthen intellectual property laws and enforcement or antipiracy restrictions. Other targets of the nonorganization include the Epilepsy Foundation, hip-hop Websites, Sarah Palin’s political campaign, the government of Iran, the government of Australia, and the Tea Party chapter in Oregon.

One of the most publicized campaigns was in support of Julian Assange, leader of the WikiLeaks Foundation, whose group made public more than a million documents classified by the United States and other governments as restricted or secret and revealing embarrassing details of several wars and internal communications among diplomats.

In January 2013, members announced that they would release large amounts of U.S. Government–restricted information. They let the world know about their plans by posting their messages on a hacked U.S. Government Website.¹²⁷

2.14.14 2013: Unlimited Operations. In May 2013, eight criminal hackers, New York City area members of a much larger worldwide ring of cybercriminals calling themselves Unlimited Operations, were charged with theft of more than \$45 million from automated teller machines (ATMs) around the planet. The gang “used

sophisticated intrusion techniques to hack into the systems of global financial institutions, steal prepaid debit card data, and eliminate withdrawal limits. The stolen card data was then disseminated worldwide and used in making fraudulent ATM withdrawals on a massive scale across the globe ...”

In the first phase, the criminals broke into National Bank of Ras Al-Khaimah PSC (RAKBANK) in the United Arab Emirates. Using these compromised data, the criminal network completed more than 4,500 ATM transactions in 20 hours and stole more than \$5 million.

The second phase began “... on the afternoon of February 19 and lasted into the early morning of February 20, 2013. This operation again breached the network of a credit card processor that serviced MasterCard prepaid debit cards, this time issued by the Bank of Muscat, located in Oman.” Total losses from 36,000 transactions in 24 countries netted \$40 million in cash from ATMs.¹²⁸

2.15 INDUSTRIAL ESPIONAGE. Why spend money developing competitive products when you can steal the work once it’s ready to apply? Many firms in countries with little or no rule of law have taken advantage of poor security, outsourcing, and liberal immigration policies to steal intellectual property and compete at a discount with the originators of the ideas.

- In 2001, Junsheng Wang of Bell Imaging Technologies pled guilty to violation of 18 USC 132(a)(2) by stealing trade secrets from Acuson Corporation. The Counterintelligence News and Developments (CIND) report noted, “In pleading guilty, Wang admitted that prior to August 24, 2000, that he took without authorization and copied for Bell Imaging a document providing the architecture for the Sequoia ultrasound machine that contained the trade secrets of Acuson Corporation. According to Wang’s plea agreement, he had been able to obtain access to the Acuson trade secret materials because his wife was employed as an engineer at that company and because she had brought that document into their home. After he had copied the document, he took it with him on business trips to the People’s Republic of China, turning it over to Bell Imaging during 2000.”¹²⁹
- In May 2001, Federal authorities arrested two Lucent scientists and a third man described as their business partner on May 4, charging them with stealing source code for software associated with Lucent’s PathStar Access Server and sharing it with Datang Telecom Technology Co., a Beijing firm majority-owned by the Chinese government. The software is considered a “crown jewel” of the company. Chinese nationals Hai Lin and Kai Xu were regarded as “distinguished members” of Lucent’s staff up until their arrests. The motivation for the theft, according to court documents, was to build a networking powerhouse akin to the “Cisco of China.” The men faced charges of conspiracy to commit wire fraud, punishable by a maximum five years in prison and a \$250,000 fine.¹³⁰ In April 2002, the two were also charged with stealing secrets from four companies in addition to Lucent: Telenetworks, NetPlane Systems, Hughes Software Systems, and Ziatech. An additional Chinese national, Yong-Qing Cheng was also charged. They developed a joint venture with the Datang Telecom Technology Company of Beijing to sell a clone of Lucent’s Path Star data and voice transmission system to Internet providers in China.¹³¹
- In September 2002, the 3DGeo company in Mountain View, CA accused Shan Yanming, an employee of the China National Petroleum Corporation on loan to

2 · 30 HISTORY OF COMPUTER CRIME

the company, of industrial espionage for trying to steal the software designed for using seismic data to map oil deposits. He was caught trying to download corporate data to his personal computer and was arrested by FBI agents.¹³²

- In April 2003, the United States Attorney's Office for the Northern District of California announced that Tse Thow Sun pled guilty on April 9, 2003, to theft of trade secrets. He admitted that in early 2002, while working for a language translation company, he delivered a laptop computer and a hard drive that contained trade secrets and confidential proprietary information to a competitor and asked for \$3 million in payment. Mr. Sun, 32, a citizen of Singapore, was indicted by a federal Grand Jury on April 9, 2002. He was charged with theft of trade secrets, in violation of 18 U.S.C. §1832(a)(3); attempted theft of trade secrets, in violation of 18 U.S.C. §1832(a)(4); and interstate transportation of stolen goods, in violation of 18 U.S.C. §2314. Under the plea agreement, Mr. Sun pled guilty to theft of trade secrets.¹³³
- In May 2003, three Swedish employees of LM Ericsson were charged with espionage for allegedly stealing intellectual property and sending it to Russian spies. "[Afshin] Bavand was arrested Nov. 5, 2002, while talking to a Russian intelligence agent in a Stockholm suburb. Police searched the Russian, who wasn't identified, and found \$4,000 in cash and Ericsson documents."¹³⁴
- The series of attacks codenamed *Titan Rain* was discovered by Shawn Carpenter in late 2003. Carpenter noticed a flood of expert hacker activity focusing on data theft from a wide range of "the country's most sensitive military bases, defense contractors and aerospace companies." Carpenter discovered that "the attacks emanated from just three Chinese routers that acted as the first connection point from a local network to the Internet." Carpenter worked with U.S. Army and FBI investigators to learn more about the attacks and the attackers. According to Thornburgh, various analysts judge that "Titan Rain is thought to rank among the most pervasive cyberespionage threats that U.S. computer networks have ever faced."¹³⁵
- In July 2004, an Indian software engineer employed by a U.S. company's software development center in India was accused of "zipping up" proprietary software source code for printing identification cards and uploading it to her personal e-mail account. Jolly Technologies shut down its Mumbai operations as a result of the breach of security.¹³⁶
- In 2005 and 2006, EMC filed lawsuits against several employees for allegedly stealing trade secrets.¹³⁷
- In December 2006, two Chinese nationals, Fei Ye and Ming Zhong, pleaded guilty in December 2006 to charges of economic espionage on behalf of the People's Republic of China. They were arrested in November 2001 with stolen trade secrets in their luggage; the information was taken from Sun Microsystems and Transmeta Corporation. The agents were planning to design a competing microprocessor using the stolen designs; profits were to have been shared with the City of Hangzhou and the Province of Zhejiang. The agents' company was funded in part by the National High Technology Research and Development Program of China.¹³⁸
- In April 2008, sleeper agent Chi Mak, a naturalized U.S. citizen who lived peacefully in Los Angeles for 20 years, was sentenced to 24.5 years in federal prison for industrial espionage. He stole detailed plans for U.S. Navy equipment including

submarine propulsion systems and tried to send them to China via his brother and sister-in-law.¹³⁹

- In 2009, Siobhan Gorman, writing in *The Wall Street Journal*, reported as follows:

Cyberspies have penetrated the U.S. electrical grid and left behind software programs that could be used to disrupt the system, according to current and former national-security officials. The spies came from China, Russia, and other countries, these officials said, and were believed to be on a mission to navigate the U.S. electrical system and its controls. The intruders haven't sought to damage the power grid or other key infrastructure, but officials warned they could try during a crisis or war. "The Chinese have attempted to map our infrastructure, such as the electrical grid," said a senior intelligence official. "So have the Russians." The espionage appeared pervasive across the U.S. and doesn't target a particular company or region, said a former Department of Homeland Security official. "There are intrusions, and they are growing," the former official said, referring to electrical systems. "There were a lot last year."¹⁴⁰

- The Office of the National Counterintelligence Executive (ONCIX) published its Report to Congress on Foreign Economic Collection and Industrial Espionage 2009–2011 with the title "Foreign Spies Stealing U.S. Economic Secrets in Cyberspace." The Executive Summary included this commentary:

Sensitive US economic information and technology are targeted by the intelligence services, private sector companies, academic and research institutions, and citizens of dozens of countries.

- Chinese actors are the world's most active and persistent perpetrators of economic espionage. U.S. private-sector firms and cybersecurity specialists have reported an onslaught of computer network intrusions that have originated in China, but the IC cannot confirm who was responsible.
- Russia's intelligence services are conducting a range of activities to collect economic information and technology from U.S. targets.
- Some U.S. allies and partners use their broad access to U.S. institutions to acquire sensitive U.S. economic and technology information, primarily through aggressive elicitation and other human intelligence (HUMINT) tactics. Some of these states have advanced cyber capabilities.¹⁴¹
- A March 2012 report detailed how a successful supervisory control and data acquisition (SCADA) software company, American Superconductor Corporation (AMSC), was practically destroyed economically by its major customer, the Chinese Sinovel company, which stole its proprietary wind-turbine software and then stopped paying for any further software services.¹⁴²
- By early 2013, Symantec's 2012 *Internet Security Threat Report*, Vol. 18 reported that small businesses were increasingly targeted for cyberattacks and industrial espionage: "In 2012, 50 percent of all targeted attacks were aimed at businesses with fewer than 2,500 employees. In fact, the largest growth area for targeted attacks in 2012 was businesses with fewer than 250 employees; 31 percent of all attacks targeted them."¹⁴³

2.16 CONCLUDING REMARKS. At some point, history becomes current events. At the time of writing (May 2013), the trends we were seeing dimly when the fifth edition of this work was published have become clearer. As the second decade

2 · 32 HISTORY OF COMPUTER CRIME

of the 21st century reaches its midpoint, organized crime has become an integral part of the computer-crime scene—and vice versa. The Russian criminal underworld has increasingly invested in high-technology forms of fraud and also relies on high-tech communications for marketing of criminal undertakings, such as international traffic in drugs, armaments, and slaves. Information warfare has become a real issue as China advances in technology by stealing industrial secrets and capitalizing on the savings in research and development—and seeks growing global power. Terrorist groups cannot ignore the power of asymmetric warfare and must be presumed to be planning attacks on critical infrastructures worldwide. As the global communications network spreads throughout the world, governments, corporations, and individuals will have to increase their collaboration and vigilance to defeat the growing army of computer criminals of every type.

3.1 PROPOSAL FOR A NEW INFORMATION SECURITY FRAMEWORK.

Information security, historically, has been limited by the lack of a comprehensive, complete, and analytically sound framework for analysis and improvement. The persistence of the classic triad of CIA (confidentiality, integrity, availability) is inadequate to describe what security practitioners include and implement when doing their jobs. We need a new information security framework that is complete, correct, and consistent

*This chapter is a revised excerpt from Donn B. Parker, *Fighting Computer Crime* (New York: John Wiley & Sons, 1998), Chapter 10, "A New Framework for Information Security," pp. 229-255.

3 · 2 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

to express, in practical language, the means for information owners to protect their information from any adversaries and vulnerabilities.

The current focus on computer systems security is attributable to the understandable tendency of computer technologists to protect what they know best—the computer and network systems rather than the application of those systems. With a technological hammer in hand, everything looks like a nail. The primary security challenge comes from people misusing or abusing information, and often—but not necessarily—using computers and networks. Yet the individuals who currently dominate the information security folk art are neither criminologists nor computer application specialists.

This chapter presents a comprehensive new information security framework that resolves the problems of the existing models. The chapter demonstrates the need for six security elements—availability, utility, integrity, authenticity, confidentiality, and possession—to replace incomplete CIA security (which does not even seem to include security for information that is not confidential) in the new security framework. This new framework is used to list all aspects of security at a basic level. The framework is also presented in another form, the *Threats, Assets, Vulnerabilities Model*, which includes detailed descriptors for each topic in the model. This model supports the new security framework, demonstrating its contribution to advance information security from its current technological stage, and as a folk art, into the basis for an engineering and business art in cyberspace.

The new security framework model incorporates six essential parts:

1. Security elements of information to be preserved are:

- Availability
- Utility
- Integrity
- Authenticity
- Confidentiality
- Possession

2. Sources of loss of these security elements of information:

- Abusers and misusers
- Accidental occurrences
- Natural physical forces

3. Acts that cause loss:

- Destruction
- Interference with use
- Use of false data
- Modification or replacement
- Misrepresentations or repudiation
- Misuse or failure to use
- Location
- Disclosure
- Observation
- Copying

- Taking
- Endangerment

4. Safeguard functions to protect information from these acts:

- Audit
- Avoidance
- Deterrence
- Detection
- Prevention
- Mitigation
- Transference
- Investigation
- Sanctions and rewards
- Recovery

5. Methods of safeguard selection:

- Use due diligence
- Comply with regulations and standards
- Enable business
- Meet special needs

6. Objectives to be achieved by information security:

- Avoid negligence
- Meet requirements of laws and regulations
- Engage in successful commerce
- Engage in ethical conduct
- Protect privacy
- Minimize impact of security on performance
- Advance an orderly and protected society

In summary, this model is based on the goal of meeting owners' needs to protect the desired *security elements* of their information from sources of loss that engage in harmful *acts* and events by applying *safeguard functions* that are selected by accepted *methods* to achieve desired *objectives*. The sections of the model are explained next. It is important to note that security risk, return on security investment (ROSI), and net present value (NPV) based on unknown future losses and enemies and their intentions are not identified in this model, since they are not measurable and, hence, not manageable.

3.2 SIX ESSENTIAL SECURITY ELEMENTS. Six security elements in the proposed framework model are essential to information security. If any one of them is omitted, information security is deficient in protecting information owners. Six scenarios of information losses, all derived from real cases, are used to demonstrate this contention. We show how each scenario involves violation of one, and only one, element of information security. Thus, if we omit that element from information security, we also remove that scenario from the concerns of information security, which would

3 · 4 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

be unacceptable. It is likely that information security professionals will agree that all of these scenarios fall well within the range of the abuse and misuse that we need to protect against.

3.2.1 Loss Scenario 1: Availability. A rejected contract programmer, intent on sabotage, removed the name of a data file from the file directories in a credit union's computer. Users of the computer and the data file no longer had the file available to them, because the computer operating system recognizes the existence of information available for users only if it is named in the file directories. The credit union was shut down for two weeks while another programmer was brought in to find and correct the problem so that the file would be available. The perpetrator was eventually convicted of computer crime.

Except for availability, the other elements of information security—utility, integrity, authenticity, confidentiality, and possession—do not address this loss, and their state does not change in the scenario. The owner of the computer (the credit union) retained possession of the data file. Only the availability of the information was lost, but it is a loss that clearly should have been prevented by information security. Thus, the preservation of availability must be accepted as a purpose of information security.

It is true that good security practice might have prevented the disgruntled programmer from having use of the credit union application system, and credit union management could have monitored his work more carefully. They should not have depended on the technical capabilities and knowledge of only one person, and they should have employed several controls to preserve or restore the availability of data files in the computer, such as by maintaining a backup directory with the names of erased files and pointers to their physical location. The loss might have been prevented, or minimized, through good backup practices, good usage controls for computers and specific data files, use of more than one name to identify and find a file, and the availability of utility programs to search for files by content or to mirror file storage. These safeguards would at least have made the attack more difficult and would have confronted the programmer with the malfeasance of his act.

The severity of availability loss can vary considerably. A perpetrator may destroy copies of a data file in a manner that eliminates any chance of recovery. In other situations, the data file may be partially usable, with recovery possible for a moderate cost, or the user may have inconvenienced or delayed use of the file for some period of time, followed by complete recovery.

3.2.2 Loss Scenario 2: Utility. In this case, an employee routinely encrypted the only copy of valuable information stored in his organization's computer and then accidentally erased the encryption key. The usefulness of the information was lost and could be restored only through difficult cryptanalysis.

Although this scenario can be described as a loss of availability or authenticity of the encryption key, the loss focuses on the usefulness of the information rather than on the key, since the only purpose of the key was to facilitate encryption. The information in this scenario is available, but in a form that is not useful. Its integrity, authenticity, and possession are unaffected, and its confidentiality, unfortunately, is greatly improved.

To preserve utility of information in this case, management should require mandatory backup copies of all critical information and should control the use of powerful protective mechanisms such as cryptography. Management should require security walk-through tests during application development to limit unusable forms of information. It should minimize the adverse effects of security on information use and should

control the types of activities that enable unauthorized persons to reduce the usefulness of information.

The loss of utility can vary in severity. The worst-case scenario would be the total loss of usefulness of the information, with no possibility of recovery. Less severe cases may range from a partially useful state with the potential for full restoration of usefulness at moderate cost.

3.2.3 Loss Scenario 3: Integrity. In this scenario, a software distributor purchased a copy (on DVD) of a program for a computer game from an obscure publisher. The distributor made copies of the DVD and removed the name of the publisher from the DVD copies. Then, without informing the publisher or paying any royalties, the distributor sold the DVD copies in a foreign country. Unfortunately, the success of the program sales was not deterred by the lack of an identified publisher on the DVD or in the product promotional materials.

Because the DVD copies of the game did not identify the publisher that created the program, the copies lacked integrity. (“Integrity” means a state of completeness, wholeness, and soundness, or adhering to a code of moral values.) However, the copies did not lack authenticity, since they contained the genuine game program and only lacked the identity of the publisher, which was not necessary for the successful use of the product. Information utility of the DVD was maintained, and confidentiality and availability were not at issue. Possession also was not at issue, since the distributor bought the original DVD. But copyright protection was violated as a consequence of the loss of integrity and unauthorized copying of the otherwise authentic program.

Several controls can be applied to prevent the loss of information integrity, including using and checking sequence numbers, checksums, and/or hash totals to ensure completeness and wholeness for a series of items. Other controls include performing manual and automatic text checks for required presence of records, subprograms, paragraphs, or titles, and testing to detect violations of specified controls.

The severity of information integrity loss also varies. Significant parts of the information can be missing or misordered (but still available), with no potential for recovery. Or missing or misordered information can be restored, with delay and at moderate cost. In the least severe cases, an owner can recover small amounts of misordered or mislocated information in a timely manner at low cost.

3.2.4 Loss Scenario 4: Authenticity. In a variation of the preceding scenario, another software distributor obtained the program (on DVD) for a computer game from an obscure publisher. The distributor changed the name of the publisher on the DVD and in title screens to that of a well-known publisher, then made copies of the DVD. Without informing either publisher, the distributor then proceeded to distribute the DVD copies in a foreign country. In this case, the identity of a popular publisher on the DVDs and in the promotional materials significantly added to the success of the product sales.

Because the distributor misrepresented the publisher of the game, the program did not conform to reality: It was not an authentic game from the well-known publisher. Availability and utility are not at issue in this case. The game had integrity because it identified a publisher and was complete and sound. (Certainly the distributor lacked *personal* integrity because his acts did not conform to ethical practice, but that is not the subject of the scenario.) The actual publisher did not lose possession of the game, even though copies were deceptively represented as having come from a different publisher.

3 · 6 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

And, although the distributor undoubtedly tried to keep his actions secret from both publishers, confidentiality of the content of the game was not at issue.

What if someone misrepresents your information by claiming that it is his? Violation of CIA does not include this act. A stockbroker in Florida cheated his investors in a Ponzi (pyramid sales) scheme. He stole \$50 million by claiming that he used a super-secret computer program on his giant computer to make profits of 60 percent per day by arbitrage, a stock trading method in which the investor takes advantage of a small difference in prices of the same stock in different markets. He showed investors the mainframe computer at a Wall Street brokerage firm and falsely claimed that it and the information stored therein were his, thereby lending believability to his claims of successful trading.

This stockbroker's scheme was certainly a computer crime, but the CIA elements do not address it as such because its definition of integrity does not include misrepresentation of information. "Integrity" means only that information is whole or complete; it does not address the validity of information. Obviously, confidentiality and availability do not cover misrepresentation either. The best way to extend CIA to include misrepresentation is to use the more general term "authenticity." We can then assign the correct English meaning to the phrase "integrity of information": wholeness, completeness, and good condition. Dr. Peter Neumann at SRI International is correct when he says that information with integrity means that the information is what you expect it to be. This does not, however, necessarily mean that the information is valid (you may expect it to be invalid). "Authenticity" is the word that means conformance to reality.

A number of controls can be applied to ensure authenticity of information. These include confirming transactions, names, deliveries, and addresses; validating products; checking for out-of-range or incorrect information; and using digital signatures and watermarks to authenticate documents.

The severity of authenticity loss can take several forms, including lack of conformance to reality with no recovery possible; moderately false or deceptive information with delayed recovery at moderate cost; or factually correct information with only annoying discrepancies. If the CIA elements included authenticity, with misrepresentation of information as an important associated threat, Kevin Mitnick (the notorious criminal hacker who used deceit as his principal tool for penetrating security barriers) might have faced a far more difficult challenge in perpetrating his crimes. The computer industry might have understood the need to prove computer operating system updates and Web sites genuine, to avoid misrepresentation with fakes before their customers used those fakes in their computers.

3.2.5 Loss Scenario 5: Confidentiality. A thief deceptively obtained information from a bank's technical maintenance staff. He used a stolen key to open the maintenance door of an automated teller machine (ATM) and secretly inserted a radio transmitter that he purchased from a Radio Shack store. The radio received signals from the touch-screen display in the ATM that customers use to enter their personal identification numbers (PINs) and to receive account balance information. The radio device broadcast the information to the thief's radio receiver in his nearby car, which recorded the PINs and account balances on tape in a modified videocassette recorder. The thief used the information to loot the customers' accounts from other ATMs. The police and the Federal Bureau of Investigation caught the thief after elaborate detective and surveillance efforts. He was sentenced to 10 years in a federal prison.

The thief violated the secrecy of the customers' PINs and account balances, and he violated their privacy. Availability, utility, integrity, and authenticity were unaffected in

this violation of confidentiality. The customers' and the bank's exclusive possession of the PINs and account balance information was lost, but not possession per se, because they still held and owned the information. Therefore, this was primarily a case of lost confidentiality.

According to most security experts, confidentiality deals with disclosure, but confidentiality also can be lost by observation, whether that observation is voluntary or involuntary, and whether the information is disclosed or not disclosed. For example, if you leave sensitive information displayed on an unattended computer monitor screen, you have disclosed it and it may or may not lose its confidentiality. If you turn the monitor off, leaving a blank screen, you have not disclosed sensitive information, but if someone turns the monitor on and reads its contents without permission, then confidentiality is lost by observation. We must prevent both disclosure and observation in order to protect confidentiality.

Controls to maintain confidentiality include using cryptography, training employees to resist deceptive social engineering attacks intended to obtain their technical knowledge, and controlling the use of computers and computer devices. Good security also requires that the cost of resources for protection not exceed the value of what may be lost, especially with low incidence. For example, protecting against radio frequency emanations in ATMs (as in this scenario) is probably not advisable, considering the cost of shielding and the paucity of such high-tech attacks.

The severity of loss of confidentiality can vary. The worst-case scenario loss is when a party with the intent and ability to cause harm observes a victim's sensitive information. In this case, unrecoverable damage may result. But information also may be known to several moderately harmful parties, with a moderate loss effect, or be known to one harmless, unauthorized party with short-term recoverable effect.

3.2.6 Loss Scenario 6: Possession. A gang of burglars aided by a disgruntled, recently fired operations supervisor broke into a computer center and stole tapes and disks containing the company's master files. They also raided the backup facility and stole all backup copies of the files. They then held the materials for ransom in an extortion attempt against the company. The burglary resulted in the company's losing possession of all copies of the master files as well as the media on which they were stored. The company was unable to continue business operations. The police eventually captured the extortionists with help from the company during the ransom payment, and they recovered the stolen materials. The burglars were convicted and served long prison sentences.

Loss of possession occurred in this case. The perpetrators delayed availability, but the company could have retrieved the files at any time by paying the ransom. Alternatively, the company could have re-created the master files from paper documents, but at great cost. Utility, integrity, and authenticity were not issues in this situation. Confidentiality was not violated because the burglars had no reason to read or disclose the files. Loss of ownership and permanent loss of possession would have been accomplished if the perpetrators had never returned the materials or if the company had stopped trying to recover them.

The security model must include protecting the possession of information so as to prevent theft, whether the information is confidential or not. Confidentiality, by definition, deals only with secret information that people may possess. Our increasing use of computers magnifies this difference; huge amounts of information are possessed for automated use and not necessarily held confidentially for only specified people to know. Computer object programs are examples of proprietary but not confidential

3 · 8 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

information we do not know but possess by selling, buying, bartering, giving, receiving, and trading until we ultimately control, transport, and use them. We have incorrectly defined possession if we include only the protective efforts for confidential material.

We protect the possession of information by preventing people from unauthorized taking, from making copies, and from holding or controlling it—whether confidentiality is involved or not. The loss of possession of information also includes the loss of control of it, and may allow the new possessor to violate its confidentiality at will. Thus, loss of confidentiality may accompany loss of possession. But we must treat confidentiality and possession separately to determine what actions criminals might take and what controls we need to apply to prevent their actions. Otherwise, we may overlook a particular threat or an effective control. The failure to anticipate a threat and vulnerability is one of the greatest dangers we face in security.

Controls that can protect the possession of information include using copyright laws, implementing physical and logical usage limitations, preserving and examining computer audit logs for evidence of stealing, inventorying tangible and intangible assets, using distinctive colors and labels on media containers, and assigning ownership to enforce accountability of organizational information assets.

The severity of loss of possession varies with the nature of the offense. In a worst-case scenario, a criminal may take information, as well as all copies of it, and there may be no means of recovery—either from the perpetrator or from other sources such as paper documentation. In a less harmful scenario, a criminal might take information for some period of time but leave some opportunity for recovery at a moderate cost. In the least harmful situation, an owner could possess more than one copy of information, leaving open the possibility of recovery from other sources (e.g., backup files) within a reasonable period of time.

3.2.7 Conclusions about the Six Elements. We need to understand some important differences between integrity and authenticity. For one, integrity deals with the intrinsic condition of information, while authenticity deals with the extrinsic value or meaning relative to external sources and uses. Integrity does not deal with the meaning of the information with respect to external sources, that is, whether the information is timely and not obsolete. Authenticity, in contrast, concerns the question of whether information is genuine or valid and not out of date with respect to its potential use. A user who enters false information into a computer possibly has violated authenticity, but as long as the information remains unchanged, it has integrity. An information security technologist who designs security into computer operating systems is concerned only with application information integrity because the designer cannot know if any user is entering false information. In this case, the security technologist's job is to ensure that both true and false information remain whole and complete. It is the information owner, with guidance from an information security advisor, who has the responsibility of ensuring that the information conforms to reality—in other words, that it has authenticity.

Some types of loss that information security must address require the use of all six elements of the framework model to determine the appropriate security to apply. Each of the six elements can be violated independently of the others, with one important exception: A violation of confidentiality always results in loss of exclusive possession, at the least. Loss of possession, however—even exclusive possession—does not necessarily result in loss of confidentiality.

Other than that exception, the six elements are unique and independent, and often require different security controls. Maintaining the availability of information does

not necessarily maintain its utility; information may be available but useless for its intended purpose, and vice versa. Maintaining the integrity of information does not necessarily mean that the information is valid, only that it remains the same or, at least, whole and complete. Information can be invalid and, therefore, without authenticity, yet it may be present and identical to the original version and, thus, have integrity. Finally, who is allowed to view and know information and who possesses it are often two very different matters.

Unfortunately, the written information security policies of many organizations do not acknowledge the need to address many kinds of information loss. This is because their policies are limited to achieving CIA. To define information security completely, the policies must address all six elements presented. Moreover, to eliminate (or at least reduce) security threats adequately, all six elements need to be considered to ensure that nothing is overlooked in applying appropriate controls. These elements are also useful for identifying and anticipating the types of abusive actions that adversaries may take—before such actions are undertaken.

For simplification and ease of reference, we can pair the six elements into three double elements, which should be used to identify threats and select proper controls, and we can associate them with synonyms so as to facilitate recall and understanding:

availability and utility	→	usability and usefulness
integrity and authenticity	→	completeness and validity
confidentiality and possession	→	secrecy and control

Availability and utility fit together as the first double element. Controls common to these elements include secure location, appropriate form for secure use, and usability of backup copies. Integrity and authenticity also fit together; one is concerned with internal structure and the other with conformance to external facts or reality. Controls for both include double entry, reasonableness checks, use of sequence numbers and checksums or hash totals, and comparison testing. Control of change applies to both as well. Finally, confidentiality and possession go together because, as discussed, they are interrelated. Commonly applied controls for both include copyright protection, cryptography, digital signatures, escrow, and secure storage.

The order of the elements here is logical, since availability and utility are necessary for integrity and authenticity to have value, and these first four elements are necessary for confidentiality and possession to have material meaning.

3.3 WHAT THE DICTIONARIES SAY ABOUT THE WORDS WE USE. CIA would be adequate for security purposes if the violation of confidentiality were defined to be anything done *with* information, if integrity were defined to be anything done *to* information, and if availability were to include utility, but these definitions would be incorrect and are not understood by many people. Information professionals are already defining the term “integrity” incorrectly, and we would not want to make matters worse. These definitions of security and the elements are relevant abstractions from *Webster’s Third New International Dictionary* and *Webster’s Collegiate Dictionary*, 10th edition.

Security—freedom from danger, fear, anxiety, care, uncertainty, doubt; basis for confidence; measures taken to ensure against surprise attack, espionage, observation, sabotage; resistance of a cryptogram to cryptanalysis usually measured by the time and effort needed to solve it.

Availability—present or ready for immediate use.

3 · 10 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

Utility—useful, fitness for some purpose.

Integrity—unimpaired or unmarred condition; soundness; entire correspondence with an original condition; adherence to a code of moral, artistic or other values; the quality or state of being complete or undivided; material wholeness.

Authenticity—quality of being authoritative, valid, true, real, genuine, worthy of acceptance or belief by reason of conformity to fact and reality.

Confidentiality—quality or state of being private or secret; known only to a limited few, containing information whose unauthorized disclosure could be prejudicial to the national interest.

Possession—act or condition of having or taking into one's control or holding at one's disposal; actual physical control of property by one who holds for himself, as distinguished from custody; something owned or controlled.

We lose credibility and confuse information owners if we do not use words precisely and consistently. When defined correctly, the six words are independent (with the exception that information possession is always violated when confidentiality is violated). They are also consistent, comprehensive, and complete. In other words, the six elements themselves possess integrity and authenticity, and therefore they have great utility. This does not mean that we will not find new elements or replace some of them as our insights develop and technology advances. (I first presented this demonstration of the need for the six elements in 1991 at the 14th U.S. National Security Agency/National Institute of Standards and Technology National Computer Security Conference in Baltimore.)

My definitions of the six elements are considerably shorter and simpler than the dictionary definitions, but appropriate for information security.

Availability—usability of information for a purpose

Utility—usefulness of information for a purpose

Integrity—completeness, wholeness, and readability of information and quality being unchanged from a previous state

Authenticity—validity, conformance, and genuineness of information

Confidentiality—limited observation and disclosure of knowledge

Possession—holding, controlling, and having the ability to use information

3.4 COMPREHENSIVE LISTS OF SOURCES AND ACTS CAUSING INFORMATION LOSSES.

The losses that we are concerned about in information security come from people who engage in unauthorized and harmful acts against information, communications, and systems, such as embezzlers, fraudsters, thieves, saboteurs, and criminal hackers. They engage in harmful using, taking, misrepresenting, observing, and every other conceivable form of human misbehavior. Natural physical forces such as air and earth movements, heat and cold, electromagnetic energy, living organisms, gravity and projectiles, and water and gases also are threats to information, as are inadvertent human errors.

Extensive lists of losses found in information security often include fraud, theft, sabotage, and espionage, along with disclosure, usage, repudiation, and copying. The first four losses in this list are criminal justice terms at a different level of abstraction from the last four and require an understanding of criminal law, which many information owners and security specialists lack. For example, fraud includes theft only if it is

performed using deception, and larceny includes burglary and theft from a victim's premises. What constitutes "premises" in an electronic network environment? This is a legal issue.

Many important types of information-related acts, such as false data entry, failure to perform, replacement, deception, misrepresentation, prolongation of use, delay of use, and even the obvious taking copies of information, are frequently omitted from lists of adverse incidents. Each of these losses may require different prevention and detection controls. This may be easily overlooked if our list of potential acts is incomplete—even though the acts that we typically omit are among the most common reported in actual loss experience. The people who cause losses often are aware that information owners have not provided adequate security and have not considered the full array of possible acts. It is, therefore, essential to include all types of potential harmful acts in our lists, especially when unique safeguards are applicable. Otherwise, we are in danger of being negligent, and those to whom we are accountable will view information security as incomplete or poorly conceived and implemented when a loss does occur.

The complete list of information loss acts in the next section is a comprehensive, nonlegalistic list of potential acts resulting in losses to or with information that I compiled from my 35 years in research about computer crime and security. I have simplified it to a single, low level of abstraction to facilitate understanding by information owners and to enable them to select effective controls. The list makes no distinction among the causes of the losses; as such, it applies equally well to accidental and intentional acts. Cause is largely irrelevant at this level of security analysis, as is the underlying intent or lack thereof. (Identifying cause is important at another level of security analysis. We need to determine the sources and motivation of threats in order to identify appropriate avoidance, deterrence, correction, and recovery controls.) In addition, the list makes no distinction between electronic and physical causes of loss, or among spoken, printed, or electronically recorded information.

The acts in the list are grouped to correspond to the six elements of information security outlined previously (e.g., availability and utility, etc.). Some types of acts in one element grouping may have a related effect in another grouping as well. For example, if no other copies of information exist, destroying the information (under *availability*) also may cause loss of possession, and taking (under *possession*) may cause loss of availability. Yet loss of possession and loss of availability are quite different, and may require different controls. I have placed acts in the most obvious categories, where a loss prevention analyst is likely to look first.

Here is an abbreviated version of the complete loss list for convenient use in the information security framework model:

- Destroy
- Interfere with use
- Introduce false data
- Modify or replace
- Misrepresent or repudiate

3.4.1 Complete List of Information Loss Acts

Availability and Utility Losses

- Destruction, damage, or contamination
- Denial, prolongation, acceleration, or delay in use or acquisition

3 · 12 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

- Movement or misplacement
- Conversion or obscuration

Integrity and Authenticity Losses

- Insertion, use, or production of false or unacceptable data
- Modification, replacement, removal, appending, aggregating, separating, or re-ordering
- Misrepresentation
- Repudiation (rejecting as untrue)
- Misuse or failure to use as required

Confidentiality and Possession Losses

- Locating
- Disclosing
- Observing, monitoring, and acquiring
- Copying
- Taking or controlling
- Claiming ownership or custodianship
- Inferring
- Exposing to all of the other losses
- Endangering by exposing to any of the other losses
- Failure to engage in or to allow any of the other losses to occur when instructed to do so

Users may be unfamiliar with some of the words in the lists of acts, at least in the context of security. For example, “repudiation” is a word that we seldom hear or use outside of the legal or security context. According to dictionaries, it means to refuse to accept acts or information as true, just, or of rightful authority or obligation. Information security technologists became interested in repudiation when the Massachusetts Institute of Technology (MIT) developed a secure network operating system for its internal use. The system was named Kerberos, taking the name of the three-headed dog that guarded the underworld in Greek mythology. Kerberos provides a means of forming secure links and paths between users and the computers serving them. Unfortunately, however, in early versions it allowed users to falsely deny using the links. This did not present any particular problems in the academic environment, but it did make Kerberos inadequate for business, even though its other security aspects were attractive. As the use of Kerberos spread into business, repudiation became an issue, and nonrepudiation controls became important.

Repudiation is an important issue in electronic transactions such as in electronic banking, purchases, and auctions used by so many people to automate their purchasing functions and Internet commerce, which require digital signatures, escrow, time stamps, and other authentication controls. I could, for example, falsely claim that I never ordered merchandise and that the order form or electronically transmitted ordering information that the merchant possesses is false. Repudiation is also a growing problem because of the difficulty of proving authorship or the source of electronic missives. And the inverse of repudiation—claiming that an act that did not happen actually did happen, or claiming that false information is true—is also important to security, although it

is often overlooked. Repudiation and its inverse are both types of misrepresentation, but I include both “repudiation” and “misrepresentation” on the list because they may require different types of controls.

Other words in the list of acts may seem somewhat obscure. For example, we seldom think of prolonging or delaying use as a loss of availability or a denial of use, yet they are losses that are often inflicted by computer virus attacks.

I use the word “locate” in the list rather than “access” because access can be confusing with regard to information security. Although it is commonly used in computer terminology, its use frequently causes confusion, as it did in the trial of Robert T. Morris for releasing the Internet worm of November 2, 1988, and in computer crime laws. For example, access may mean just knocking on a door or opening the door but not going in. How far “into” a computer must you go to “access” it? A perpetrator can cause a loss simply by locating information, because the owner may not want to divulge possession of such information. In this case, no access is involved. For these reasons, I prefer to use the terms “entry,” “intrusion,” and “usage”—as well as “locate”—to refer to a computer as the object of the action. I have a similar problem with the use of the word “disclosure” and ignoring observation as I indicated earlier. “Disclose” is a verb that means to divulge, reveal, make known, or report knowledge to others. We can disclose knowledge by:

- Broadcasting
- Speaking
- Displaying
- Showing
- Leaving it in the presence and view of another person
- Leaving it in possible view where another person is likely to be
- Handing or sending it to another person

Disclosure is what an owner or potential victim might do inadvertently or intentionally, not what a perpetrator does, unless it is the second act after stealing, such as selling stolen intellectual property to another person. Disclosure can be an abuse if a person authorized to know information discloses it to an unauthorized person, or if an unauthorized person discloses knowledge to another person without permission. In any case, confidentiality is lost or is potentially lost, and the person disclosing the information may be accused of negligence, violation of privacy, conspiracy, or espionage.

Loss of confidentiality also can occur by observation, whether the victim or owner disclosed knowledge, resisted disclosure, or did nothing either to protect or to disclose it. Observing is an abuse of listening, spying by eavesdropping, shoulder surfing (looking over another person’s shoulder or overhearing), looking at or listening to a stolen copy of information, or even by tactile feeling, as in the case of reading Braille. We should think about loss of confidentiality as a loss caused by inadvertent disclosure by the victim, observation by the perpetrator, and disclosure by the perpetrator who passes information to a third party. Disclosure and observation of information that is not knowledge converts it into knowledge if cognition takes place. Disclosure always results in loss of confidentiality by putting information into a state where there is no longer any secrecy, but observation results in loss of confidentiality only if cognition or use to the detriment of the owner takes place. Privacy is a right that is a whole other topic that I do not cover here. (This issue is discussed in Chapter 69.)

3 · 14 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

Loss of possession of information (including knowledge) is the loss from the unintended or regretful giving or taking of information. At a higher level of crime description, we call it larceny (theft or burglary) or fraud (when deceit is involved). Possession seems to be most closely associated with confidentiality. The two are placed together in the list because they share the common losses of taking and copying (loss of exclusive possession). I could have used “ownership” of information, since it is a synonym for possession, but “ownership” seems to be not as broad, because someone may rightly or wrongly possess information that is rightfully owned by another. The concepts of owner or possessor of information, along with user, provider, or custodian of information, are important distinctions in security for assigning asset accountability. This provides another reason for including possession in the list.

The act of *endangerment* is quite different from, but applies to, the other losses. It means putting information in harm’s way, or that a person has been remiss (and possibly negligent) by not applying sufficient protection to information, such as leaving sensitive or valuable documents in an unlocked office or open trash bin. Leaving a computer unnecessarily connected to the Internet is another example. Endangerment of information may lead to charges of negligence or criminal negligence and civil liability suits that may be more costly than direct loss incidents. My objectives of security in the framework model invoke a standard of due diligence to deal with this exposure.

The last act in the list—failure to engage in or allow any of the other acts when instructed to do so—may seem odd at first glance. It means that an information owner may require an act resulting in any of the other acts to be carried out. Or the owner may wish that an act be allowed to occur, or information to be put into danger of loss. There are occasions when information should be put in harm’s way for testing purposes or to accomplish a greater good. For example, computer programmers and auditors often create information files that are purposely invalid for use as input to a computer to make sure that the controls to detect or mitigate a loss are working correctly. A programmer bent on crime might remove invalid data in a test input file to avoid testing a control that the perpetrator has neutralized or has avoided implementing for nefarious purposes. The list would surely be incomplete without this type of loss, yet I have never seen it included or discussed in any other information security text.

The acts in the list are described at the appropriate level for deriving and identifying appropriate security controls. At the next lower level of abstraction (e.g., read, write, and execute), the losses would not be so obvious and would not necessarily suggest important controls. At the level that I choose, there is no attempt to differentiate acts that make no change to information from those that do, since these differences are not important for identifying directly applicable controls or for performing threat analyses. For example, an act of modification changes the information, while an act of observation does not, but encryption is likely to be employed as a powerful primary control against both acts.

3.4.2 Examples of Acts and Suggested Controls. The next examples illustrate the relationships between acts and controls in threat analysis. Groups of acts are followed by examples of the losses and applicable controls.

3.4.2.1 Destroy, Damage, or Contaminate. Perpetrators or harmful forces can damage, destroy, or contaminate information by electronically erasing it, writing other data over it, applying high-energy radio waves to damage delicate electronic circuits, or physically damaging the media (e.g., paper, flash memory, or disks) containing it.

Controls include disaster prevention safeguards such as locked facilities, safe storage of backup copies, and write-usage authorization requirements.

3.4.2.2 Deny, Prolong, Delay Use or Acquisition. Perpetrators can make information unavailable by hiding it or denying its use through encryption and not revealing the means to restore it, or by keeping critical processing units busy with other work, such as in a denial-of-service attack. Such actions would not necessarily destroy the information. Similarly, a perpetrator may prolong information use by making program changes that slow the processing in a computer or by slowing the display of the information on a screen. Such actions might cause unacceptable timing for effective use of the information. Information acquisition may be delayed by requiring too many passwords to retrieve it or by slowing retrieval. These actions can make the information obsolete by the time it becomes available.

Controls include making multiple copies available from different sources, preventing overload of processing by selective allowance of input, or preventing the activation of harmful mechanisms such as computer viruses by using antiviral utilities.

3.4.2.3 Enter, Use, or Produce False Data. Data diddling, my term for false data entry and use, is a common form of computer crime, accounting for much of the financial and inventory fraud. Losses may be either intentional, such as those resulting from the use of Trojan horses (including computer viruses), or unintentional, such as those from input errors.

Most internal controls such as range checks, audit trails, separation of duties, duplicate data entry detection, program proving, and hash totals for data items protect against these threats.

3.4.2.4 Modify, Replace, or Reorder. These acts are often intelligent changes rather than damage or destruction. *Reordering*, which is actually a form of modification, is included separately because it may require specific controls that could otherwise be overlooked. Similarly, *replacement* is included because users might not otherwise include the idea of replacing an entire data file when considering modification. Any of these actions can produce a loss inherent in the threats of entering and modifying information, but including all of them covers modifying data both before entry and after entry, since each requires different controls.

Cryptography, digital signatures, usage authorization, and message sequencing are examples of controls to protect against these acts, as are detection controls to identify anomalies.

3.4.2.5 Misrepresent. The claim that information is something different from what it really is or has a different meaning from what was intended arises in counterfeiting, forgery, fraud, impersonation (of authorized users), and many other deceptive activities. Hackers use misrepresentation in social engineering to deceive people into revealing information needed to attack systems. Misrepresenting old data as new information is another act of this type.

Controls include user and document authentication methods such as passwords, digital signatures, and data validity tests. Making trusted people more resistant to deception by reminders and training is another control.

3.4.2.6 Repudiate. This type of loss, in which perpetrators generally deny having made transactions, is prevalent in electronic data interchange (EDI) and Internet

3 · 16 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

commerce. Oliver North's denial of the content of his email messages is a notable example of repudiation, but as I mentioned earlier, the inverse of repudiation also represents a potential loss.

Repudiation can be controlled most effectively through the use of digital signatures and public key cryptography. Trusted third parties, such as certificate authorities with secure computer servers, provide the independence of notary publics to resist denial of truthful information as long as they can be held liable for their failures.

3.4.2.7 Misuse or Fail to Use as Required. Misuse of information is clearly an act resulting in many information losses. Misuse by failure to perform duties such as updating files or backing up information is not so obvious and needs explicit identification. Implicit misuse by conforming exactly to inadequate or incorrect instructions is a sure way to sabotage systems.

Information usage control and internal application controls that constrain the modification or use of trusted software help to avoid these problems. Keeping secure logs of routine activities can help catch operational vulnerabilities.

3.4.2.8 Locate. Unauthorized use of someone's computer or data network to locate and identify information is a crime under most computer crime statutes—even if there is no overt intention to cause harm. Such usage is a violation of privacy, and trespass to engage in such usage is a crime under other laws.

Log-on and usage controls are major features in many operating systems such as Microsoft Windows and some versions of UNIX as well as in add-on security utilities such as *RACF* and *ACF2* for large IBM computers and many security products for personal computers.

3.4.2.9 Disclose. Preventing information from being revealed to people not authorized to know it is the purpose of business, personal, and government secrecy. Disclosure may be verbal, by mail, or by transferring messages or files electronically or on disks, flash memories, or tape. Disclosure can result in loss of privacy and trade secrets.

Military organizations have advanced protection of information confidentiality to an elaborate art form.

3.4.2.10 Observe or Monitor. Observation, which requires action on the part of a perpetrator, is the inverse of disclosure, which results from actions of a possessor. Workstation display screens, communication lines, and monitoring devices such as recorders and audit logs are common targets of observation and monitoring. Observation of output from printers is another possible source, as is shoulder surfing—the technique of watching screens of other computer users.

Physical entry protection for input and output devices represents the major control to prevent this type of loss. Preventing wiretapping and eavesdropping is also important.

3.4.2.11 Copy. Copy machines and the software *copy* command are the major sources of unauthorized copying. Copying is used to violate exclusive possession and privacy. Copying can destroy authenticity, as when used to counterfeit money or other business instruments.

Location and use controls are effective against copying, as are unique markings such as those used on U.S. currency and watermarks on paper and in computer files.

3.4.2.12 Take. Transferring data files in computers or networks constitutes taking. So does taking small computers and DVDs or documents for the value of the information stored in them. Perpetrators can easily take copies of information without depriving the owner of possession or confidentiality.

A wide range of physical and logical location controls applies to these losses; most are based on common sense and a reasonable level of due care.

3.4.2.13 Endanger. Putting information into locations or conditions in which others may cause loss in any of the previously described ways clearly endangers the information, and the perpetrator may be accused of negligence, at least.

Physical and logical means of preventing information from being placed in danger are important. Training people to be careful, and holding them accountable for protecting information, may be the most effective means of preventing endangerment.

3.4.3 Physical Information and Systems Losses. Information also can suffer from physical losses such as those caused by floods, earthquakes, radiation, and fires. Although these losses may not directly affect the information itself (e.g., knowledge of operating procedures held in the minds of operators), they can damage or destroy the media and the environment that contain representations of the information. Water, for example, can destroy printed pages and damage magnetic disks; physical shaking or radio frequency radiation can short-out electronic circuits, and fires can destroy all types of media. Overall, physical loss may occur in seven natural ways by application of:

1. Extreme temperature
2. Gases
3. Liquids
4. Living organisms
5. Projectiles
6. Movements
7. Energy anomalies

Each way, of course, comes from specific sources of loss (e.g., smoke or water). And the various ways can be broken down further, to identify the underlying cause of the source of loss. For example, the liquid that destroys information may be water flowing from a plumbing break above the computer workstation, caused in turn by freezing weather. The next list presents examples of each of the seven major sources of physical loss.

- 1. Extreme temperature.** Heat or cold. Examples: sunlight, fire, freezing, hot weather, and the breakdown of air-conditioning equipment.
- 2. Gases.** War gases, commercial vapors, humid or dry air, suspended particles. Examples: sarin nerve gas, PCBs from exploding transformers, release of Freon from air conditioners, smoke and smog, cleaning fluid, and fuel vapors.
- 3. Liquids.** Water, chemicals. Examples: floods, plumbing failures, precipitation, fuel leaks, spilled drinks, acid and base chemicals used for cleaning, and computer printer fluids.

3 · 18 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

4. **Living organisms.** Viruses, bacteria, fungi, plants, animals, and human beings. Examples: sickness of key workers, molds, contamination from skin oils and hair, contamination and electrical shorting from defecation and release of body fluids, consumption of information media such as paper or of cable insulation, and shorting of microcircuits from cobwebs.
5. **Projectiles.** Tangible objects in motion, powered objects. Examples: meteorites, falling objects, cars and trucks, airplanes, bullets and rockets, explosions, and windborne objects.
6. **Movement.** Collapse, shearing, shaking, vibration, liquefaction, flows, waves, separation, slides. Examples: dropping or shaking fragile equipment, earthquakes, earth slides, lava flows, sea waves, and adhesive failures.
7. **Energy anomalies.** Electric surge or failure, magnetism, static electricity, aging circuitry; radiation, sound, light, radio, microwave, electromagnetic, atomic. Examples: electric utility failures, proximity of magnets and electromagnets, carpet static, electromagnetic pulses (EMP) from nuclear explosions, lasers, loudspeakers, high-energy radio frequency (HERF) guns, radar systems, cosmic radiation, and explosions.

Although meteorites, for example, clearly pose little danger to computers, it is nonetheless important to include all such unlikely events in a thorough analysis of potential threats. In general, include every possible act included in a threat analysis. Then consider it carefully; if it is too unlikely, document the consideration and discard the item. It is better to have thought of a source of loss and to have discarded it than to have overlooked an important one. Invariably, when you present a threat analysis to others, someone will try to surprise the developer with another source of loss that has been overlooked.

Insensitive practitioners have ingrained inadequate loss lists in the body of knowledge from the very inception of information security. Proposing a major change at this late date is a bold action that may take significant time to accomplish. However, we must not perpetuate our past inadequacies by using the currently accepted destruction, disclosure, use, and modification (DDUM) as a complete list of losses. We must not underrate or simplify the complexity of our subject at the expense of misleading information owners. Our adversaries are always looking for weaknesses in information security, but our strength lies in anticipating sources of threats and having plans in place to prevent the losses that they may cause.

It is impossible to collect a truly complete list of the sources of information losses that can be caused by the intentional or accidental acts of people. We really have no idea what people may do—now or in the future. We base our lists on experience, but until we can conceive of an act, or until a threat actually surfaces or occurs, we cannot include it on the list. And not knowing the threat means that we cannot devise a plan to protect against it. This is one of the reasons that information security is still a folk art rather than a science.

3.4.4 Challenge of Complete Lists. I believe that my lists of physical sources of loss and information losses are complete, but I am always interested in expanding them to include new sources of loss that I may have overlooked.

While I was lecturing in Australia, for example, a delegate suggested that I had omitted an important category. His computer center had experienced an invasion of field mice with a taste for electrical insulation. The intruders proceeded to chew through the computer cables, ruining them. Consequently, I had to add rodents to my list of

sources. I then heard about an incident in San Francisco in which the entire evening shift of computer operations workers ate together in the company cafeteria to celebrate a birthday. Then they all contracted food poisoning, leaving their company without sufficient operations staff for two weeks. I combined the results of these two events into a category named “Living Organisms.”

3.5 FUNCTIONS OF INFORMATION SECURITY. The model for information security that I have proposed includes 12 security functions instead of the 3 (prevention, detection, and recovery) included in previous models. These functions describe the activities that information security practitioners and information owners engage in to protect information, as well as the objectives of the security controls that they use. Every control serves one or more of these functions.

Although some security specialists add other functions to the list, such as quality assurance and reliability, I consider these to be outside the scope of information security; other specialized fields deal with them. Reliability is difficult to relate to security except as endangerment when perpetrators destroy the reliability of information and systems, which is a violation of security. Thus, security must preserve a state of reliability but need not necessarily attempt to improve it. Security must protect the auditability of information and systems while, at the same time, security itself must be reliable and auditable. I believe that my security definitions include destruction of the reliability and auditability of information at a high level of abstraction. For example, reliability is reduced when the authenticity of information is put into question by changing it from a correct representation of fact.

Similarly, I do not include such functions as authentication of users and verification in my lists, since I consider these to be control objectives to achieve the 12 functions of information security.

There is a definite logic to the order in which I present the 12 functions in my list. A methodical information security practitioner is likely to apply the functions in this order when resolving security vulnerabilities.

1. Information security must first be independently *audited* in an adversarial manner in order to document its state and to identify its weaknesses and strengths.
2. The practitioner must determine if a security problem can be *avoided* altogether.
3. If the problem cannot be avoided, the practitioner needs to try to *deter* potential abusers or forces from misbehaving.
4. If the threat cannot be avoided or deterred, the practitioner attempts to *detect* its activation.
5. If detection is not assured, then the practitioner tries to *prevent* the act from occurring.
6. If prevention fails and an act occurs, then the practitioner needs to stop it or minimize its harmful effects through *mitigation*.
7. The practitioner needs to determine if *transferring* the responsibility to another individual or department might be more effective at resolving the situation resulting from the attack, or if another party (e.g., an insurer) might be held accountable for the cost of the loss.
8. After a loss occurs, the practitioner needs to *investigate* and search for the individual(s) or force(s) that caused or contributed to the incident as well as for any parties that played a role in it—positively or negatively.
9. When identified, all parties should be *sanctioned or rewarded* as appropriate.

3 · 20 TOWARD A NEW FRAMEWORK FOR INFORMATION SECURITY

10. After an incident is concluded, the victim needs to *recover* or assist with recovery.
11. The stakeholders should take *corrective* actions to prevent the same type of incident from occurring again.
12. The stakeholders must learn from the experience in order to advance their knowledge of information security and *educate* others.

3.6 SELECTING SAFEGUARDS USING A STANDARD OF DUE DILIGENCE.

Information security practitioners usually refer to the process of selecting safeguards as risk assessment, risk analysis, or risk management. Selecting safeguards based on risk calculations can be a fruitless and expensive process. Although many security experts and associations advocate using risk assessment methods, many organizations ultimately find that using a standard of due diligence (or care) is far superior and more practical. Often one sad experience of using security risk assessment is sufficient to convince information security departments and corporate management of their limitations. Security risk is a function of probability or frequency of occurrence of rare loss events and their impact, and neither is sufficiently measurable or predictable for investment in security. Note that risk applies only to rare events. Events such as computer virus attacks or credit card fraud are occurring continuously and are not risks; they are certainties and can be measured, controlled, and managed.

The standard of due diligence approach is simple and obvious; it is the default process that I recommend and that is commonly used today instead of more elaborate “scientific” approaches. The standard of due diligence approach is recognized and accepted by many legal documents and organizations and is documented in numerous business guides. The 1996 U.S. federal statute on protecting trade secrets (18 USC §1831), for example, states in (3)(a) that the owner of information must take “reasonable measures to keep such information secret” for it to be defined as a trade secret. (See Chapter 45.)

3.7 THREATS, ASSETS, VULNERABILITIES MODEL. Pulling all of the aspects together in one place is a useful way to analyze security threats and vulnerabilities and to create effective scenarios to test real information systems and organizations. The model illustrated in Exhibit 3.1 is designed to help readers do this. Users can outline a scenario or analyze a real case by circling and connecting the appropriate descriptors in each column of the model.

In this version of the model, the Controls column lists only the subject headings of control types; a completed model would contain hundreds of controls. If the model is being used to conduct a review, I suggest that the Vulnerabilities section of the model be renamed to Recommended Controls.

3.8 CONCLUSION. The security framework proposed in this chapter represents an attempt to overcome the dominant technologist view of information security by focusing more broadly on all aspects of security, including the information that we are attempting to protect, the potential sources of loss, the types of loss, the controls that we can apply to avoid loss, the methods for selecting those controls, and our overall objectives in protecting information. This broad focus should have two beneficial effects: advancing information security from a narrow folk art to a broad-based discipline and—most important—helping to reduce many of the losses associated with information, wherever it exists.

4 · 2 **HARDWARE ELEMENTS OF SECURITY**

4.1 INTRODUCTION. Computer hardware has always played a major role in computer security. Over the years, that role has increased dramatically, due to both the increases in processing power, storage capacity, and communications capabilities as well as the decreases in cost and size of components. The ubiquity of cheap, powerful, highly connected computing devices poses significant challenges to computer security. At the same time, the challenges posed by large, centralized computing systems have not diminished. An understanding of the hardware elements of computing is thus essential to a well-rounded understanding of computer security.

Chapter 1 of this *Handbook* has additional history of the evolution of information technology.

4.2 BINARY DESIGN. Although there are wide variations among computer architectures and hardware designs, all have at least one thing in common: They utilize a uniquely coded series of electrical impulses to represent any character within their range. Like the Morse code with its dots and dashes, computer pulse codes may be linked together to convey alphabetic or numeric information. Unlike the Morse code, however, computer pulse trains may also be combined in mathematical operations or data manipulation.

In 1946, Dr. John von Neumann, at the Institute for Advanced Study of Princeton University, first described in a formal report how the binary system of numbers could be used in computer implementations. The binary system requires combinations of only two numbers, 0 and 1, to represent any digit, letter, or symbol and, by extension, any group of digits, letters, or symbols. In contrast, the conventional decimal system requires combinations of 10 different numbers, from 0 to 9, letters from a to z, and a large number of symbols, to convey the same information. Von Neumann recognized that electrical and electronic elements could be considered as having only two states, on and off, and that these two states could be made to correspond to the 0 and 1 of the binary system. If the turning on and off of a computer element occurred at a rapid rate, the voltage or current outputs that resulted would best be described as pulses. Despite 60 years of intensive innovation in computer hardware, and the introduction of some optically based methods of data representation, the nature of these electrical pulses and the method of handling them remain the ultimate measure of a computer's accuracy and reliability.

4.2.1 Pulse Characteristics. Ideally, the waveform of a single pulse should be straight-sided, flat-topped, and of an exactly specified duration, amplitude, and phase relationship to other pulses in a series. It is the special virtue of digital computers that they can be designed to function at their original accuracy despite appreciable degradation of the pulse characteristics. However, errors will occur when certain limits are exceeded, and thus data integrity will be compromised. Because these errors are difficult to detect, it is important that a schedule of preventive maintenance be established and rigidly adhered to. Only in this way can operators detect degraded performance before it is severe enough to affect reliability.

4.2.2 Circuitry. To generate pulses of desirable characteristics, and to manipulate them correctly, requires components of uniform quality and dependability. To lower manufacturing costs, to make servicing and replacement easier, and generally to improve reliability, computer designers try to use as few different types of components as possible and to incorporate large numbers of each type into any one machine.

First-generation computers used as many as 30,000 vacuum tubes, mainly in a half-dozen types of logic elements. The basic circuits were flip-flops, or gates, that produced an output pulse whenever a given set of input pulses was present. However, vacuum tubes generated intense heat, even when in a standby condition. As a consequence, the useful operating time between failures was relatively short.

With the development of solid state diodes and transistors, computers became much smaller and very much cooler than their vacuum-tube predecessors. With advances in logic design, a single type of gate, such as the not-and (NAND) circuit, could replace all other logic elements. The resulting improvements in cost and reliability have been accelerated by the use of monolithic integrated circuits. Not least in importance is their vastly increased speed of operation. Since the meantime between failures of electronic computer circuitry is generally independent of the number of operations performed, it follows that throughput increases directly with speed; speed is defined as the rate at which a computer accesses, moves, and manipulates data. The ultimate limitation on computer speed is the time required for a signal to move from one physical element to another. At a velocity of 299,792,458 meters per second (186,282 miles per second) in vacuum, an electrical signal travels 3.0 meters or 9.84 feet in 10 nanoseconds (0.000.000.01 seconds). If components were as large as they were originally, and consequently as far apart, today's nanosecond computer speeds would clearly be impossible, as would be the increased throughput and reliability now commonplace.

4.2.3 Coding. In a typical application, data may be translated and retranslated automatically into a half-dozen different codes thousands of times each second. Many of these codes represent earlier technology retained for backward compatibility and economic reasons only. In any given code, each character appears as a specific group of pulses. Within each group, each pulse position is known as a *bit*, since it represents either of the two *binary digits*, 0 or 1. Exhibit 4.1 illustrates some of the translations that may be continuously performed as data move about within a single computer.

A *byte* is the name originally applied to the smallest group of bits that could be read and written (accessed or addressed) as a unit. Today a byte is always considered by convention to have 8 bits. In modern systems, a byte is viewed as the storage unit for a single American Standard Code for Information Interchange (ASCII) character, although newer systems such as Unicode, which handle international accented characters

and many other symbols, use up to 4 bytes per character. By convention, most people use metric prefixes (kilo-, mega-, giga-, tera-) to indicate collections of bytes; thus *KB* refers to *kilobytes* and is usually defined as 1,024 bytes. Outside the data processing field, *K* would normally indicate the multiplier 1,000. Because of the ambiguity in definitions, the United States National Institute of Standards and Technology (NIST) proposed, and in 2000 the International Electrotechnical Commission established, a new set of units for information or computer storage. These units are established by a series of prefixes to indicate powers of 2; in this scheme, *KB* means *kibibytes* and refers exclusively to 1,024 (2^{10} or $\sim 10^3$) bytes. However, *kibibytes*, *mebibytes* (2^{20} or $\sim 10^6$), *gibibytes* (2^{30} or $\sim 10^9$), and *tebibytes* (2^{40} or $\sim 10^{12}$) are terms that have not yet become widely used.

Because translations between coding systems are accomplished at little apparent cost, any real incentive to unify the different systems is lacking. However, all data movements and translations increase the likelihood of internal error, and for this reason parity checks and validity tests have become indispensable.

4.3 PARITY. Redundancy is central to error-free data processing. By including extra bits in predetermined locations, certain types of errors can be detected immediately by inspection of these *metadata* (data about the original data). In a typical application, data move back and forth many times, among primary memory, secondary storage, input and output devices, as well as through communications links. During these moves, the data may lose integrity by dropping 1 or more bits, by having extraneous bits introduced, and by random changes in specific bits. To detect some of these occurrences, parity bits are added before data are moved and are checked afterward.

4.3.1 Vertical Redundancy Checks. In this relatively simple and inexpensive scheme, a determination is initially made as to whether there should be an odd or an even number of “1” bits in each character. For example, using the binary-coded decimal representation of the numerical “5,” we find that the 6-bit pulse group 000101 contains two 1s, an even number. Adding a seventh position to the code group, we may have either type of parity. If odd parity has been selected, a 1 would be added in the leftmost checkbit position:

Odd parity	1000101 three 1s
Even parity	0000101 two 1s

After any movement the number of 1 bits would be counted, and if not an odd number, an error would be assumed and processing halted. Of course, if 2 bits, or any even number, had been improperly transmitted, no error would be indicated since the number of “1” bits would still be odd.

To compound the problem of nonuniformity illustrated in Exhibit 4.1, each of the 4-, 5-, 6-, 7-, 8-, and 16-bit code groups may have an additional bit added for parity checking. Furthermore, there may be inconsistency of odd or even parity between manufacturers, or even between different equipment from a single supplier.

4.3.2 Longitudinal Redundancy Checks. Errors may not be detected by a vertical redundancy check (VRC) alone, for reasons just discussed. An additional safeguard, of particular use in data transmission and media recording such as tapes and disks, is the longitudinal redundancy check (LRC). With this technique, an extra

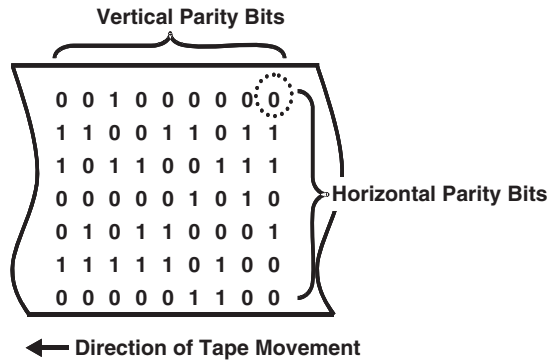

EXHIBIT 4.2 Vertical and Longitudinal Parity, Seven-Track Magnetic Tape

character is generated after some predetermined number of data characters. Each bit in the extra character provides parity for its corresponding row, just as the vertical parity bits do for their corresponding columns. Exhibit 4.2 represents both types as they would be recorded on 7-track magnetic tape. One bit has been circled to show that it is ambiguous. This bit appears at the intersection of the parity row and the parity column, and must be predetermined to be correct for one or the other, as it may not be correct for both. In the illustration, the ambiguous bit is correct for the odd parity requirement of the VRC character column; it is incorrect for the even parity of the LRC bit row.

In actual practice, the vertical checkbits would be attached to each character column as shown, but the longitudinal bits would follow a block of data that might contain 80 to several hundred characters. Where it is possible to use both LRC and VRC, any single data error in a block will be located at the intersection of incorrect row and column parity bits. The indicated bit may then be corrected automatically. The limitations of this method are: (1) multiple errors cannot be corrected, (2) an error in the ambiguous position cannot be corrected, and (3) an error that does not produce both a VRC and LRC indication cannot be corrected.

4.3.3 Cyclical Redundancy Checks. Where the cost of a data error could be high, the added expense of cyclical redundancy checks (CRCs) is warranted. In this technique, a relatively large number of redundant bits is used. For example, each 4-bit character requires 3 parity bits, while a 32-bit computer word needs 6 parity bits. Extra storage space is required in main and secondary memory, and transmissions take longer than without such checks. The advantage, however, is that any single error can be detected, whether in a data bit or a parity bit, and its location can be positively identified. By a simple electronic process of complementation, an incorrect 0 is converted to a 1, and vice versa.

4.3.4 Self-Checking Codes. Several types of codes are in use that inherently contain a checking ability similar to that of the parity system. Typical of these is the 2-of-5 code, in which every decimal digit is represented by a bit configuration containing exactly two 1s and three 0s. Where a parity test would consist of counting 1s to see if their number was odd or even, a 2-of-5 test would indicate an error whenever the number of 1s was more or less than 2.

4 · 6 HARDWARE ELEMENTS OF SECURITY

4.4 HARDWARE OPERATIONS. Input, output, and processing are the three essential functions of any computer. To protect data integrity during these operations, several hardware features are available.

- **Read-after-write.** In disk and tape drives, it is common practice to read the data immediately after they are recorded and to compare them with the original values. Any disagreement signals an error that requires rewriting.
- **Echo.** Data transmitted to a peripheral device, to a remote terminal (see Section 4.9.1), or to another computer can be made to generate a return signal. This echo is compared with the original signal to verify correct reception. However, there is always the risk that an error will occur in the return signal and falsely indicate an error in the original transmission.
- **Overflow.** The maximum range of numerical values that any computer can accommodate is fixed by its design. If a program is improperly scaled, or if an impossible operation such as dividing by zero is called for, the result of an arithmetic operation may exceed the allowable range, producing an overflow error. Earlier computers required programmed instructions to detect overflows, but this function now generally is performed by hardware elements at the machine level. Overflows within application programs still must be dealt with in software. (Indeed, failure to do so can render software susceptible to abuse by malicious parties.)
- **Validation.** In any one computer coding system, some bit patterns may be unassigned, and others may be illegal. In the IBM System/360 Extended Binary Coded Decimal Interchange Code (EBCDIC), for example, the number 9 is represented by 11111001, but 11111010 is unassigned. A parity check would not detect the second group as being in error, since both have the same number of 1 bits. A validity check, however, would reject the second bit configuration as invalid.

Similarly, certain bit patterns represent assigned instruction codes while others do not. In one computer, the instruction to convert packed-decimal numbers to zoned-decimal numbers is 11110011, or F3 in hexadecimal notation; 11110101, or F5, is unassigned, and a validity check would cause a processing halt whenever that instruction was tested.

- **Replication.** In highly sensitive applications, it is good practice to provide backup equipment on site, for immediate changeover in the event of failure of the primary computer. For this reason, it is sometimes prudent to retain two identical, smaller computers rather than to replace them with a single unit of equivalent or even greater power. Fault-tolerant, or fail-safe, computers use two or more processors that operate simultaneously, sharing the load and exchanging information about the current status of duplicate processes running in parallel. If one of the processors fails, another continues the processing without pause.

Many sensitive applications, such as airline reservation systems, have extensive data communications facilities. It is important that all of this equipment be duplicated as well as the computers themselves. (The failure of an airline reservation system, if permitted to extend beyond a relatively small number of hours, could lead to failure of the airline itself.)

Replacements should also be immediately available for peripheral devices. In some operating systems, it is necessary to inform the system that a device is down and to reassign its functions to another unit. In the more sophisticated systems, a malfunctioning device is automatically cut out and replaced. For example, the New York Stock Exchange operates and maintains two identical trading systems so that failure of the primary system should not result in any interruption to trading.

4.5 INTERRUPTS. The sequence of operations performed by a computer system is determined by a group of instructions: a program. However, many events that occur during operations require deviations from the programmed sequence. *Interrupts* are signals generated by hardware elements that detect changed conditions and initiate appropriate action. The first step is immediately to store the status of various elements in preassigned memory locations. The particular stored bit patterns, commonly called program status words, contain the information necessary for the computer to identify the cause of the interrupt, to take action to process it, and then to return to the proper instruction in the program sequence after the interrupt is cleared.

4.5.1 Types of Interrupts. Five types of interrupts are in general use. Each of them is of importance in establishing and maintaining data processing integrity.

4.5.1.1 Input/Output Interrupts. Input/output (I/O) interrupts are generated whenever a device or channel that had been busy becomes available. This capability is necessary to achieve error-free use of the increased throughput provided by buffering, overlapped processing, and multiprogramming.

After each I/O interrupt, a check is made to determine whether the data have been read or written without error. If so, the next I/O operation can be started; if not, an error-recovery procedure is initiated. The number of times that errors occur should be recorded so that degraded performance can be detected and corrected.

4.5.1.2 Supervisor Calls. The supervisor, or monitor, is a part of the operating system software that controls the interactions between all hardware and software elements.

Every request to read or write data is scheduled by the supervisor when called upon to do so. I/O interrupts also are handled by supervisor calls that coordinate them with read/write requests. Loading, executing, and terminating programs are other important functions initiated by supervisor calls.

4.5.1.3 Program Check Interrupts. Improper use of instructions or data may cause an interrupt that terminates the program. For example, attempts to divide by zero and operations resulting in arithmetic overflow are voided. Unassigned instruction codes, attempts to access protected storage, and invalid data addresses are other types of exceptions that cause program check interrupts.

4.5.1.4 Machine Check Interrupts. Among the exception conditions that will cause machine check interrupts are parity errors, bad disk sectors, disconnection of peripherals in use, and defective circuit modules. It is important that proper procedures be followed to clear machine checks without loss of data or processing error.

4.5.1.5 External Interrupts. External interrupts are generated by timer action, by pressing an Interrupt key, or by signals from another computer. When two central processing units are interconnected, signals that pass between them initiate external interrupts. In this way, control and synchronization are continuously maintained while programs, data, and peripheral devices may be shared and coordinated.

In mainframes, an electronic clock generally is included in the central processor unit for time-of-day entries in job logs and for elapsed-time measurements. As an interval timer, the clock can be set to generate an interrupt after a given period. This feature should be used as a security measure, preventing sensitive jobs from remaining on the computer long enough to permit unauthorized manipulation of data or instructions.

4 · 8 **HARDWARE ELEMENTS OF SECURITY**

4.5.2 Trapping. Trapping is a type of hardware response to an interrupt. Upon detecting the exception, an unconditional branch is taken to some predetermined location. An instruction there transfers control to a supervisor routine that initiates appropriate action.

4.6 MEMORY AND DATA STORAGE. Just as the human mind is subject to aberrations, so is computer memory. In the interests of data security and integrity, various therapeutic measures have been developed for the several types of storage.

4.6.1 Main Memory. Random access memory (RAM), and its derivatives, such as dynamic RAM (DRAM), synchronous DRAM (SDRAM, introduced in 1996 and running at 133 megaHertz [MHz]), and DDR-3 (Double Data Rate 3 SDRAM, announced in 2005 and running at 800 MHz), share the necessary quality of being easily and quickly accessed for reading and writing of data. Unfortunately, this necessary characteristic is at the same time a potential source of difficulty in maintaining data integrity against unwanted read/write operations. The problems are greatly intensified in a multiprogramming environment, especially with dynamic memory allocation, where the possibility exists that one program will write improperly over another's data in memory. Protection against this type of error must be provided by the operating system. Chapter 24 in this *Handbook* discusses operating system security in more detail.

One form of protection requires that main memory be divided into blocks or *pages*; for example, 2,048 eight-bit bytes each. Pages can be designated as read-only when they contain constants, tables, or programs to be shared by several users. Additionally, pages that are to be inaccessible except to designated users may be assigned a lock by appropriate program instructions. If a matching key is not included in the user's program, access to that page will be denied. Protection may be afforded against writing only or against reading and writing.

4.6.2 Read-Only Memory. One distinguishing feature of main memory is the extremely high speed at which data can be entered or read out. The set of sequential procedures that accomplishes this and other functions is the program, and the programmer has complete freedom to combine any valid instructions in a meaningful way. However, certain operations, such as system start-up, or *booting*, are frequently and routinely required, and they may be performed automatically by a preprogrammed group of memory elements. These elements should be protected from inadvertent or unauthorized changes.

For this purpose, a class of memory elements has been developed that, once programmed, cannot be changed at all, or require a relatively long time to do so. These elements are called *read-only memory*, or ROM; the process by which sequential instructions are set into these elements is known as *microprogramming*. The technique can be used to advantage where data integrity is safeguarded by eliminating the possibility of programmer error.

Variations of the principle include programmable read-only memories (PROM) and erasable, programmable read-only memory (EPROM), all of which combine microprogramming with a somewhat greater degree of flexibility than read-only memory itself. The data on these chips can be changed through a special operation often referred to as *flashing* (literally exposure to strong ultraviolet light; this is different from *flash memory* used today for storage of such data as digital music files and digital photographs—we will return to the subject of *flash memory* in the next section).

4.6.3 Secondary Storage. The term “secondary storage” traditionally has been used to describe storage such as magnetic disks, diskettes, tapes, and tape cartridges. Although the 1.44 megabyte (MB) magnetic floppy disk is obsolete, the magnetic hard drive, with capacities up to terabytes, remains an essential element of virtually all computers, and terabyte-capacity external hard drives the size of a paperback book are now available off-the-shelf for a few hundred dollars.

A more recent development are optical drives such as the removable, *compact disc read-only memory* (CD-ROM), originally made available in the early 1980s, which are useful for long-term archival storage of around 700 MB per disc. Hybrid forms of this type exist as well, such as CD-Rs, which can be written to once, and CD-RWs, which accommodate multiple reads and writes. The digital video disc (DVD), or as it has been renamed, the digital versatile disc, was introduced in 1997 and provides capacities ranging from 4.7 gigabytes (GB) per disc up to 30 GB for data archiving. The higher-capacity optical discs use Blu-ray technology introduced in 2002 and can store 25 GB per side; they typically are used for distributing movies, but BD-R (single use) and BD-RE (rewritable) discs hold much potential for generalized data storage.

The newest addition to secondary storage is RAM that simulates hard disks, known as *flash memory*. Derived from electrical EPROMs (EEPROMs) and introduced by Toshiba in the 1980s, this kind of memory now exists in a huge variety of formats, including relatively inexpensive Universal Serial Bus (USB) tokens with storage capacities now in the gigabyte range. These devices appear as external disk drives when plugged into a plug-and-play personal computer. Another flash memory format is small cards, many the size of postage stamps, that can be inserted into mobile phones, cameras, printers, and other devices as well as computers.

Hardware safeguards described earlier, such as redundancy, validity, parity, and read-after-write, are of value in preserving the integrity of secondary storage. These safeguards are built into the equipment and are always operational unless disabled or malfunctioning. Other precautionary measures are optional, such as standard internal labeling procedures for drives, tapes, and disks. Standard internal labels can include identification numbers, record counts, and dates of creation and expiration. Although helpful, external plastic or paper labels on recordable media are not an adequate substitute for computer-generated labels, magnetically inscribed on the medium itself and automatically checked by programmed instructions.

Another security measure sometimes subverted is write-protection on removable media. Hardware interlocks prevent writing to them. These locks should be activated immediately when the media are removed from the system. Failure to do so will cause the data to be destroyed if the same media are improperly used on another occasion.

Hard drives, optical discs, and flash memory cards are classified as direct access storage devices (DASDs). Unlike magnetic tapes with their exclusively sequential processing, DASDs may process data randomly as well as in sequence. This capability is essential to online operations, where it is not possible to sort transactions prior to processing. The disadvantage of direct access is that there may be less control over entries and more opportunity to degrade the system than exists with sequential batch processing.

One possible source of DASD errors arises from the high rotational velocity of the recording medium and, except on head-per-track devices, the movement of heads as well. To minimize this possibility, areas on the recording surface have their addresses magnetically inscribed. When the computer directs that data be read from or into a particular location, the address in main memory is compared with that read from the DASD. Only if there is agreement will the operation be performed.

4 · 10 **HARDWARE ELEMENTS OF SECURITY**

Through proper programming, the integrity of data can be further assured. In addition to the address check, comparisons can be made on identification numbers or on key fields within each record. Although the additional processing time is generally negligible, there can be a substantial improvement in properly posting transactions.

Several other security measures often are incorporated into DASDs. One is similar to the protection feature in main memory and relies on determining “extents” for each data set. If these extents, which are simply the upper and lower limits of a data file’s addresses, are exceeded, the job will terminate.

Another safety measure is necessitated by the fact that defective areas on a disk surface may cause errors undetectable in normal operations. To minimize this possibility, disks should be tested and certified prior to use and periodically thereafter. Further information is provided by operating systems that record the number of disk errors encountered. Reformatting or replacement must be ordered when errors exceed a predetermined level. Many personal computer hard drives now have some form of Self-Monitoring, Analysis, and Reporting Technology (SMART). Evolved from earlier technology such as IBM’s Predictive Failure Analysis (PFA) and Intellisafe by computer manufacturer Compaq, and disk drive manufacturers Seagate, Quantum, and Conner, SMART can alert operators to potential drive problems. Unfortunately, the implementation of SMART is not standardized, and its potential for preventive maintenance and failure prediction is often overlooked.

Note that SMART is different from the range of technologies used to protect hard drives from head crashes. A head crash occurs when the component that reads data from the disk actually touches the surface of the disk, potentially damaging it and the data stored on it. Many hard drives have systems in place to withdraw heads from the disk before such contact occurs. These protective measures have reached the point where an active hard drive can be carried around in relative safety as part of a music and video player (e.g., Apple iPod or Microsoft Zune).

4.7 TIME. Within the computer room and in many offices, a wall clock is usually a dominant feature. There is no doubt that this real-time indicator is of importance in scheduling and regulating the functions of people and machines, but the computer’s internal timings are more important for security.

4.7.1 Synchronous. Many computer operations are independent of the time of day but must maintain accurate relationships with some common time and with each other. Examples of this synchronism include the operation of gates, flip-flops, and registers, and the transmission of data at high speeds. Synchronism is obtained in various ways. For gates and other circuit elements, electronic clocks provide accurately spaced pulses at a high-frequency rate, while disk and tape drives are maintained at rated speed by servomotor controls based on power-line frequency.

Of all computer errors, the ones most difficult to detect and correct are probably those caused by timing inconsistencies. Internal clocks may produce 1 billion pulses per second (known as 1 gigahertz [GHz]), or more, when the computer is turned on. The loss of even a single pulse, or its random deformation or delay, can cause undetected errors. More troublesome is the fact that even if errors are detected, their cause may not be identified unless the random timing faults become frequent or consistent.

An example of the insidious nature of timing faults is the consequence of electrical power fluctuations when voltage drops below standard. During these power transients, disk drives may slow down; if sectors are being recorded, their physical size will be

correspondingly smaller. Then, when the proper voltage returns, the incorrect sector sizes can cause data errors or loss.

4.7.2 Asynchronous. Some operations do not occur at fixed time intervals and therefore are termed “asynchronous.” In this mode, signals generated by the end of one action initiate the following one. As an example, low-speed data transmissions such as those using ordinary modems are usually asynchronous. Coded signals produced by the random depression of keyboard keys are independent of any clock pulses.

4.8 NATURAL DANGERS. To preserve the accuracy and timeliness of computer output, computers must be protected against environmental dangers. Chapters 22 and 23 of this *Handbook* discuss such threats in extensive detail.

4.8.1 Power Failure. Probably the most frequent cause of computer downtime is power failure. Brownouts and blackouts are visible signs of trouble; undetected voltage spikes are far more common, although hardly less damaging.

Lightning can produce voltage spikes on communications and power lines of sufficient amplitude to destroy equipment or, at the very least, to alter data randomly. Sudden storms and intense heat or cold place excessive loads on generators. The drop in line voltage that results can cause computer or peripheral malfunction. Even if it does not, harmful voltage spikes may be created whenever additional generators are switched in to carry higher loads.

Where warranted, a recording indicator may be used to detect power-line fluctuations. Such monitoring often is recommended when computer systems show unexplained, erratic errors. At any time that out-of-tolerance conditions are signaled, the computer output should be checked carefully to ensure that data integrity has not been compromised. If such occurrences are frequent, or if the application is a sensitive one, auxiliary power management equipment should be considered. These range from simple voltage regulators and line conditioners to uninterruptible power supplies (UPSs).

4.8.2 Heat. Sustained high temperatures can cause electronic components to malfunction or to fail completely. Air conditioning (AC) is therefore essential, and all units must be adequate, reliable, and properly installed. If backup electrical power is provided for the computer, it must also be available for the air conditioners. For example, after the San Francisco earthquake of 1989, the desktop computers and network servers in at least one corporate headquarters were damaged by a lack of synchronization between air conditioning and power supply. The AC was knocked out by the quake, and the building was evacuated, but the computers were left on. Many of them failed at the chip and motherboard level over the next few days because the temperature in the uncooled offices got too high. A frequently unrecognized cause of overheating is obstruction of ventilating grilles. Printouts, tapes, books, and other objects must not be placed on cabinets where they can prevent free air circulation. A digital thermometer is a good investment for any room in which computers are used. Today, many electronic devices include thermostats that cut off the power if internal temperatures exceed a danger limit.

4.8.3 Humidity. Either extreme of humidity can be damaging. Low humidity—below about 20 percent—permits buildup of static electricity charges that

4 · 12 **HARDWARE ELEMENTS OF SECURITY**

may affect data pulses. Because this phenomenon is intensified by carpeting, computer room floors should either be free of carpeting or covered with antistatic carpet.

High humidity—above about 80 percent—may lead to condensation that causes shorts in electrical circuits or corrodes metal contacts. To ensure operation within acceptable limits, humidity controls should be installed and a continuous record kept of measured values.

4.8.4 Water. Water introduced by rain, floods, bursting pipes, and overhead sprinklers probably has been responsible for more actual computer damage than fire or any other single factor. Care taken in locating computer facilities, in routing water pipes, and in the selection of fire-extinguishing agents will minimize this significant danger.

The unavailability of water—following a main break, for example—will cause almost immediate shutdown of water-cooled mainframes. Mission-critical data centers should be prepared for this contingency. As an example, when the Des Moines River flooded in 1993, it caused the skyscraper housing the headquarters of the Principal Financial Group to be evacuated, but not because of water in the building. The building stayed high and dry, but the flood forced the city water plant to shut down, depriving the building of the water necessary for cooling. After the flood, the company installed a 40,000-gallon water tank in the basement, to prevent any recurrence of this problem.

4.8.5 Dirt and Dust. Particles of foreign matter can interfere with proper operation of magnetic tape and disk drives, printers, and other electromechanical devices. All air intakes must be filtered, and all filters must be kept clean. Cups of coffee seem to become especially unstable in a computer environment; together with any other food or drink, they should be banned entirely. Throughout all areas where computer equipment is in use, good housekeeping principles should be rigorously enforced.

4.8.6 Radiation. Much has been written about the destructive effect of magnetic fields on tape or disk files. However, because magnetic field strength diminishes rapidly with distance, it is unlikely that damage actually could be caused except by large magnets held very close to the recorded surfaces. For example, storing a CD or DVD by attaching it to a filing cabinet with a magnet is not a good idea, but simply walking past a refrigerator decorated with magnets while holding a CD or DVD is unlikely to do any damage.

The proliferation of wireless signals can expose data to erroneous pulses. Offices should be alert for possible interference from and between cordless phones, mobile phones, wireless Internet access points and peripherals, and microwave ovens.

Radioactivity may be a great threat to personnel but not to the computer or its recording media.

4.8.7 Downtime. It is essential to the proper functioning of a data center that preventive maintenance be performed regularly and that accurate records be kept of the time and the reason that any element of the computer is inoperative. The more often the computer is down, the more rushed operators will be to catch up on their scheduled workloads. Under such conditions, controls are bypassed, shortcuts are taken, and human errors multiply.

Downtime records should be studied to detect unfavorable trends and to pinpoint equipment that must be overhauled or replaced before outages become excessive.

If unscheduled downtime increases, preventive maintenance should be expanded or improved until the trend is reversed.

4.9 DATA COMMUNICATIONS. One of the most dynamic factors in current computer usage is the proliferation of devices and systems for data transmission. These range from telephone modems to wired networks, from Internet-enabled cell phones to 802.11 wireless Ethernet, and include Bluetooth, infrared, personal digital assistants (PDAs), music players, and new technologies that appear almost monthly. Computers that do not function at least part time in a connected mode may well be rarities. For fundamentals of data communications, see Chapter 5 of this *Handbook*.

The necessity for speeding information over great distances increases in proportion to the size and geographic dispersion of economic entities; the necessity for maintaining data integrity and security, and the difficulty of doing so, increases even more rapidly. Major threats to be guarded against include human and machine errors, unauthorized accession, alteration, and sabotage. The term “accession” refers to an ability to read data stored or transmitted within a computer system; it may be accidental or purposeful. “Alteration” is the willful entering of unauthorized or incorrect data. “Sabotage” is the intentional act of destroying or damaging the system or the data within it. For each of these threats, the exposure and the countermeasures will depend on the equipment and the facilities involved.

4.9.1 Terminals. In these discussions, a *terminal* is any input/output device that includes facilities for receiving, displaying, composing, and sending data. Examples include personal computers and specialized devices such as credit card validation units.

Data communications are carried on between computers, between terminals, or between computers and terminals. The terminals themselves may be classified as *dumb* or *intelligent*. Dumb terminals have little or no processing or storage capability and are largely dependent on a host computer for those functions. Intelligent terminals generally include disk storage and capabilities roughly equivalent to those of a personal computer. In addition to vastly improved communications capabilities, they are capable of stand-alone operation.

In the simplest of terminals, the only protection against transmission errors lies in the inability to recognize characters not included in the valid set and to display a question mark or other symbol when one occurs. Almost any terminal can be equipped to detect a vertical parity error. More sophisticated terminals are capable of detecting additional errors through longitudinal and cyclical redundancy characters, as well as by vertical parity and validity checks. Of course, error detection is only the first step in maintaining data integrity. Error correction is by far the more important part, and retransmission is the most widely used correction technique.

Intelligent terminals and personal computers are capable of high-speed transmission and reception. They can perform complicated tests on data before requesting retransmission, or they may even be programmed to correct errors internally. The techniques for self-correction require forward-acting codes, such as the Hamming cyclical code. These are similar to the error-detecting cyclic redundancy codes, except that they require even more redundant bits. Although error correction is more expensive and usually slower than detection with retransmission, it is useful under certain circumstances. Examples include simplex circuits where no return signal is possible, and half-duplex circuits where the time to turn the line around from transmission to reception is too long. Forward correction is also necessary where errors are so

4 · 14 **HARDWARE ELEMENTS OF SECURITY**

numerous that retransmissions would clog the circuits, with little or no useful information throughput.

A more effective use of intelligent terminals and personal computers is to preserve data integrity by encryption, as described in this chapter and in Chapter 7. Also, they may be used for compression or compaction. Reducing the number of characters in a message reduces the probability of an error as well as the time required for transmission. One technique replaces long strings of spaces or zeroes with a special character and a numerical count; the procedure is reversed when receiving data.

Finally, the intelligent terminal or microprocessor may be used to encode or decipher data when the level of security warrants cryptography.

All terminals, of every type, including desktop and notebook personal computers (PCs), have at least one thing in common: the need to be protected against sabotage or unauthorized use. Although the principles for determining proper physical location and the procedures for restricting access are essentially the same as those that apply to a central computer facility, the actual problems of remote terminals are even more difficult. Isolated locations, inadequate supervision, and easier access by more people all increase the likelihood of compromised security.

4.9.2 Wired Facilities. Four types of wired facilities are in widespread use: dial-up access, leased lines, digital subscriber lines (DSL), and cable carriers. Both common carriers and independent systems may employ various media for data transmission. The increasing need for higher speed and better quality in data transmission has prompted utilization of coaxial and fiber optic cables, while microwave stations and communication satellites often are found as wireless links within wired systems.

Generally, decisions as to the choice of service are based on the volume of data to be handled and on the associated costs, but security considerations may be even more important.

4.9.2.1 Dial-Up Lines. Still widely used for credit and debit card terminals, dial-up lines have been replaced for many other applications by leased lines, DSL lines, and cables carrying Internet traffic (using the TCP/IP protocol discussed in Chapter 5 of this *Handbook*). Dial-up connections are established between modems operating over regular voice lines sometimes referred to as *plain old telephone service* (POTS).

Where dial-up access to hardware still exists, for example, for maintenance of certain equipment, proper controls are essential to protect both the equipment and the integrity of other systems to which it might be connected. Dial-up ports may be reached by anyone with a phone, anywhere on the planet, and the practice of *war-dialing* to detect modems is still used by those seeking unauthorized access to an organization's network. (War dialing involves dialing blocks of numbers to find which ones respond as modems or fax machines. These numbers are recorded and may be dialed later in an attempt to gain unauthorized access to systems or services.) It is advisable to:

- Compile a log of unauthorized attempts at entry, and use it to discourage further efforts.
- Compile a log of all accesses to sensitive data, and verify their appropriateness.
- Equip all terminals with internal identification generators or answer-back units, so that even a proper password would be rejected if sent from an unauthorized

terminal. This technique may require the availability of an authorized backup terminal in the event of malfunction of the primary unit.

- Provide users with personal identification in addition to a password if the level of security requires it. The additional safeguard could be a magnetically striped or computerized plastic card to be inserted into a special reader. The value of such cards is limited, since they can be used by anyone, whether authorized or not. For high-security requirements, other hardware-dependent biometric identifiers, such as handprints and voiceprints, should be considered.
- Where appropriate, utilize call-back equipment that prevents a remote station from entering a computer directly. Instead, the device dials the caller from an internal list of approved phone numbers to make the actual connection.

With proper password discipline, problems of accession, alteration, and data sabotage can be minimized. However, the quality of transmissions is highly variable. Built into the public telephone system is an automatic route-finding mechanism that directs signals through uncontrollable paths. The distance and the number of switching points traversed, and the chance presence of cross-talk, transients, and other noise products will have unpredictable effects on the incidence of errors. Parity systems, described earlier, are an effective means of reducing such errors.

4.9.2.2 Leased Lines. Lines leased from a common carrier for the exclusive use of one subscriber are known as *dedicated lines*. Because they are directly connected between predetermined points, normally they cannot be reached through the dial-up network. Traditionally, leased lines were copper, but point-to-point fiber optic and coaxial cable lines can also be leased.

Wiredtapping is a technically feasible method of accessing leased lines, but it is more costly, more difficult, and less convenient than dialing through the switched network. Leased lines are generally more secure than those that can be readily war-dialed.

To this increased level of security for leased lines is added the assurance of higher-quality reception. The problems of uncertain transmission paths and switching transients are eliminated, although other error sources are not. In consequence, parity checking remains a minimum requirement.

4.9.2.3 Digital Subscriber Lines. Falling somewhere in between a leased line and POTS, a digital subscriber line offers digital transmission locally over ordinary phone lines that can be used simultaneously for voice transmission. This is possible because ordinary copper phone lines can carry, at least for short distances, signals that are in a much higher-frequency range than the human voice. A DSL modem is used by a computer to reach the nearest telephone company switch, at which point the data transmission enters the Internet backbone. Computers connected to the Internet over DSL communicate using TCP/IP and are said to be hosts rather than terminals. They are prone to compromise through a wide range of exploits. However, few if any of these threats are enabled by the DSL itself. As with leased lines, wiredtapping is possible, but other attacks, such as exploiting weaknesses in TCP/IP implementations on host machines, are easier.

4.9.2.4 Cable Carriers. Wherever cable television (TV) is available, the same optical fiber or coaxial cables that carry the TV signal also can be used to provide high-speed data communications. The advantages of this technology include download

4 · 16 **HARDWARE ELEMENTS OF SECURITY**

speeds that can, in the case of coaxial cables, exceed 50 megabits per second, or in the case of fiber optic cable, exceed 100 gigabits per second.

The disadvantages arise from the fact that connections to the carrier may be shared by other subscribers in the same locality. Unless the service provider limits access, perhaps in accordance with a quality-of-service agreement, multiple subscribers can be online simultaneously and thus slow down transmission speeds. Even more serious is the possibility of security breaches, since multiple computers within a neighborhood may be sharing part of a virtual local area network, and thus each is potentially accessible to every other node on that network. For this reason alone, cable connections should be firewalled. For details of firewalls and their uses, see Chapter 26 in this *Handbook*. Another reason for using firewalls is that cable connections are always on, providing maximal opportunity for hackers to access an unattended computer.

4.9.3 Wireless Communications. Data transfers among multinational corporations have been growing very rapidly, and transoceanic radio and telephone lines have proved too costly, too slow, too crowded, and too error-prone to provide adequate service. An important alternative is the communications satellite. Orbiting above Earth, the satellite reflects ultra-high-frequency radio signals that can convey a television program or computer data with equal speed and facility.

For communications over shorter distances, the cost of common-carrier wired services has been so high as to encourage competitive technologies. One of these, the microwave radio link, is used in many networks. One characteristic of such transmissions is that they can be received only on a direct line-of-sight path from the transmitting or retransmitting antenna. With such point-to-point ground stations, it is sometimes difficult to position the radio beams where they cannot be intercepted; with satellite and wireless broadcast communications, it is impossible. This is a significant issue with wireless local area network technology based on the IEEE 802.11 standards and commonly known as Wi-Fi (a brand name owned by the Wi-Fi Alliance; the term is short for *wireless fidelity*). The need for security is consequently greater, and scramblers or cryptographic encoders are essential for sensitive data transfers.

Because of the wide bandwidths at microwave frequencies, extremely fast rates of data transfer are possible. With vertical, longitudinal, and cyclical redundancy check characters, almost all errors can be detected, yet throughput remains high.

4.10 CRYPTOGRAPHY. Competitive pressures in business, politics, and international affairs continually create situations where morality, privacy, and the laws all appear to give way before a compelling desire for gain. Information, for its own sake or for the price it brings, is an eagerly sought after commodity. We are accustomed to the sight of armored cars and armed guards transporting currency, yet often invaluable data are moved with few precautions. When the number of computers and competent technicians was small, the risk in careless handling of data resources was perhaps not great. Now, however, a very large population of knowledgeable computer people exists, and within it are individuals willing and able to use their knowledge for illegal ends. Others find stimulation and satisfaction in meeting the intellectual challenge that they perceive in defeating computer security measures.

Acquiring information in an unauthorized manner is relatively easy when data are communicated between locations. One method of discouraging this practice, or rendering it too expensive to be worth the effort, is cryptographic encoding of data prior to transmission. This technique is also useful in preserving the security of files within data storage devices. If all important files were stored on magnetic or optical media

in cryptographic cipher only, the incidence of theft and resale would unquestionably be less.

Many types of ciphers might be used, depending on their cost and the degree of security required. Theoretically, any code can be broken, given enough time and equipment. In practice, if a cipher cannot be broken fairly quickly, the encoded data are likely to become valueless. However, since the key itself can be used to decipher later messages, it is necessary that codes or keys be changed frequently.

For further information on cryptography, refer to Chapter 7 in this *Handbook*.

4.11 BACKUP. As with most problems, the principal focus in computer security ought to be on prevention rather than on cure. No matter how great the effort, however, complete success can never be guaranteed. There are four reasons for this being so:

1. Not every problem can be anticipated.
2. Where the cost of averting a particular loss exceeds that of recovery, preventive measures may not be justified.
3. Precautionary measures, carried to extremes, can place impossible constraints on the efficiency and productivity of an operation. It may be necessary, therefore, to avoid such measures aimed at events whose statistical probability of occurrence is small.
4. Even under optimum conditions, carefully laid plans may go astray. In the real world of uncertainty and human fallibility, where there is active or inadvertent interference, it is almost a certainty that at one time or another, the best of precautionary measures will prove to be ineffective.

Recognizing the impossibility of preventing all undesired actions and events, it becomes necessary to plan appropriate means of recovering from them. Such plans must include backup for personnel, hardware, power, physical facilities, data, and software. Data backups are discussed more fully in Chapter 57 of this *Handbook*.

Responding to emergencies is described in Chapters 56 of this *Handbook* and business continuity planning and disaster recovery are discussed in Chapter 58 and 59.

Backup plans should be evaluated with respect to:

- The priorities established for each application, to ensure that they are properly assigned and actually observed.
- The time required to restore high-priority applications to full-functioning status.
- The degree of assurance that plans actually can be carried out when required. For important applications, alternative plans should be available in the event that the primary plan cannot be implemented.
- The degree of security and data integrity that will exist if backup plans actually are put into effect.
- The extent to which changing internal or external conditions are noted, and the speed with which plans are modified to reflect such changes.

The assignment of priorities in advance of an actual emergency is an essential and critically important process. In most organizations, new applications proliferate, while old ones are rarely discarded. If backup plans attempt to encompass all jobs,

4 · 18 **HARDWARE ELEMENTS OF SECURITY**

they are likely to accomplish none. Proper utilization of priorities will permit realistic scheduling, with important jobs done on time and at acceptable costs.

4.11.1 Personnel. The problems of everyday computer operation require contingency plans for personnel on whose performance hardware functioning depends. Illnesses, vacations, dismissals, promotions, resignations, overtime, and extra shifts are some of the reasons why prudent managers are continuously concerned with the problem of personnel backup. The same practices that work for everyday problems can provide guidelines for emergency backup plans. This subject is covered more fully in Chapter 45 of this *Handbook*.

4.11.2 Hardware. Hardware backup for data centers can take several forms:

- Multiple processors at the same site to protect against loss of service due to breakdown of one unit
- Duplicate installations at nearby facilities of the same company
- Maintaining programs at a compatible service bureau, on a test or standby basis
- A contract for backup at a facility dedicated to disaster recovery
- A reciprocal agreement with a similar installation at another company

The probability of two onsite processors both being down at the same time due to internal faults is extremely small. Consequently, most multiple installations rarely fall behind on mission-critical applications. However, this type of backup offers no protection against power failure, fire, vandalism, or any disaster that could strike two or more processors at once. The disasters of September 11, 2001, proved that even a highly unlikely event actually could occur. With duplicate processors at different but commonly owned sites, there is little chance of both being affected by the same forces. Although the safety factor increases with the distance separating them, the difficulty of transporting people and data becomes greater. An alternate site must represent a compromise between these conflicting objectives. Furthermore, complete compatibility of hardware and software will have to be preserved, even though doing so places an undue operational burden on one of the installations. Shortly after September 11, a number of New York financial firms were back in operation with their alternative computer sites across the Hudson River.

The backup provided by service bureaus can be extremely effective, particularly if the choice of facility is carefully made. Although progressive service bureaus frequently improve both hardware and software, they almost never do so in a way that would cause compatibility problems for their existing customers. Once programs have been tested, they can be stored offline on tape or disk at little cost. Updated masters can be rotated in the service bureau library, providing offsite data backup as well as the ability to become fully operational at once.

Effective hardware backup is also available at independent facilities created expressly for that purpose. In one type of facility, there are adequate space, power, air conditioning, and communication lines to accommodate a very large system. Most manufacturers are able to provide almost any configuration on short notice when disaster strikes a valued customer. The costs for this type of base standby facility are shared by a number of users so that expenses are minimal until an actual need arises. However, if two or more sharers are geographically close, their facilities may be rendered inoperative by the same fire, flood, or power failure. Before contracting for such a facility,

it is necessary to analyze this potential problem; the alternative is likely to be a totally false sense of security. Several firms whose facilities were damaged or destroyed on September 11 were provided with complete replacement equipment by their vendors within a short time.

Another type of backup facility is already equipped with computers, disk and tape drives, printers, terminals, and communications lines so that it can substitute instantly for an inoperative system. The standby costs for this service are appreciably more than for a base facility, but the assurance of recovery in the shortest possible time is far greater. Here, too, it would be prudent to study the likelihood of more than one customer requiring the facility at the same time and to demand assurance that one's own needs will be met without fail. Several companies successfully availed themselves of this type of backup and disaster recovery after September 11.

Backup by reciprocal agreement was for many years an accepted practice, although not often put to the test. Unfortunately, many managers still rely on this outmoded safeguard. One has only to survive a single major change of operating system software to realize that when it occurs, neither the time nor the inclination is available to modify and test another company's programs. Even the minor changes in hardware and software that continuously take place in most installations could render them incompatible. At the same time, in accordance with Parkinson's Law, workloads always expand to fill the available time and facilities. In consequence, many who believe that they have adequate backup will get little more than an unpleasant surprise, should they try to avail themselves of the privilege.

4.11.3 Power. The one truly indispensable element of any data processing installation is electric power. Backing up power to PCs and small servers by uninterruptible power supplies is reasonable in cost and quite effective. For mainframes and large servers, several types of power backup are available. The principal determinant in selection should be the total cost of anticipated downtime and reruns versus the cost of backup to eliminate them. Downtime and rerun time may be extrapolated from records of past experience.

Problems due to electrical power may be classified by type and by the length of time that they persist. Power problems as they affect computers consist of variations in amplitude, frequency, and waveform, with durations ranging from fractions of a millisecond to minutes or hours. Long-duration outages usually are due to high winds, ice, lightning, vehicles that damage power lines, or equipment malfunctions that render an entire substation inoperative. For mainframes in data centers, it is usually possible, although costly, to contract for power to be delivered from two different substations, with one acting as backup.

Another type of protection is afforded by gasoline or diesel motor generators. Controls are provided that sense a power failure and automatically start the motor. Full speed is attained in less than a minute, and the generator's output can power a computer for days if necessary.

The few seconds' delay in switching power sources is enough to abort programs running on the computer and to destroy data files. To avoid this, the "uninterruptible" power supply was designed. In one version, the AC power line feeds a rectifier that furnishes direct current to an inverter. The inverter in turn drives a synchronous motor coupled to an alternator whose AC output powers the computer. While the rectifier is providing DC to the inverter, it also charges a large bank of heavy-duty batteries. As soon as a fault is detected on the main power line, the batteries are instantaneously and automatically switched over to drive the synchronous motor. Because the huge drain

4 · 20 **HARDWARE ELEMENTS OF SECURITY**

on the batteries may deplete them in a few minutes, a diesel generator must also be provided. The advantages of this design are:

- Variations in line frequency, amplitude, and waveform do not get through to the computer.
- Switchover from power line to batteries is undetectable by the computer. Programs keep running, and no data are lost.
- Millisecond spikes and other transients that may be responsible for equipment damage, and undetected data loss are completely suppressed.

A fuller treatment of physical threats is presented in Chapters 22 and 23 of this *Handbook*.

4.11.4 Testing. The most important aspect of any backup plan is its effectiveness. Will it work? It would be a mistake to wait for an emergency to find out. The only sensible alternative is systematic testing.

One form of test is similar to a dress rehearsal, with the actual emergency closely simulated. In this way the equipment, the people, and the procedures can all be exercised, until practice assures proficiency. Periodically thereafter the tests should be repeated, so that changes in hardware, software, and personnel will not weaken the backup capability.

4.12 RECOVERY PROCEDURES. The procedures required to recover from any system problem will depend on the nature of the problem and on the backup measures that were in place. Hardware recovery ranges from instantaneous and fully automatic, through manual repair or replacement of components, to construction, equipping, and staffing of an entirely new data center. Chapters 58 and 59 of this *Handbook* provide extensive information about these issues.

Almost every data center is a collection of equipment, with options, modifications, additions, and special features. Should it become necessary to replace the equipment, a current configuration list must be on hand and the procedures for reordering established in advance. An even better practice would be to keep a current list of *desired* equipment that could be used as the basis for replacement. Presumably, the replacements would be faster and more powerful, but additional time should be scheduled for training and conversion.

4.13 MICROCOMPUTER CONSIDERATIONS. Four factors operate to intensify the problems of hardware security as they relate to small computers:

1. Accessibility
2. Knowledge
3. Motivation
4. Opportunity

4.13.1 Accessibility. *Accessibility* is a consequence of operating small computers in a wide-open office environment rather than in a controlled data center. No security guards, special badges, man-traps, cameras, tape librarians, or shift supervisors limit access to equipment or data media in the office, as they do in a typical data center.

4.13.2 Knowledge. *Knowledge* and its lack are equally dangerous. On one hand, as personal computers pervade the office environment, technical knowledge becomes widely disseminated. Where once this knowledge was limited to relatively few computer experts who could be controlled rather easily, its growing universality now makes control extremely difficult, if not impossible. On the other hand, when computers are operated by people with minimal knowledge and skills, the probability of security breaches through error and inadvertence is greatly increased.

4.13.3 Motivation. *Motivation* exists in numerous forms. It is present wherever valuable assets can be diverted for personal gain; it arises when real or fancied injustice creates a desire for revenge; and it can simply be a form of self-expression.

The unauthorized diversion of corporate assets always has provided opportunities for theft; now, with many employees owning computers at home, the value of stolen equipment, programs, and data can be realized without the involvement of third parties. When a third party is added to the equation and the thriving market in purloined personal data is factored in, the potential for data theft, a low-risk/high-return crime, is greatly increased.

Computers and networks are also a target for sabotage as well as data theft. The reliance upon such systems by governments, the military, large corporations, and other perceived purveyors of social or economic ills means that criminal acts are likely to continue. Because personal computers are now part of these systems, they are also a link to any policy or practice of which one or more groups of people disapprove. The motivation for sabotaging personal computers is more likely in the near term to increase than it is to disappear.

A third motivation for breaching computer security is the challenge and excitement of doing so. Whether trying to overcome technical hurdles, to break the law with impunity, or merely to trespass on forbidden ground, some hackers find these challenges irresistible, and they become criminal hackers. To view such acts with amused tolerance or even mild disapproval is totally inconsistent with the magnitude of the potential damage and the sanctity of the trust barriers that are crossed. Since the technology exists to lock out all but the most determined and technically proficient criminal hacker, failure to protect sensitive systems is increasingly viewed as negligence.

4.13.4 Opportunity. With so many personal computers in almost every office, with virtually no supervision during regular hours, and certainly none at other times, opportunities are plentiful for two types of security breaches: intentional by those with technical knowledge and unintentional by those without.

4.13.5 Threats to Microcomputers. Among the most significant threats to microcomputers are those pertaining to:

- Physical damage
- Theft
- Electrical power
- Static electricity
- Data communications
- Maintenance and repair

4.22 HARDWARE ELEMENTS OF SECURITY

4.13.5.1 Physical Damage. Microcomputers and their peripheral devices are not impervious to damage. Disk drives are extremely susceptible to failure through impact; keyboards cannot tolerate dirt or rough handling. It is essential that computers be recognized as delicate instruments and that they be treated accordingly.

Even within an access-controlled data center, where food and drinks are officially banned, it is not uncommon for a cup of coffee to be spilled when set on or near operating equipment. In an uncontrolled office environment, it is rare that one does not see personal computers in imminent danger of being doused with potentially damaging liquids. The problem is compounded by the common practice of leaving unprotected media such as CDs and DVDs lying about on the same surface where food and drink could easily reach them. Although it may not be possible to eliminate these practices entirely, greater discipline will protect data media and equipment from contamination.

As mentioned in the section on heat, damage also can result from blocking vents necessary for adequate cooling. Such vents can be rendered ineffective by placing the equipment too close to a wall or, in the case of laptops, on soft surfaces, such as carpets, that block vents on the base of the machine. Vents on top of computer housings and cathode ray tube-style displays are too often covered by papers or books that prevent a free flow of cooling air. As a result, the internal temperature of the equipment increases, so that marginal components malfunction, intermittent contacts open, errors are introduced, and eventually the system malfunctions or halts.

4.13.5.2 Theft. The opportunities for theft of personal computers and their data media are far greater than for their larger counterparts. Files containing proprietary information or expensive programs are easily copied to removable media as small as a postage stamp and taken from the premises without leaving a trace. External disk drives are small enough to be carried out in a purse or an attaché case, and new thumb-size USB drives look like key fobs to the uninitiated. (For more information about removable, miniaturized, file storage, see Chapter 1 in this *Handbook*.) The widespread practice of taking portable computers home for evening or weekend work eventually renders even the most conscientious guards indifferent. In offices without guards, the problem is even more difficult. Short of instituting a police state of perpetual surveillance, what is to be done to discourage theft? Equipment can be chained or bolted to desks, or locked within cabinets built for the purpose. Greater diligence in recording and tracking serial numbers, more frequent inventories, and a continuing program of education can help. Most of all, it is essential that the magnitude of the problem be recognized at a sufficiently high management level so that adequate resources are applied to its solution. Otherwise, there will be a continuing drain of increasing magnitude on corporate profitability.

4.13.5.3 Power. Even in a controlled data center, brownouts, blackouts, voltage spikes, sags and surges, and other electrical power disturbances represent a threat. The situation is much worse in a typical office, where personal computers are plugged into existing outlets with little or no thought to the consequences of bad power.

Some of the rudimentary precautions that should be taken are:

- Eliminating, or at least controlling, the use of extension cords, cube taps, and multiple outlet strips. Each unit on the same power line may reduce the voltage available to all of the others, and each may introduce noise on the line.

- Providing line voltage regulators and line conditioners where necessary to maintain power within required limits.
- Banning the use of vacuum cleaners or other electrical devices plugged into the same power line as computers or peripheral devices. Such devices produce a high level of electrical noise, in addition to voltage sags and surges.
- Connecting all ground wires properly. This is especially important in older offices equipped with two-prong outlets that require adapter plugs. The third wire of the plug must be connected to a solid earth ground for personnel safety, as well as for reduction of electrical noise.

In addition, the use of UPSs is highly recommended for all computers and ancillary equipment. These devices are available in capacities from about 200 watts for PCs to virtually unlimited sizes for mainframes. While the power line is operational, a UPS is capable of conditioning the line by removing electrical noise, sags, spikes, and surges. When line voltage drops below a preset value, or when power is completely lost, the UPS converts DC from its internal batteries to the AC required to supply the associated equipment.

Depending on its rating and the load, the UPS may provide standby power for several minutes to several hours. This is enough time to shut down a computer normally, or in the case of large installations, to have a motor generator placed online.

The services of a qualified electrician should be utilized wherever there is a possibility of electric power problems.

4.13.5.4 Static Electricity. After one walks across a carpeted floor on a dry day, the spark that leaps from fingertip to computer may be mildly shocking to a person, but to the computer it can cause serious loss of memory, degradation of data, and even component destruction. These effects are even more likely when people touch components inside a computer without proper grounding.

To prevent this, several measures are available:

- Use a humidifier to keep the humidity above 20 percent relative.
- Remove ordinary carpeting. Replace, if desired, with static-free types.
- Use an antistatic mat beneath chairs and desks.
- Use a grounding strip near each keyboard.
- Wear a grounding bracelet when installing or repairing the components of any electronic equipment.

Touching the grounding strip before operating the computer will drain any static electricity charge through the attached ground wire, as will spraying the equipment periodically with an antistatic spray.

Some combination of these measures will protect personnel, equipment, and data from the sometimes obscure, but always real, dangers of static electricity.

4.13.5.5 Data Communications. Although personal computers perform significant functions in a stand-alone mode, their utility is greatly enhanced by communications to mainframes, to information utilities, and to other small computers, remotely via phone lines or the Internet, or through local area networks. All of the security

4 · 24 **HARDWARE ELEMENTS OF SECURITY**

issues that surround mainframe communications apply to personal computers, with added complications.

Until the advent of personal computers, almost all terminals communicating with mainframes were “dumb.” That is, they functioned much like teletype machines, with the ability only to key in or print out characters, one at a time. In consequence, it was much more difficult to breach mainframe security, intentionally or accidentally, than it is with today’s fully intelligent personal computers.

The image of thousands of dedicated hackers dialing up readily available computer access numbers or probing Internet addresses, for illicit fun and games or for illegal financial gain, is no less disturbing than it is real. Countermeasures are available, including:

- Two-way encryption (see Chapter 7)
- Frequent password changes (see Chapter 28)
- Automatic call-back before logging on
- Investigation of unsuccessful logons
- Monitoring of hackers’ bulletin boards (see Chapters 12 and 15)
- Firewalls to restrict traffic into and out of the computer (see Chapter 26)
- Antivirus software (see Chapter 41)

Legislation that makes directors and senior officers personally liable for any corporate losses that could have been prevented should have a marked effect on overcoming the current inertia. Prudence dictates that preventive action be taken before, rather than corrective action after, such losses are incurred.

4.13.6 Maintenance and Repair. A regular program of preventive maintenance should be observed for every element of a personal computer system. This should include scheduled cleaning of disk drives and their magnetic heads, keyboards, and printers. A vital element of any preventive maintenance program is the frequent changing of air filters in every piece of equipment. If this is not done, the flow of clean, cool air will be impeded, and failure will almost surely result.

Maintenance options for personal computers, in decreasing order of timeliness, include:

- Onsite management by regular employees
- Onsite maintenance by third parties under an annual agreement
- On-call repair, with or without an agreement
- Carry-in service
- Mail-in service

As personal computers are increasingly applied to functions that affect the very existence of a business, their maintenance and repair will demand more management attention. Redundant equipment and onsite backup will always be effective, but the extended time for offsite repairs will no longer be acceptable. For most business applications, “loaners” or “swappers” should be immediately available, so that downtime will be held to an absolute minimum. Management must assess the importance of each functioning personal computer and select an appropriate maintenance and repair policy.

Accessibility, knowledge, motivation, and opportunity are the special factors that threaten every personal computer installation. Until each of these factors has been addressed, no system can be considered secure.

4.14 CONCLUSION. This chapter has dealt principally with the means by which hardware elements of a data processing system affect the security and integrity of its operations. Many safeguards are integral parts of the equipment itself; others require conscious effort, determination, and commitment.

An effective security program—one that provides both decreased likelihood of computer catastrophe and mitigation of the consequences of damage—cannot be designed or implemented without considerable expenditures of time and money. As with other types of loss avoidance, the premium should be evaluated against the expected costs. Once a decision has been made, however, this equivalent to an insurance policy should not be permitted to lapse. The premiums must continue to be paid in the form of periodic testing, continuous updating, and constant vigilance.

For more detailed information about risk management, see Chapter 62 in this *Handbook*. For a discussion of insurance policies against information systems disasters of all kinds, see Chapter 60.

4.15 HARDWARE SECURITY CHECKLIST

Mainframes

- Are security and integrity requirements considered when selecting new equipment?
- Is a schedule of preventive maintenance enforced?
- Is a log kept of all computer malfunctions and unscheduled downtime?
- Is there an individual with responsibility for reviewing the log and initiating action?
- Are parity checks used wherever possible?

5 · 2 DATA COMMUNICATIONS AND INFORMATION SECURITY

5.1 INTRODUCTION. Sometimes, an attacker can simply walk up to a target computer. In most cases, however, attackers must use networks to reach their targets. Some attacks even aim *at* networks, trying to bring down local area networks, wide area networks, and even the global Internet. This chapter provides an overview of networking to help readers of this *Handbook* when they come across networking concepts in other chapters or in other contexts. This chapter covers a limited number of networking concepts. Specifically, it focuses on aspects of networking that are most relevant to security.

Before beginning, readers should note three important pieces of terminology that pervade the chapter.

1. This chapter often uses the term *octet*, which is a *byte*—a collection of eight bits. Networking grew out of electrical engineering, where octet is the preferred term; it is also widely used in the international technical community.
2. The second term is *host*. Any device attached to the global Internet is called a host. This includes everything from large server hosts to client PCs, personal digital assistants, mobile telephones, and even Internet-accessible coffeepots.
3. We will distinguish between the terms *internet* and *Internet*; the latter refers to the global Internet. However, *internet* spelled in lower case is either the Internet layer in the TCP architecture (see Section 5.6) or a collection of networks that is not the global Internet.

5.2 SAMPLING OF NETWORKS. This section looks briefly at a series of increasingly complex networks, giving the reader a high-level overview of what networks look like in the real world.

5.2.1 Simple Home Network. Exhibit 5.1 shows a simple home PC network. The home has two personal computers. The network allows the two PCs to share files and the family's single laser printer. The network also connects the two computers to the Internet.

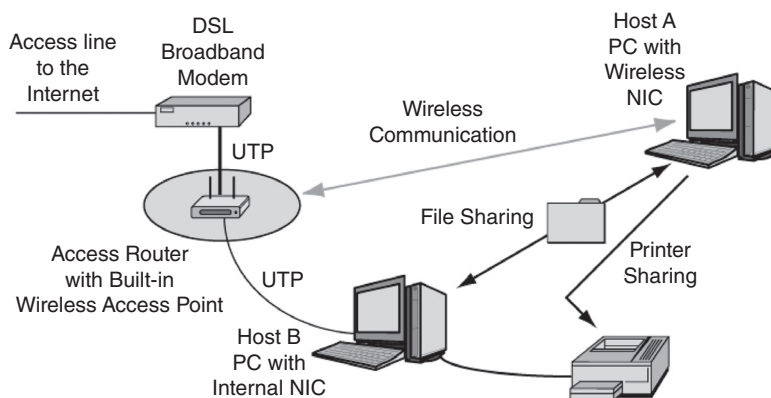

EXHIBIT 5.1 Simple Home Network

5.2.1.1 Access Router. The heart of this network is its *access router*. This small device performs a variety of functions, most importantly these five:

1. It performs as a switch. When one PC in the home sends messages (called packets) to the other hosts, the switch transfers the packets between them.
2. The access router is a wireless access point (WAP), which permits wireless computers to connect to it. Host A connects to the access router wirelessly.
3. A router connects a network to another network—in this case, it connects the internal network to the global Internet.
4. To use the Internet, each computer needs an Internet Protocol (IP) address. We will see later that IP is the main protocol that governs communication over the Internet. The access router has a built-in Dynamic Host Configuration Protocol (DHCP) server that gives each home PC an IP address.
5. The router provides *network address translation* (NAT), which hides internal IP addresses from potential attackers. Most routers also have a firewall for added security. WAPs are easily exploited if not configured with proper authentication security. Wireless signals can be transferred up to 800 feet away or more with special equipment. Without constant monitoring to defeat intrusions, an attacker can connect to an access point without the user's knowledge and intercept all passing traffic. Using NAT is essential to keeping a home network secure. Users should always enable this feature in order to prevent their hosts from being directly accessible to the public Internet, where direct scans and attacks are prevalent.

5.2.1.2 Personal Computers. Each of the two PCs needs circuitry to communicate over the network. Traditionally, this circuitry came in the form of a printed circuit board, so the circuitry was called the computer's *network interface card* (NIC). In most computers today, the circuitry is built into the computer; there is no separate printed circuit board. However, the circuitry is still called the computer's NIC.

In this small network, the two computers share their files. Given the wireless access capability of the network, drive-by hackers could potentially read shared files as well. File sharing without strong wireless security is dangerous. It is important to set up *Wi-Fi Protected Access* (WPA or WPA2) or 802.11i security in pre-shared key (PSK) mode on both the access router/access point and each of the client PCs.

It is important to configure the PCs for security. Although NAT by itself is strong, and most routers also provide stateful-inspection firewalls (see Chapter 26 in this *Handbook*), some attacks will inevitably get through to the internal network. Hosts must have strong firewalls, antivirus programs, and antispyware programs (see Chapter 41); and they must be updated automatically when security patches are released by the operating system vendor and by application program vendors (see Chapter 40).

5.2.1.3 UTP Wiring. In Exhibit 5.1, Host B connects to the access router via copper wiring called a UTP cable, Ethernet (IEEE 802.3) cable, or commonly Cat5 (Cat5 stands for Category 5 cabling, defined in standard ANSI/TIA/EIA-568-A). It uses four-pair *unshielded twisted pair* (UTP) wiring inside the cord jacket. As Exhibit 5.2 shows, a UTP cord contains eight copper wires organized as four pairs. The two wires of each pair are twisted around each other. The *RJ-45* connectors at the ends of a UTP cord look like RJ-11 home telephone connectors but are a little wider. (*RJ* means

5 · 4 DATA COMMUNICATIONS AND INFORMATION SECURITY

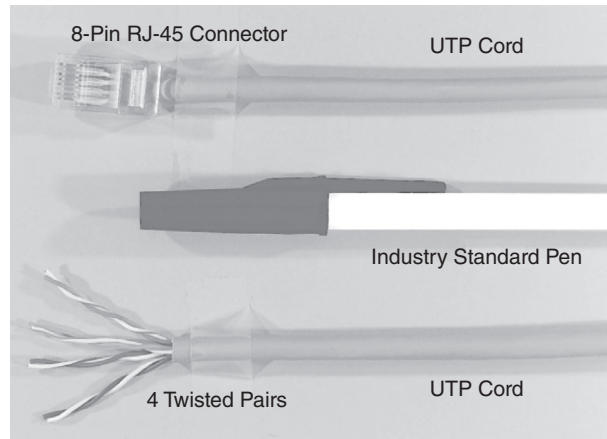

EXHIBIT 5.2 Unshielded Twisted Pair (UTP) Wiring Cord

Registered Jack and originally referred to Bell System order codes; it is now defined by the Administrative Council for Terminal Attachment, ACTA.)

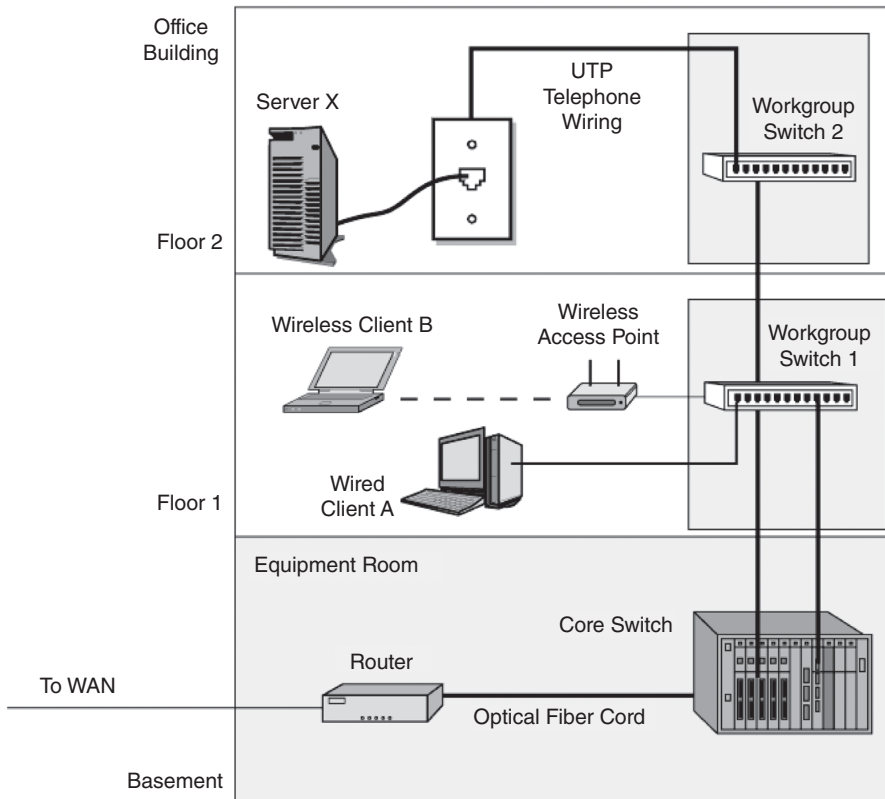

5.2.1.4 Internet Access Line. The home network needs an Internet access line to connect the home to the Internet. In Exhibit 5.1, this access line is a *digital subscriber line* (DSL) high-speed access line, and the home connects to this access line via a small box called a *DSL modem*. (The DSL modem connects to the access router via a UTP cord; it connects to the wall jack via an ordinary telephone cord.) Other Internet access technologies include slow telephone modems, fast cable modems, geosynchronous-satellite connections, and even wireless access systems. Most of these technologies are called *broadband access lines*. In general, *broadband* simply means *very fast*, although in radio transmission it describes a wide range of frequencies.

5.2.2 Building LAN. The home network shown in Exhibit 5.1 is a *local area network* (LAN). A LAN operates on a customer's premises—the property owned by the LAN user. (For historical reasons, *premises* is always spelled in the plural.) In the case of the home network, the premises consist of the user's home or apartment. Exhibit 5.3 shows a much larger LAN. Here, the premises consist of a corporate multistory office building.

On each floor, computers connect to the floor's workgroup switch via a UTP cord or a wireless access point. The workgroup switch on each floor connects to a *core switch* in the basement equipment room. The router in the basement connects the building LAN to the outside world.

Suppose that Client A on Floor 1 sends a packet to Server X on Floor 2. Client A sends the packet to Workgroup Switch 1 on the first floor. That workgroup switch sends the packet down to the core switch in the basement. The core switch then sends the packet up to Workgroup Switch 2, which passes the packet to Server X.

UTP is easy to wiretap, allowing attackers to read all packets flowing through the cord. Telecommunications closets should be kept locked at all times, and cords should be run through thick metal wiring conduits wherever possible (for more details of physical and facilities security, see Chapters 22 and 23 in this *Handbook*). UTP also generates weak radio signals when traffic flows through it. It is possible to read these signals from some distance away using highly specialized equipment. Newer

**EXHIBIT 5.3** Building LAN

specifications called Cat5e and Cat6 were developed to cut down on interference and cables can be purchased with shielding, but even then it is possible to eavesdrop.

Eavesdropping by tapping a UTP cable is not difficult once physical access is gained; however, typically there are far easier ways of gaining access to a network and far more desirable targets. Eavesdropping on a wire would reveal any passing traffic, but eavesdropping on a router or switch would reveal passing traffic on *many* wires. Physical security is an important facet of network security and must be properly addressed, but most attacks today rely on more virtual vulnerabilities.

For more extensive details of LAN security, see Chapter 25 in this *Handbook*.

5.2.3 Firms' Wide Area Networks (WANs). Although LANs operate within a company's premises, *wide area networks* (WANs) connect geographically separate sites—usually within a single corporation. Corporations do not have the regulatory rights-of-way needed to run wires through public areas. For WAN service, companies must use companies called *carriers* that do have these rights-of-way.

Exhibit 5.4 shows that most firms use multiple-carrier WANs. In the exhibit, some sites in this company are connected by point-to-point *leased lines* from a telephone company. The companies also subscribe to *switched network services* that transfer traffic between several sites. The exhibit shows that these switched network services use the *Frame Relay* technology. The company uses two separate Frame Relay networks—one to connect its own sites to one another and another to connect it to another firm.

5 · 6 DATA COMMUNICATIONS AND INFORMATION SECURITY

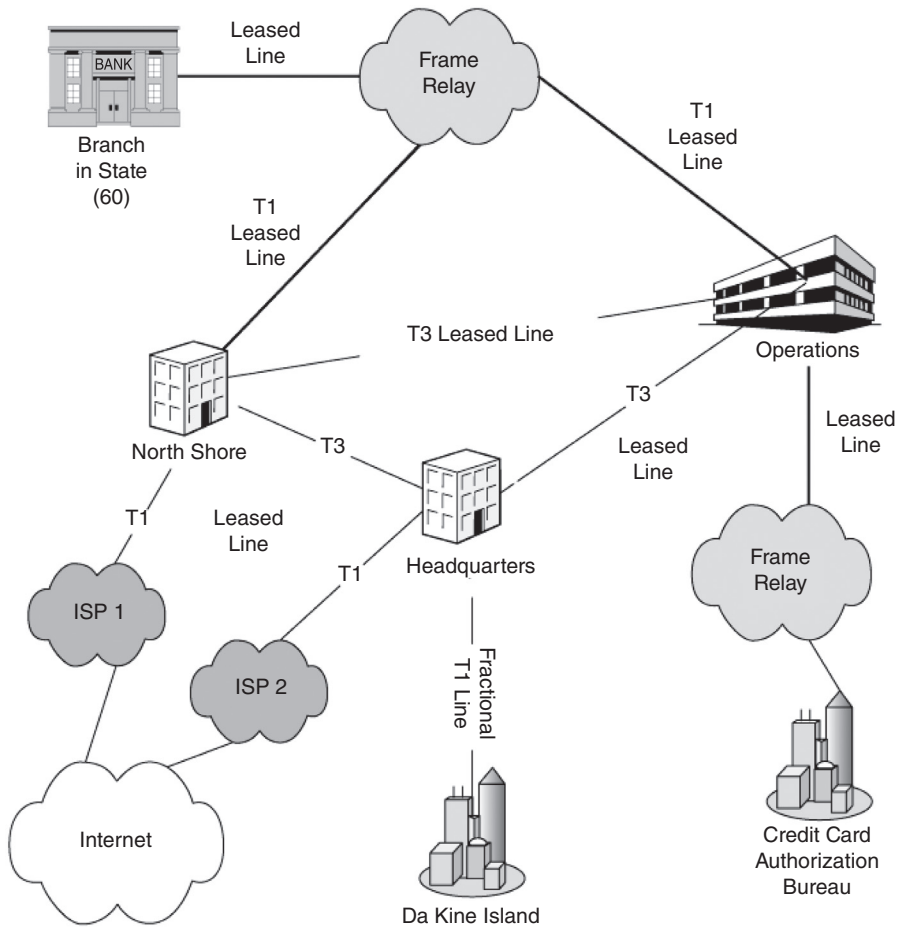

EXHIBIT 5.4 Wide Area Networks (WANs)

Carrier technology is usually considered more secure by security professionals due to its closed-access nature. Unlike the Internet, which allows anyone to connect to it, only commercial firms may connect to carrier WANs, which makes attacker access very difficult. However, attacker access is not impossible. For example, if an attacker hacks a computer owned by the carrier (or even by a customer), this breach may permit access.

In addition, the carrier alone knows how it routes traffic through its network. This should stymie attackers even if they somehow get access to the network. However, such *security through obscurity* is considered a poor practice by security professionals because it is possible for attackers who hack carrier computers to get access to routing information. (Attackers usually have much simpler attack vectors; see Chapters 15 and 19 in this *Handbook* for more details.)

Although carrier technology is more secure, it is also extremely expensive. With the development of virtual private networks (VPNs), companies can connect geographically disparate groups of computers *virtually* over the common internet. This provides much of the security benefit of WANs while cutting the implementation cost dramatically. See Chapter 32 for more information about VPN security.

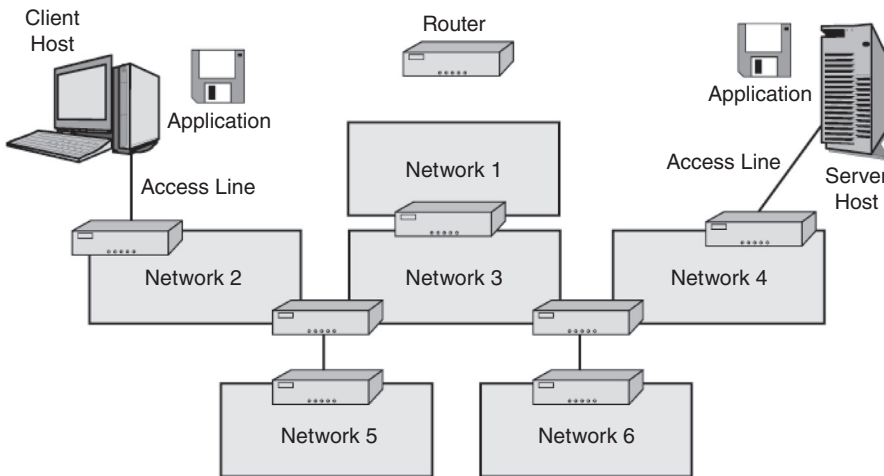

EXHIBIT 5.5 Internet

5.2.4 Internet. By the end of the 1970s, there were many LANs and WANs in the world. Many of the WANs were nonprofit networks that connected universities and research institutions. Unfortunately, computers on one network could not talk to computers on other networks. To address this problem, the Defense Advanced Research Projects Agency (DARPA) created ARPANET in 1969, the origin of today's Internet, based on the pioneering conceptual design for what J. C. R. Licklider called the *Intergalactic Computer Network* in a 1963 paper. By definition, an *internet* connects individual networks together. Later, commercial networks were allowed to join later versions of ARPANET, and it became the Internet we know today.

Exhibit 5.5 shows that devices called *routers* connect the individual networks together. Initially, these devices were called *gateways*. The term *gateway* was used instead of "router" in some early standards, but most vendors have now adopted the name "router." There are two exceptions, the first being Microsoft, which still tends to call routers "gateways." The second is the router directly accessible to a network, and thus the first hop when exiting a network is often called the *default gateway*.

Any computer on any network on the Internet can send messages to any computer on any other network on the Internet. The messages that travel all the way from one computer to another across the Internet are called *packets*.

Exhibit 5.6 shows that the packet travels all the way from the source host to the destination host. Along the way, it is routed through different networks until arriving at its destination.

The global Internet uses a suite of communication protocols known as *Transmission Control Protocol/Internet Protocol* (TCP/IP). In addition, many firms build separate internal TCP/IP networks for their own communication. These internal networks are called *intranets* to distinguish them from the *Internet*.

Initially, security on internal networks was comparatively light because it was assumed that external attackers would have a difficult time getting into corporate intranets. However, if a hacker takes over an internal computer connected to the intranet, light security becomes a serious problem. Consequently, most firms have been progressively hardening their intranet security.

Exhibit 5.7 shows that individual homes and corporations connect to the Internet via carriers called *Internet service providers* (ISPs). The Internet has many ISPs, but

5 · 8 DATA COMMUNICATIONS AND INFORMATION SECURITY

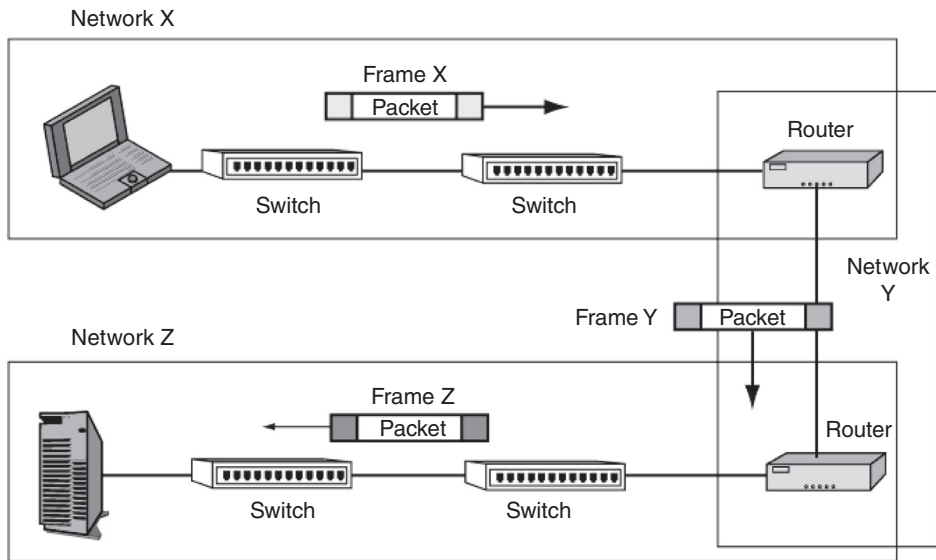

EXHIBIT 5.6 Frames and Packets

they all connect at centers that usually are called *network access points* (NAPs). These connections allow global communications for all connected hosts.

Most ISPs are commercial organizations run for profit to provide Internet access for home users. There is no central access control to the Internet; however, there are central agencies for controlling Domain Name Systems (DNSs) called *registrars*.

When the Internet was designed in the late 1970s, there was a conscious decision to promote openness and not to add the burdens of security. As a consequence of a lack of security technology and open access to almost anyone, the Internet is a security nightmare. Companies that transmit sensitive information over the Internet need to consider cryptographic protections. (See Chapters 7, 32, 33, 34, 35, and 37 in this *Handbook* for more details of cryptography and other means for achieving security on networks.)

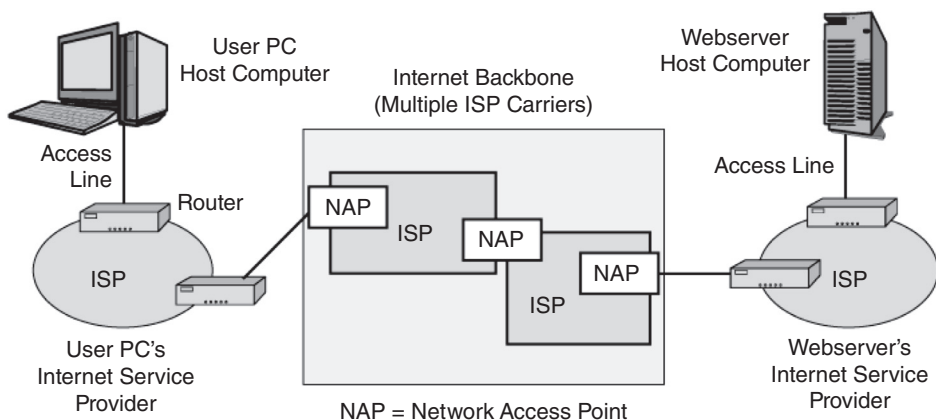

EXHIBIT 5.7 Internet Service Providers (ISPs)

5.2.5 Applications. Although the inner workings of the Internet rely on networks, most users are only aware of the applications they commonly use that run on top of networks. Familiar personal applications include the World Wide Web, email, and instant messaging, among many others. Corporations use some of these applications, but they also use many business-specific applications, such as accounting, payroll, billing, and inventory management. Often, business applications are transaction-processing applications, which are characterized by high volumes of simple repetitive transactions. The traffic volume generated by transaction-processing and other business-oriented applications usually far outweighs the traffic of personal applications in the firm. (See Chapter 30 in this *Handbook* for details of e-commerce security.)

All programs have bugs, including security vulnerabilities. There are many applications, and keeping track of application vulnerabilities and constantly patching many applications is an enormous task that is all too easy to put off or complete only partially. (See Chapter 40 for an overview of patch management.) Also, each application must be configured with options that have high security, and security must be managed on each application (e.g., anti-virus and spam blocking in email). (See Chapter 20 for a review of spam and anti-spam measures.)

5.3 NETWORK PROTOCOLS AND VULNERABILITIES. The products of different network vendors must be able to work together (interoperate). This is possible only if there are strong communication standards to govern how hardware and software processes interact. With such standards, two or more programs can interoperate effectively.

Standards raise three security issues. One is the standard itself. For instance, the TCP standard discussed later in this chapter is difficult to attack because an attacker cannot send a false message unless he or she can guess the sequence number of the next message. This normally is very difficult to do. However, if the attacker sends an RST (reset) message, which terminates a connection, this protection is greatly reduced. In fact, it is fairly easy to send RST messages that close legitimate open connections.

A second issue is security built into the standard. Most standards were created without security, and security was added only in later versions, sometimes in an awkward way. For instance, IP, which is the main protocol for delivering packets over the Internet, originally had no security. The *IP security (IPsec, pronounced eye-pea-sek)* standards were created to address this weakness, but IPsec is burdensome and not widely used.

Another security weakness of early versions of IP, including the widely used IPv4, is the limitation on address space due to the 32 bit address field in the IPv4 packet (yielding an address space of about 4×10^9); as this edition of this *Handbook* goes to press, IPv4 address exhaustion is being addressed by the migration to IPv6, with its 128-bit addresses (an address space of about 3×10^{38}).

A further issue is the security of the implementation of standards in vendor products. Most attacks that aim at standards weaknesses attack vendor products that have security vulnerabilities unrelated to the protocols they implement.

5.4 STANDARDS. Networks and network security depend on standards. Standards have permitted global interconnectivity, unlike the early years of networking when proprietary products dominated the world of computing and interconnection was difficult or impossible.

5 · 10 DATA COMMUNICATIONS AND INFORMATION SECURITY

EXHIBIT 5.8 Three Standards Core Layers

Super Layer	Description
Application	Communication between application programs on different hosts attached to different networks on a network.
Internetworking	Transmission of packets across a routed internet. Packets contain application-layer messages.
Single network	Transmission of packets across a single-switched network.

5.4.1 Core Layers. Standards are complex, and when people deal with complex problems, they usually break these problems into smaller parts and have different specialists work on the different parts. Exhibit 5.8 shows that standards are divided into three core layers that collectively have the functionality needed to allow an application program on one network in an internet to interoperate with another program on another computer on another network.

At the *application core layer*, the two applications must be able to interact effectively. For instance, in World Wide Web access, the two application programs are the browser on the client PC and the Web server program on the Web server. The standard for Web interactions is the *Hypertext Transfer Protocol* (HTTP). Both the browser and the Web server applications have to send messages that comply with the HTTP standard.

The middle layer is the *internet core layer*. Standards at this layer govern how packets are delivered across a routed internet. One of the main standards at the internet core layer is the Internet Protocol (IP). We will see other internetworking standards later.

The lowest core layer is the *single-network core layer*. Standards at this layer govern the transmission of packets across the switches and transmission lines in a single-switched network (a LAN or WAN).

5.4.2 Layered Standards Architectures. Standards are created by standards agencies. These standards agencies first create detailed layering plans for creating standards. These specific layering plans are called *layered standards architectures*. Afterward, standards agencies create standards in the individual layers. Exhibit 5.9 shows two popular layered standards architectures and relates these standards architectures to the three core layers we saw earlier.

The *Internet Engineering Task Force* (IETF) is the standards agency for the Internet. Its standards architecture is called TCP/IP—a name taken from two of its most

EXHIBIT 5.9 Layered Standards Architectures

Super Layer	TCP/IP	OSI	Hybrid TCP/IP-OSI
Application	Application	Application Presentation Session	Application
Internet	Transport Internet	Transport Network	Transport Internet
Network	Subnet access	Data link Physical	Data link Physical

important standards, TCP and IP. Exhibit 5.9 shows that TCP/IP has four layers. The bottom layer, the *subnet access layer*, corresponds to the single-network core layer. The top layer, in turn, is the *application layer*, which corresponds to the application core layer. The two middle layers—the *internet* and *transport* layers—correspond to the internet core layer. TCP/IP focuses primarily on internet working. Dividing this core layer into two TCP/IP layers permits greater division of labor in standards development.

The other standards architecture shown in the figure is *OSI*, which is rarely spelled out by its full name, the *Reference Model of Open Systems Interconnection*. OSI is governed by two standards agencies. One is ISO, the *International Organization for Standardization*. The other is ITU-T, the *International Telecommunications Union—Telecommunications Standards Sector*. (The official names and the official acronyms do not match because they originated in different languages.)

Exhibit 5.9 shows that OSI divides the three core layers into a total of seven layers. OSI single networks use standards at two layers—the *physical* and *data link* layers. OSI's market dominance is so strong at the physical and data link layers that the IETF rarely develops standards at these layers. The *subnet access* indication in the TCP/IP framework basically means *Use OSI standards here*.

Neither of these two standards architectures dominates. What nearly all firms use today is the hybrid TCP/IP–OSI standards architecture, which Exhibit 5.9 illustrates. This hybrid architecture uses OSI standards at the physical and data link layer and TCP/IP standards at the internet and transport layer. Corporations also use standards from some other standards architectures at the internet and transport layers, but TCP/IP standards dominate.

At the application core layer, the situation is complex. Both OSI and TCP/IP standards are used, often in combination. In fact, OSI standards often reference TCP/IP standards and vice versa. Although OSI and TCP/IP are often viewed as rivals, this is not the case at all. Several other standards agencies also create application layer standards, complicating the picture even further.

5.4.3 Single-Network Standards. As just noted, OSI standards dominate in the two single-network layers—the physical and data link layers. Exhibit 5.10 shows how the physical and data link layers are related.

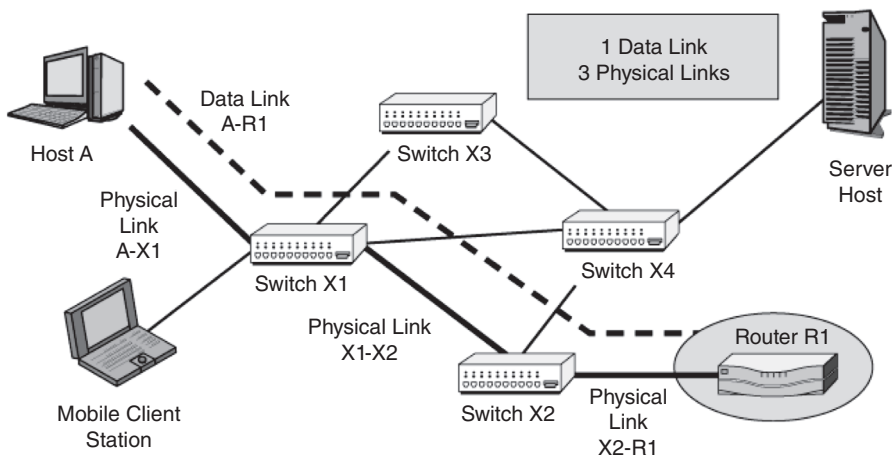

EXHIBIT 5.10 Physical and Data Link Layers

5 · 12 DATA COMMUNICATIONS AND INFORMATION SECURITY

5.4.3.1 Data Link Layer. The path that a frame takes through a single network is called the frame's data link. In Exhibit 5.10, the data link runs between Host A and Router R1. This data link passes through Switch X1 and Switch X2.

The source computer sends the frame to the first switch, which forwards the frame to the next switch along the data link, which forwards the frame further. The last switch along the data link passes the frame to the destination computer (or router, if the packet in the frame is destined for a computer on another network).

5.4.3.2 Physical Layer. Physical-layer standards govern the physical connections between consecutive devices along a data link. In Exhibit 5.10, these physical links are A–X1, X1–X2, and X2–R1. Earlier, we saw one popular transmission medium, unshielded twisted pair wire in Cat5 cables. UTP dominates in links between computers and workgroup switches (see Exhibit 5.3). UTP signals typically involve voltage changes. For instance, a high voltage may indicate a 1, while a low voltage may indicate a 0. (Actual voltage patterns usually are much more complex.)

For longer distances and very high speeds, another popular transmission medium is optical fiber, which sends light signals through thin glass tubes. Optical fiber signals actually are very simple. In a clock cycle, the light is turned on for a 1 or off for a 0.

UTP cords act like radio antennas when they carry signals. Some of the signal always radiates out, allowing people to intercept transmission signals by placing devices near (but not touching) the cord. Intercepting and interpreting electromagnetic emissions from computing devices is called van Eck phreaking (also famously codenamed “TEMPEST” by the NSA) after the Dutch scientist Wim van Eck published a paper in 1985 demonstrating how to monitor and reconstitute leaked signals from *cathode-ray terminals* (CRTs). In contrast, optical fiber requires physically tapping into the fiber cords. Physical wiretapping can also be done with UTP, but there are often far easier methods to intercept or steal traffic rather than trying to physically tap the wires.

Wireless transmission uses radio waves. This permits mobile devices to be served in ways never before possible. Wireless transmission is used for both LAN and WAN transmission.

Radio signals spread widely, even when dish antennas are used. Consequently, it is very easy for eavesdroppers to listen in on radio transmissions and do other mischief. Radio signals must be strongly encrypted, and the parties must be strongly authenticated to prevent impostors from sending radio transmission.

Radio signaling is very complex. Most radio signaling uses spread spectrum transmission, in which the information is sent over a wide range of frequencies. *Spread spectrum* transmission is used to improve propagation reliability. Radio transmission has many propagation problems, such as interference from other sources. Many propagation problems occur only at certain frequencies. By spreading the signal across a wide spectrum of frequencies and doing so redundantly, the signal will still be intelligible even if there are strong problems at some frequencies.

Prabakar Prabakaran summarized the benefits of spread-spectrum communications as follows:

Spread-spectrum systems provide some clear advantages to designers ... [H]ere are nine benefits that designers can expect when using a spread-spectrum-based wireless system.

1. Reduced crosstalk interference: In spread-spectrum systems, crosstalk interference is greatly attenuated due to the processing gain of the spread spectrum system as described earlier ...
2. Better voice quality/data integrity and less static noise ...

3. Lowered susceptibility to multipath fading ...
4. Inherent security: In a spread spectrum system, a PN [pseudo-random number] sequence is used to either modulate the signal in the time domain (direct sequence systems) or select the carrier frequency (frequency hopping systems). Due to the pseudo-random nature of the PN sequence, the signal in the air has been “randomized.” Only the receiver having the exact same pseudo-random sequence and synchronous timing can de-spread and retrieve the original signal. Consequently, a spread spectrum system provides signal security that is not available to conventional analog wireless systems.
5. Co-existence: A spread spectrum system is less susceptible to interference than other non-spread spectrum systems. In addition, with the proper designing of pseudo-random sequences, multiple spread spectrum systems can co-exist without creating severe interference to other systems. This further increases the system capacity for spread spectrum systems or devices.
6. Longer operating distances ...
7. Hard to detect: Spread-spectrum signals are much wider than conventional narrowband transmission (of the order of 20 to 254 times the bandwidth of narrowband transmissions). Since the communication band is spread, it can be transmitted at a low power without being detrimentally by background noise ...
8. Hard to intercept or demodulate: The very foundation of the spreading technique is the code used to spread the signal ...
9. Harder to jam: The most important feature of spread spectrum is its ability to reject interference ...¹

The military uses frequency-hopping spread-spectrum (FHSS) transmission for security. Military spread-spectrum transmission works in such a way that makes intercepting transmissions very difficult. Civilian spread-spectrum transmission, in contrast, is designed to make connecting simple and therefore offers relatively little security.

Switches spend almost all of their time forwarding frames. However, switches spend some of their time exchanging supervisory information packets with one another to keep the network running efficiently. For example, in *Ethernet* (IEEE 802.3), which dominates LAN standards, if there are loops among the switches, the network will malfunction. If a switch detects a loop, it sends supervisory packets to other switches. The switches in the network then communicate until they determine the most appropriate path and disable other ports to prevent the internal looping. This process is governed by the *Spanning Tree Protocol* (STP, part of IEEE 802.1) or the newer *Rapid Spanning Tree Protocol* (RSTP, defined in IEEE 802.1 w and now part of IEEE 802.1D-2004).

Attackers can create denial-of-service (DOS) attacks on the switches in a network by impersonating a switch and sending a flood of false messages to the network’s real switches indicating the presence of a loop. The switches may spend so much of their time reorganizing the network that they will be unable to serve legitimate traffic. They also can attack several other supervisory protocols to make switches unavailable for processing normal packets. The 802.1AE standard is designed to limit switch-to-switch communication to authenticated switches.

5.4.4 Internetworking Standards. As noted earlier, the IETF divided the internetworking core layer into two layers—the internet and transport layers. Exhibit 5.11 shows how the two layers are related.

The internet layer forwards packets, hop by hop, among routers until the packet reaches the destination host. The main standard at the internet layer is the Internet Protocol (IP).

5 · 14 DATA COMMUNICATIONS AND INFORMATION SECURITY

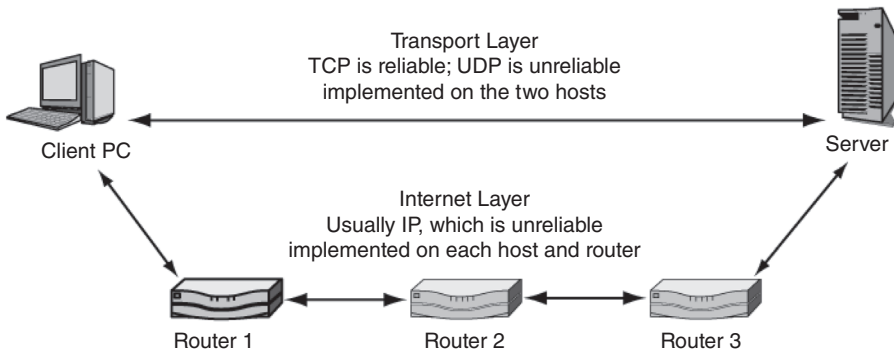

EXHIBIT 5.11 Internet- and Transport-Layer Standards

The designers of TCP/IP realized that they could not predict what services the single networks connecting routers would provide. IP was made a simple best-effort protocol, in order to assume minimal functionality in the single networks along the way. There are no guarantees that packets will arrive at all or, if they do arrive, that they will arrive in order.

To make up for the limitations of IP, a transport layer was added. The main standard designed for this layer, the *Transmission Control Protocol* (TCP), was created as a high-capability protocol that would fix any errors made along the way, ensure that packets arrived in order, slow transmission when the network became overloaded, and do several other things. For applications that did not need this level of reliability, a simpler standard was created, the *User Datagram Protocol* (UDP).

5.5 INTERNET PROTOCOL (IP). The Internet Protocol (IP) does two main things. First, it governs how packets are organized. Second, it determines how routers along the way move packets to the destination host. (Analogously, data-link-layer standards govern how frames containing packets are organized and how switches along the way move the frame across a single-switched network.)

5.5.1 IP Version 4 Packet. The main version of the Internet Protocol is Version 4 (IPv4). (There were no Versions 0, 1, 2, or 3.) This version has been in use since its definition in 1981 and will continue to be used for many years to come, although IPv6 is intended to supersede it. Exhibit 5.12 shows the IPv4 packet's organization.

A packet is a long stream of 1s and 0s. The IP *header* normally is shown on several rows, with 32 bits on each row. The first row has bits 0 through 31; the next row shows bits 32 through 63 and so on.

The header is divided into smaller units called *fields*. Fields are defined by their bit position in the packet. For example, the first four bits comprise the *version number* field. These are bits 0 through 3. In IPv4, this field holds 0100, which is 4 in binary. The *header length* field comprises the next four bits (bits 3 through 7).

5.5.1.1 First Row. As just noted, the first field (bits 0 through 3) is the version number field. In IPv4, the value is 0100 (4). In the newer version of the Internet Protocol, *IP Version 6* (IPv6), the value is 0110.

The next field is the header length field. This gives the length of the headers in 32-bit units. As Exhibit 5.12 shows, a header without options has five 32-bit lines, so this field will have the value 0101 (5 in binary).

Bit 0			Bit 31	
Version (4 bits) Value is 4 (0100)	Header Length (4 bits)	Diff-Serv (8 bits)	Total Length (16 bits) length in octets

Source IP Address (32 bits)				
Destination IP Address (32 bits)				
Options (if any)				Padding
Data Field				

EXHIBIT 5.12 Internet Protocol (IP) Packet

The use of options is uncommon in practice. In fact, options tend to indicate attacks. Therefore, a value larger than 5 in the header length field indicates that the packet header has options and is therefore suspicious.

The 1-octet *dif-serv* (differential services) field was created to allow different services (priority, etc.) to be given to this packet. However, this field typically is not used.

The *total length* field gives the length of the entire IP packet in octets (bytes). Given the 16-bit length of this field, the maximum number of octets in the IP packet is 65,536 (216). Most IP packets, however, are far smaller. The length of the data field is this total length minus the length of the header in octets.

5.5.1.2 Second Row. If an IP packet is too long for a single network along the way, the router sending the packet into that network will fragment the packet, dividing its contents into a number of smaller packets. For assembly on the destination host, all fragment packets are given the same *identification field* value as in the original packet. The data octets in the original packets are numbered, and the number of the first data octet in the packet is given a *fragment offset* value (13 bits long). There are three *flag* fields (1-bit fields). One of these, *more fragments*, is set to 1 in all but the last packet, in which it is made 0. The information in these three fields allows the destination host to place the packets in order and know when there are no more packets to arrive.

IP fragmentation by routers is usually rare, and attackers can use fragmentation to hide attack information. Even if the first fragment packet is dropped by the firewall, other packets that do not have the signature information in the first header can get through. Therefore, IP fragmentation is suspicious.

5.5.1.3 Third Row. The third line begins with an ominous-sounding *time to live* (TTL) field, which has a value between 0 and 255. The sending host sets the initial value (64 or 128 in most operating systems). Each router along the way decreases the

5 · 16 DATA COMMUNICATIONS AND INFORMATION SECURITY

value by 1. If a router decreases the value to 0, it discards the packet. This process was created to prevent misaddressed packets from circulating endlessly around the Internet.

To identify hosts, attackers will use the Internet Control Message Protocol (ICMP) to *ping* many IP addresses (as discussed in Section 5.8.1). A reply tells the attacker that a host exists with that IP address. In addition, by guessing the initial TTL value and looking at the TTL value in the arriving packet, the attacker can guess how many router hops separate the attacker's host from the victim host. Sending many pings to different IP addresses can help the attacker map the routers in the target network. Often, administrators will turn off ICMP traffic outside of the internal networks in order to prevent anyone who isn't an authorized user from mapping active internal hosts.

The *data* field of the IP packet may contain a TCP message segment, a UDP datagram message, or something else, such as the ICMP messages we will discuss in Section 5.8.1. A value of 1 in this field indicates that the data field is an ICMP message. In turn, 6 indicates a TCP segment, and 17 indicates that the data field contains a UDP header.

The *header checksum* field contains a value placed there by the sender. This number is determined by a calculation based on the values of other fields. The receiving internet process redoes the calculation. If the two numbers are different, then there must have been an error along the way. If so, the router or destination host receiving the packet will simply discard the packet. There is no retransmission, so *IP* is not inherently reliable; however, one of the functions of *TCP* is to monitor the sequence numbers and initiate retransmission of missing packets. See Section 5.6.2.

5.5.1.4 Source and Destination IP Address. When you send a letter, the envelope has an address and a return address. The analogous addresses in IP headers are the source and destination IP addresses. Note that IP addresses are 32 bits long. For human reading, these 32 bits are divided into four 8-bit *segments*, and each segment's bits are converted into a decimal number between 0 and 255. The four segment numbers are then separated by dots. An example is *128.171.17.13*. Note that this dotted decimal notation is a memory and writing crutch for inferior biological entities (people). Computers and routers work with 32-bit IP addresses directly.

Many forms of firewall filtering are based on IP addresses. In addition, many attackers spoof their packet's source IP address (i.e., replace the real IP address with a false IP address).

5.5.2 IP Version 6. Although IP Version 4 is widely used, its 32-bit IP address size causes problems: It can address only 4,294,967,296 ($\sim 10^9$) devices. This relatively small size limits the number of possible IP addresses. In addition, when IP addresses were distributed, most addresses were assigned to the United States because the Internet was invented there. In fact, some U.S. universities received more IP addresses than China.

To address the limitations of the 32-bit IP address size, a new version of the Internet Protocol was created. This is *IP Version 6* (IPv6). (A Version 5 was defined, but it was never used.) Exhibit 5.13 shows the IPv6 packet organization.

One obvious change is that the IP addresses are much larger—128 bits. Each IP address, then, requires four 32-bit lines to write and is equivalent to $\sim 10^{38}$. This will provide IP addresses to allow almost every device to be a host on the Internet—including toasters and coffeepots. To give us a sense of the scale of this enormous number, it is enough to address every single molecule of water in a cube over 2 km on a side. Another popular description of the difference in size of the IPv4 and IPv6 address space is that if the address space of IPv4 were represented as a square roughly 4 cm on a side,

the equivalent area for IPv6 address space would cover the solar system out to Pluto’s orbit.

The version number field is 4 bits long, and its value is 6 (0110). There also is a *diff-serv* field and a *flow label* field that is 20 bits long. These fields allow the packet to be assigned to a category of packets with similar needs. All packets in this category would be assigned the same flow label and would be treated the same way by routers. However, this capability is not widely used.

There is a *hop limit* field that serves the same function as the time to live (TTL) field in IPv4. The *payload length*, in turn, gives the length of the data field in octets.

A major innovation in IPv6 is the *next header* field. There can be multiple headers following the first header shown in Exhibit 5.13. For instance, IPsec security is implemented with a security header. Although options are unusual in IPv4, IPv6 uses additional headers extensively. The next header field tells what the next header is. Each additional header has a *next header* field that identifies the next header or says that there is no next header.

5.5.3 IPsec. IP, which was created in the early 1980s, initially had no security at all. Finally, in the 1990s, the Internet Engineering Task Force developed a general way to secure IP transmission. This was IP security, which normally is just called IPsec. IPsec functions by protecting a packet or most of a packet and sending the protected packet inside another packet. IPsec is a general security solution because everything within the data field of the protected packet is securely encrypted, including the transport and application layer information. This includes the transport message and the application message contained in the transport message. Originally developed for IPv6, it was extended to IPv4 as well, becoming a completely general solution. See Chapter 32 in this *Handbook* for further discussion of IPsec.

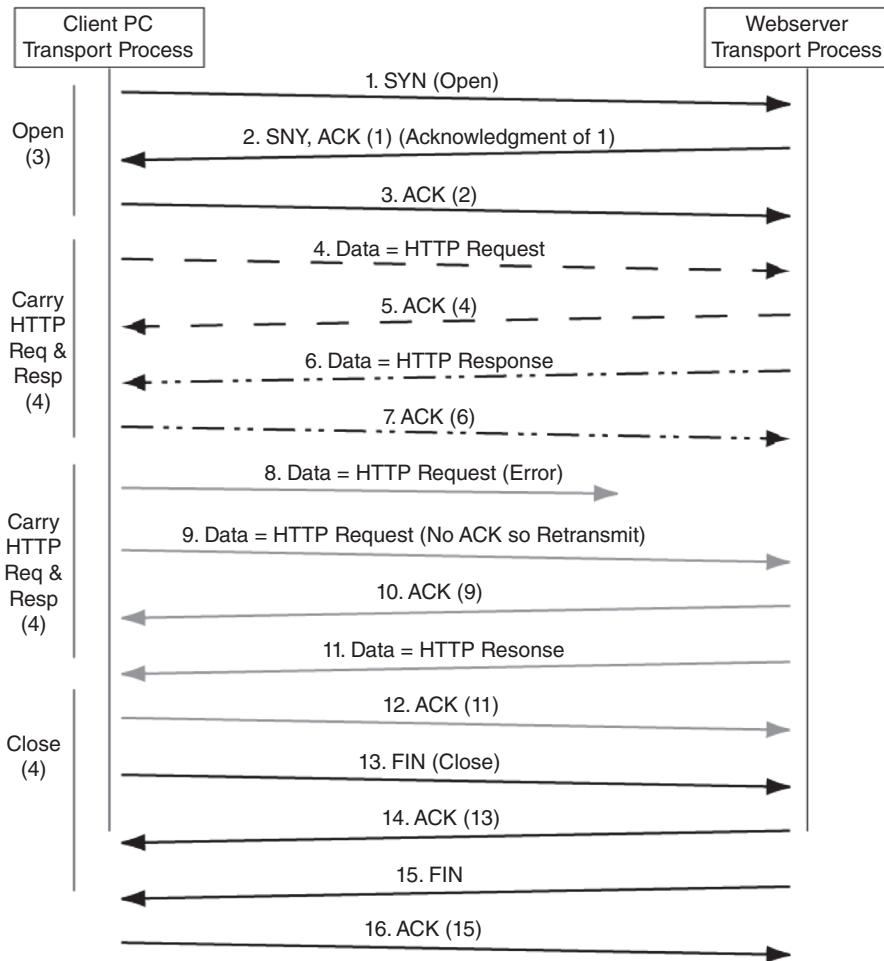

EXHIBIT 5.14 Transmission Control Protocol (TCP) Segment

5.6 TRANSMISSION CONTROL PROTOCOL (TCP). As noted earlier, the Transmission Control Protocol (TCP) is one of the two possible TCP/IP protocols at the transport layer. Exhibit 5.14 shows the TCP message, which is called a TCP *segment*.

5.6.1 Connection-Oriented and Reliable Protocol. Protocols are either connectionless or connection-oriented.

- Connection-oriented protocols are like telephone conversations. When you call someone, there is at least tacit agreement at the beginning of the conversation that you are able to speak. Explicit indicators such as “Hold, please.” and “Can I call you back?” indicate an unwillingness to proceed at the moment. Also, there is at least tacit agreement that you are done talking at the end of the conversation; simply hanging up is considered rude. “Bye” or “Talk to you later” are examples of termination signals.
- Connectionless protocols, in turn, are like email. When you send a message, there is no prior agreement, and after the message is sent, there is no built-in provision for a reply (unless you are one of those people who asks to be notified when the receiver reads the message).

Exhibit 5.15 shows a sample TCP connection. Three messages are sent to open a connection. The originator sends a TCP SYN segment to indicate that it wishes to open a TCP session. The other transport process sends back a TCP SYN/ACK segment that acknowledges the connection opening message and indicates that it is willing to open the connection. The originator then sends an ACK segment to indicate reception of the SYN/ACK segment.

Note: An ACK may be combined with the next message if the next message is sent quickly enough.

EXHIBIT 5.15 Messages in a TCP Session

Attackers can use TCP connection openings to execute denial-of-service attacks that make a server unable to respond to legitimate traffic. The attacker sends a *SYN* segment to open a connection to the victim server. The victim server responds with a *SYN/ACK* message. The victim server also sets aside resources for the connection. The attacker never responds with an *ACK*, so this is called a *half-open SYN attack*. If the attacker floods a server host with *SYN* segments, the victim server will reserve so many resources that it will be overloaded and unable to serve legitimate connection opening attempts. The server may even crash. See Chapter 18 for discussion of denial-of-service attacks.

Ending a conversation, in contrast, normally takes four messages. One side sends a *FIN* segment, which the other party acknowledges. Then the other party sends a *FIN* segment, which the other side acknowledges. After the first side sends the original *FIN* segment, it will not send any new information, but it will send acknowledgments for segments sent by the other party.

There is another way to end a session or even to reject opening one. At any point, either party can send a *RST* (reset) message. An *RST* message ends the conversation abruptly. There is not even an acknowledgment. It is like hanging up in a telephone conversation.

Attackers often preface an attack by attempting to identify the IP addresses of running hosts—much like thieves casing a neighborhood. One way to do this is to send TCP SYN segments to hosts. If hosts reject the SYN segment, they often send back an *RST* message. As noted earlier, TCP segments are carried in the data fields of IP packets. The source IP address in the packet delivering the TCP *RST* segment will be that of the internal host. Whenever the attacker receives an *RST* segment, this verifies the existence of a working host at that packet's IP address. Firewalls often stop *RST* segments from leaving a site to prevent them from reaching the attacker.

5.6.2 Reliability. In addition to being connectionless or connection-oriented, protocols are either *reliable* or *unreliable*. An unreliable protocol does not detect and correct errors. Some unreliable protocols do not even check for errors. Others check for errors but simply discard a message if they find that it contains an error.

TCP is a reliable protocol. It actually corrects errors. The TCP *checksum* field is calculated using values from other fields. The sender places the result of its calculation in the checksum field. The receiver redoes the calculation and compares it with the transmitted value. If the receiving transport layer process finds that a message is correct (the values are the same), it sends an acknowledgment message. However, if the receiver detects an error in the TCP segment it receives (the values are different), it discards the segment and does nothing else.

How does a receiver know that there is an error in the message? The sender computes a value based on the other bits in the TCP segment (not just the header). The receiver redoes the calculation. If the two values match, the receiver sends an acknowledgment. If they do not match, the receiver merely drops the segment and does not send an acknowledgment.

If the segment arrives correctly, the original sender receives an acknowledgment. However, if the segment never arrives or is discarded because of damage, no reply is sent. If the original sender does not receive an acknowledgment in a specified period of time, it will resend the original segment. It will even use the original sequence number.

5.6.3 Flag Fields. *Flag* field is a general name for a 1-bit field that is logical (true or false). To say that a flag field is *set* means that its value is 1. To say that a flag field is *not set* means that its value is 0.

The TCP header contains a number of flag fields. One of these is *SYN*. To request a connection opening, the sender sets the SYN bit. The other sends a *SYN/ACK* segment, in which both the SYN and ACK bits are set. Other commonly used flags are *FIN*, *RST*, *URG*, and *PSH*.

The URG flag indicates the presence of urgent data that should be handled before earlier data octets. The urgent pointer field indicates the location of the urgent data.

If an application message is large, TCP will divide the application message into multiple TCP segments and send the segments individually. To help the receiving TCP process, the sending transport process may set the PSH (*push*) bit in the application message's last segment. This tells the receiving transport process to push the data up to the application program immediately without buffering and delays.

5.6.4 Octets and Sequence Number. The *sequence number* field value allows the receiver to put arriving TCP segments in order even if the packets carrying them arrive out of order (including when a segment is retransmitted). Sequence numbers are also used in acknowledgments, albeit indirectly. In TCP transmission, every octet that is sent, from the very first, is counted. This octet counting is used to select each segment's sequence number.

- For the first segment, a random initial sequence number (*ISN*) is placed in the sequence number field.
- If the segment contains data, the number of the first octet contained in the data field is used as the segment's sequence number.
- For a purely supervisory message that carries no data, such as an ACK, SYN, SYN/ACK, FIN, or RST segment, the sequence number is increased by 1 over the previous message.

One dangerous attack is *TCP session hijacking*, in which an attacker takes over the role of one side. This allows the hijacker to read messages and send false messages to the other side. To accomplish session hijacking, the attacker must be able to predict sequence numbers because if a segment arrives with an inappropriate sequence number, the receiver will reject it. TCP session hijacking is likely to be successful only if the initial sequence number is predictable. Few operating systems today pick initial sequence numbers in a predictable way, but predictable sequence numbers were common in earlier operating systems, some of which are still in use.

5.6.5 Acknowledgment Numbers. When a receiver sends an acknowledgment, it sets the ACK bit. It also puts a value in the *acknowledgment number* field to indicate which segment is being acknowledged. This process is needed because the sender sends many segments and because acknowledgments may be delayed.

You might think that the acknowledgment number would be the sequence number of the segment being acknowledged. Instead, it is the number of the last octet in the data field plus 1. In other words, the acknowledgment number gives the octet number of the first octet in the next segment to be sent. This seems a bit odd, but it makes certain calculations easier for the receiver.

5.6.6 Window Field. Flow control limits the rate at which a side sends TCP segments. The TCP *window* field allows one to limit how many more octets the other side may send before getting another acknowledgment. The process is somewhat complex and has no known security implications at the time of this writing (June 2013). In acknowledgments, the ACK bit is set, and both the acknowledgment and window size fields are filled in.

5.6.7 Options. Like the IPv4 header, the TCP header can have options. However, while IP options are rare and cause for suspicion, TCP uses options extensively. One common option, often sent with the initial SYN or SYN/ACK segment, is the *maximum segment size* (MSS) option. This gives the other side a limit on the maximum size of TCP segment data fields (not on segment sizes as a whole). The presence of TCP options, then, is not suspicious by itself.

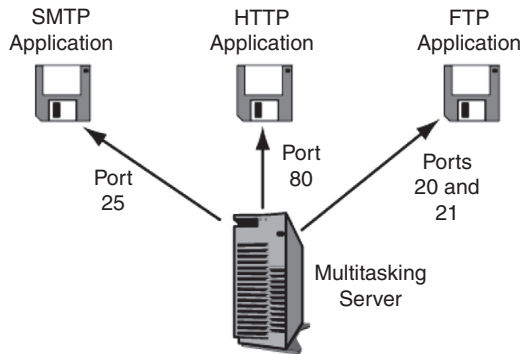

EXHIBIT 5.16 Multitasking Server Host and Port Numbers

5.6.8 Port Numbers. We have now looked at most fields in the TCP header. The first two fields warrant special mention.

5.6.8.1 Port Numbers on Servers. *Port number* fields mean different things for clients and servers. For a server, it represents a specific application running on that server, as Exhibit 5.16 shows. Servers are multitasking computers, which means that they can run multiple applications at the same time. Each application is specified by a different port number.

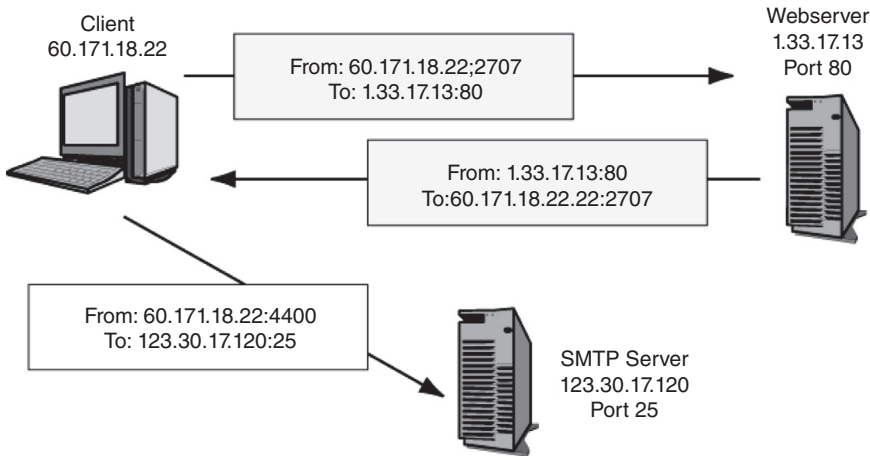

For instance, on a server, a Web server application program may run on TCP Port 80. Incoming TCP segments that have 80 as their destination port number are passed to the Web server application. Actually, TCP Port 80 is the well-known port for Web server programs, meaning that it is the usual port number for the application. Although Web servers can be given other TCP port numbers, this makes it impossible for users to establish connections unless they know or can guess the nonstandard TCP port number.

The TCP port range from 0 to 1023 is reserved for the well-known port numbers of major applications, such as HTTP and email. For instance, *Simple Mail Transfer Protocol* (SMTP) mail server programs usually are run on TCP Port 25, while *File Transfer Protocol* (FTP) requires two well-known port numbers—TCP Port 21 for supervisory control and TCP Port 20 for the actual transfer of files.

5.6.8.2 Port Numbers on Clients. Client hosts use TCP port numbers differently. Whenever a client connects to an application program on a server, it generates a random *ephemeral port number* that it uses only for that connection. On Windows machines, the ephemeral TCP port numbers range from 1024 to 4999.

The Microsoft port number range for ephemeral port numbers may differ from the official IETF range, with values of 5000–65534. The use of nonstandard ephemeral port numbers by Windows and some other operating systems causes problems for firewall filtering.

5.6.8.3 Sockets. Exhibit 5.17 shows that the goal of internetworking is to deliver application messages from one application on one machine to another application on another machine. On each machine, there is a TCP port number that specifies the application (or connection) and an IP address to specify a computer. A *socket* is a combination of an IP address and a TCP port number. It is written as the IP address,

**EXHIBIT 5.17** Sockets

a colon, and the TCP port number. A typical socket, then, would be something like *128.171.17.13:80*.

Attackers often do *socket spoofing*—both IP address spoofing and port spoofing. For instance, in TCP session hijacking, if the attacker wishes to take over the identity of a client, it must know both the client's IP address and ephemeral port number. Of course, these fields are transmitted in the clear (without encryption) in TCP, so an attacker with a sniffer that captures and reads traffic flowing between the client and server can easily obtain this information.

5.6.9 TCP Security. Like IP, TCP was created without security. However, although IPsec has made IP secure, the IETF has not created a comparable way to secure TCP. One reason for this is IPsec's ability to secure all transport layer traffic transparently, without modification to transport layer protocols. The IETF has made IPsec the centerpiece of its security protections and a single method to handle upper-layer security. Communicating partners that want TCP security should implement IPsec.

However, few TCP sessions are protected by IPsec. Consequently, some pairs of users employ an option in TCP, which adds an electronic signature to each TCP session. This signature proves the identity of the sender. This option, described in RFC 2385, requires the two parties to share a secret value. This option is awkward because it provides no way to share keys automatically, and it does not provide encryption or other protections. The option is used primarily in the Border Gateway Protocol (BGP). BGP is used to exchange routing information between administrative systems—say a corporate system and an internet service provider. BGP always uses one-to-one connections, the communicating parties usually know each other quite well, and the two parties have long-term relationships, which makes key exchange less burdensome and risky. Outside of BGP, however, the RFC 2385 electronic signature option does not appear to be used significantly. Even in BGP, it is widely seen as very weak security.

5.7 USER DATAGRAM PROTOCOL. As noted earlier, TCP is a protocol that makes up for the limitations of IP. TCP adds error correction, the sequencing of IP packets, flow control, and other functionality that we have not discussed.

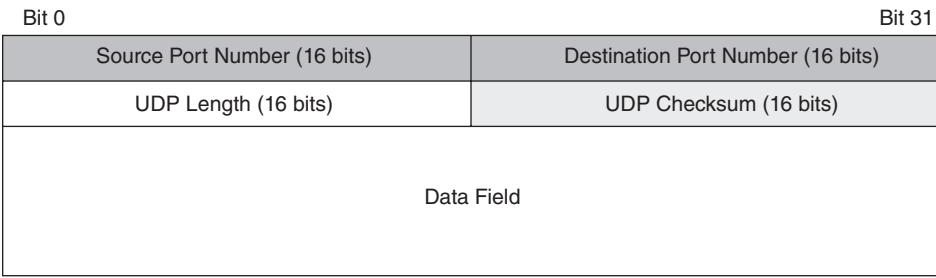

EXHIBIT 5.18 User Datagram Protocol (UDP)

Not all applications need the reliable service offered by TCP. For instance, in voice over IP (VOIP), there is no time to wait for the retransmission of lost or damaged packets carrying voice. In turn, the *Simple Network Management Protocol* (SNMP), which is used for network management communications, sends so many messages back and forth that the added traffic of connection-opening packets, acknowledgments, and other TCP supervisory segments could overload the network. Consequently, voice over IP, SNMP, and many other applications do not use TCP at the transport layer.

Instead, they use the *User Datagram Protocol* (UDP). This protocol is connectionless and unreliable. Each UDP message (called a UDP *datagram*) is sent on its own. There are no openings, closings, or acknowledgments.

As a consequence of the simplicity of UDP’s operation, the UDP datagram’s organization is also very simple, as Exhibit 5.18 illustrates. There are no sequence numbers, acknowledgment numbers, flag fields, or most of the other fields found in TCP.

There are source and destination port numbers, a UDP header length to allow variable-length UDP datagrams, and a UDP checksum. If the receiver detects an error using the checksum, it simply discards the message. There is no retransmission.

The fact that both TCP and UDP use port numbers means that whenever you refer to port numbers for well-known applications, you also need to refer to whether the port numbers are TCP or UDP port numbers. This is why the well-known port number for Web servers is TCP port 80.

TCP’s sequence numbers make TCP session hijacking very difficult. The receiver will discard messages with the wrong sequence numbers even if the source and destination sockets are correct. UDP lacks this protection, making UDP a somewhat more dangerous protocol than TCP.

Like TCP, UDP has no inherent security. Companies that wish to secure their UDP communication must use IPsec.

5.8 TCP/IP SUPERVISORY STANDARDS. So far, we have looked at standards that deliver a stream of packets across an internet and that perhaps check for errors and provide other assurances. However, the TCP/IP architecture also includes a number of supervisory protocols that keep the Internet functioning.

5.8.1 Internet Control Message Protocol (ICMP). The first supervisory protocol on the Internet was the Internet Control Message Protocol (ICMP). As Exhibit 5.19 shows, ICMP messages are delivered in the data fields of IP packets.

The best-known pair of ICMP message types is the ICMP *echo* message and the *echo reply* message. Suppose that a host sends an ICMP echo message to an IP address. If a host is active at that address, it may send back an ICMP echo reply message. This

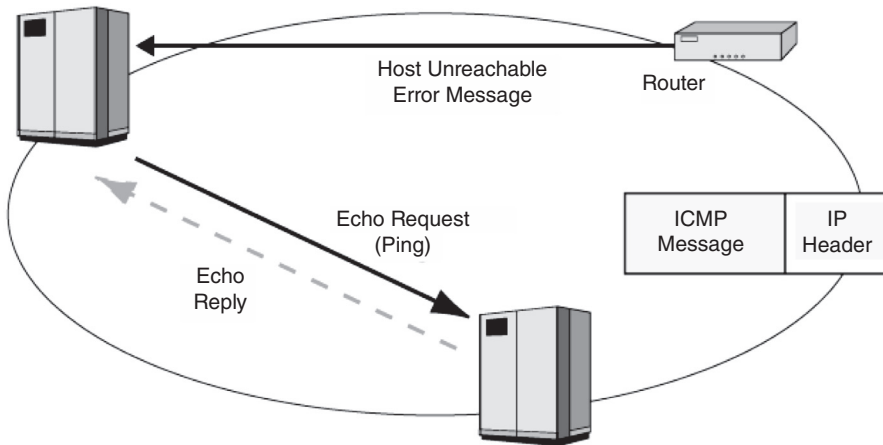

EXHIBIT 5.19 Internet Control Message Protocol (ICMP)

process is often called *pinging* because the most popular program for sending ICMP echo message is called *Ping*. The echo message is a very important tool for network management. If the network manager suspects a problem, he or she will ping a wide range of host addresses to see which of them are reachable. The pattern of responses can reveal where problems exist within a network.

Attackers also love to ping a wide range of host IP addresses. This can give them a list of hosts that are reachable for attacks. Another popular network management and attack tool is *traceroute* (or *tracert* on Windows PCs). *Traceroute* is similar to ping, but *traceroute* also lists the routers that lie between the sending host and the host that is the target of the *traceroute* command. This allows an attacker to map the network. Border firewalls often drop echo reply messages leaving the firm to the outside.

Many ICMP messages are error messages. For instance, if a router cannot deliver the packet, it may send back an ICMP error message to the source host. This error message will provide as much information as possible about the type of error that occurred.

If an attacker cannot ping destination hosts because a firewall stops them, attackers often send IP packets that are malformed and so will be rejected. The ICMP error message is delivered in an IP packet, and the source IP address in this packet will reveal the IP address of the sending router. By analyzing error messages, the attacker can learn how routers are organized in a network. This information can be very useful to attackers.

5.8.2 Domain Name System (DNS). To send a packet to another host, a source host must place the destination host's IP address in the destination address field of the packets. Often, however, the user merely types the host name of the destination host, for instance, *cnn.com*.

Unfortunately, host names are only nicknames. If the user types a host name, the computer must learn the corresponding IP address. As Exhibit 5.20 shows, the host wishing to send a packet to a target host sends a *Domain Name System* (DNS) request message to the DNS server. This message contains the host name of the target host. The DNS response message sends back the target host's IP address. To give an analogy, if you know someone's name, you must look up their telephone number in a telephone directory if you want to call them. In DNS, the human name corresponds to the

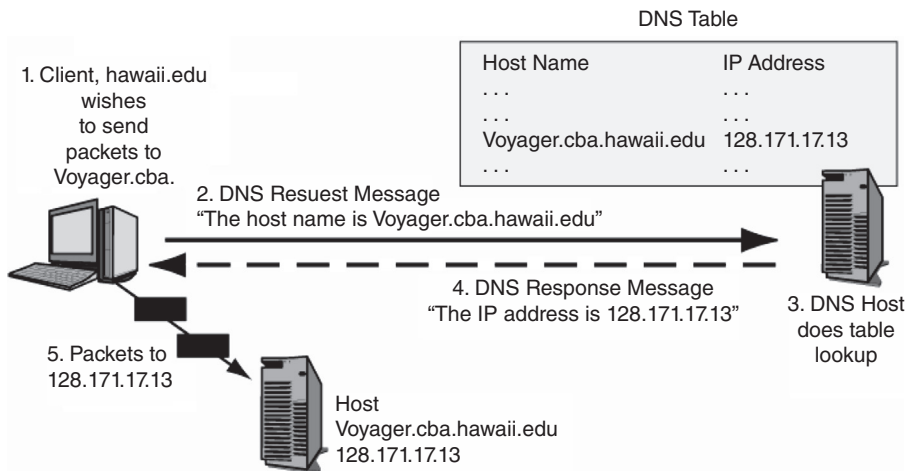

EXHIBIT 5.20 Domain Name System (DNS) Server

host name, the telephone number corresponds to the IP address, and the DNS server corresponds to the telephone directory.

DNS is critical to the Internet's operation. Unfortunately, DNS is vulnerable to several attacks. For example, in *DNS cache poisoning*, an attacker replaces the IP address of a host name with another IP address. After cache poisoning, a legitimate user who contacts a DNS server to look up the host name will be given the false IP address, sending the user to the attacker's chosen site. Denial-of-service attacks are also too easy to accomplish. RFC 3833 lists a number of DNS security issues.²

Several attempts to strengthen DNS security have been developed, under the general banner of Domain Name System Security Extensions (*DNSSEC*), especially RFC 2535.³ However, both the original DNSSEC specifications and the newer DNSSEC *bis* specifications (RFCs 4033-4035⁴) have proven to be insufficient. Developing a security standard that is sufficiently backwardly compatible for Internet-scale implementation has proven to be extremely difficult.

If the DNS server does not know the host name, it contacts another DNS server. The DNS system contains many DNS servers organized in a hierarchy. At the top of the hierarchy are 13 *DNS root servers*. Below these are DNS servers for *top-level domains*, such as *.com*, *.edu*, *.ie*, *.uk*, *.nl*, and *.ca*. Each top-level domain has two or more top-level DNS servers for their domain. Second-level domain names are given to organizations (e.g., *Hawaii.edu* and *Microsoft.com*). Organizations are required to maintain DNS servers for computers within their domain.

If attackers could bring down the 13 root servers, they could paralyze the Internet. Widespread paralysis would not occur immediately, but in a few days, the Internet would begin experiencing serious outages.

5.8.3 Dynamic Host Configuration Protocol (DHCP). Server hosts are given static (permanent) IP addresses. Client PCs, however, are given dynamic (temporary) IP addresses whenever they use the Internet. The *Dynamic Host Configuration Protocol* (DHCP) standard that we saw earlier in the chapter makes this possible. A DHCP server has a database of available IP addresses. When a client requests an IP address, the DHCP server picks one from the database and sends it to the client. The next time the client uses the Internet, the DHCP server may give it a different IP address.

The fact that clients may receive different IP addresses each time they get on the Internet causes problems for *peer-to-peer* (P2P) applications. A presence server or some other mechanism must be used to find the other party's IP address. A lack of accepted standards for presence (including presence security) is a serious issue now that P2P applications are widespread. In fact, most security considerations in P2P presence servers have been used in P2P piracy applications, with an eye toward avoiding discovery by legitimate authorities.

5.8.4 Dynamic Routing Protocols. How do routers on the Internet learn what to do with packets addressed to various IP addresses? They frequently talk to one another, exchanging information about the organization of the Internet. These exchanges must occur frequently because the structure of the Internet changes frequently as routers are added or dropped. Protocols for exchanging organization information are called *dynamic routing protocols*. There are many dynamic routing protocols, including the *Routing Information Protocol* (RIP), *Open Shortest Path First* (OSPF), the *Border Gateway Protocol* (BGP), and Cisco Systems' proprietary *Enhanced Interior Gateway Routing Protocol* (EIGRP). Each is used under different circumstances. These protocols have widely different security features, and different versions of each protocol have different levels of functionality.

An attacker who can impersonate a router can send false dynamic routing protocol messages to other routers. These false messages could cause the routers to fail to deliver their packets. The attacker could even cause packets to pass through the attacker's computer (called a *man-in-the-middle attack* or MIMA) in order to read their contents.

The protocols just listed have widely different security features, and different versions of each protocol have different levels of security functionality.

5.8.5 Simple Network Management Protocol (SNMP). Networks often have many elements—routers, switches, and host computers. Managing dozens, hundreds, or thousands of devices can be nearly impossible. To make management easier, the IETF developed the *Simple Network Management Protocol* (SNMP). As Exhibit 5.21 shows, the manager program can send SNMP messages to managed devices to determine their conditions. The manager program can even send configuration messages that can change the ways in which remote devices operate. This allows the manager to fix many problems remotely.

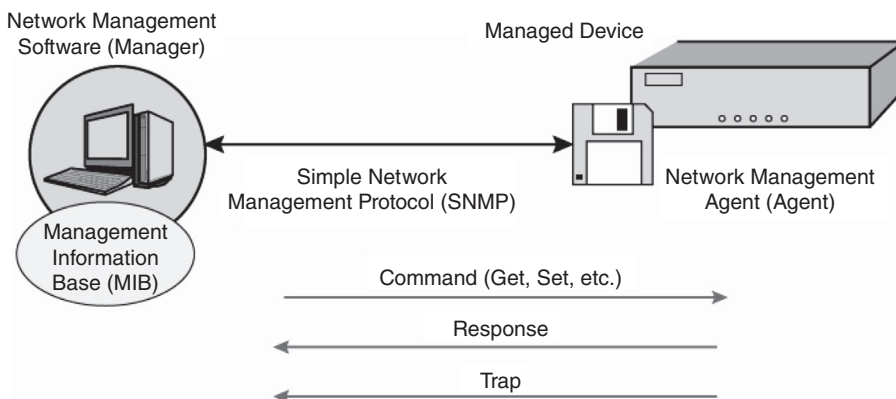

EXHIBIT 5.21 Simple Network Management Protocol (SNMP)

Many firms disable remote configuration because of the damage that attackers could do with it. They could simply turn off all ports on switches and routers, or they could do more subtle damage.

5.9 APPLICATION STANDARDS. Most applications have their own application-layer standards. In fact, given the large number of applications in the world, there are literally hundreds of application-layer standards.

As corporations get better at defending against attacks at lower layers, attackers have begun to focus their attention on application vulnerabilities. If an attacker can take over an application running with high privileges, he or she obtains these privileges. Many applications run at the highest privileges, and attackers that compromise them own the box.

5.9.1 HTTP and HTML. Many applications have two types of standards. The *transport standard* transfers application-layer messages between applications on different machines; for the World Wide Web, this is the *Hypertext Transfer Protocol* (HTTP). The other is a standard for *document structure*. The main document-structure standard for the WWW is the *Hypertext Markup Language* (HTML).

Netscape, which created the first widely used browser, also created a security standard to protect HTTP communication. This was *Secure Sockets Layer* (SSL). Later, the Internet Engineering Task Force took over SSL and changed the name of the standard to *Transport Layer Security* (TLS).

5.9.2 E-Mail. Popular transfer standards for email are the *Simple Mail Transfer Protocol* (SMTP), *Post Office Protocol* (POP), and *Internet Message Access Protocol* (IMAP) for downloading email to a client from a mailbox on a server. Popular document-body standards include RFC 2822 (for all-text messages), HTML, and Multipurpose Internet Mail Extensions (MIME). S/MIME (Secure MIME) adds public-key encryption (see Chapter 7) to MIME and is defined in RFCs 2634, 3850, and 3851.

An obvious security issue in email is content filtering. Viruses, spam, phishing messages, and other undesirable content should be filtered out before they reach users and can do damage. (For more information on spam and other low-technology attacks, see Chapter 20 in this *Handbook*; for malware and spam countermeasures see Chapters 26, 27, 31, and 41.)

Another security issue in email is securing messages flowing from the sending client to the sender's mail server, to the receiver's mail server, and to the receiving client. Fortunately, there are security standards for part or all of the message flows, including SSL/TLS and S/MIME among others. Unfortunately, the IETF has been unable to agree on a security standard.

When Web mail, which uses HTTP and HTML for email communication, is used, then SSL/TLS can work between the sender and the sender's mail server and between the receiver's mail server and the receiver. Transmission between the email servers is another issue. Of course, senders can send encrypted message bodies directly to receivers. However, this prevents filtering at firewalls. Users should be particularly careful about using Web mail via wireless connections. (See Chapters 32 and 33.)

5.9.3 Telnet, FTP, and SSH. The two earliest applications on the Internet were the *File Transfer Protocol* (FTP) and *Telnet*. FTP provides bulk file transfers between hosts. Telnet allows a user to launch a command shell (user interface) on another computer. Neither of these standards has any security. Of particular concern is that

both send passwords in the clear (without encryption) during login. The newer *Secure SHell* (SSH) standard can be used in place of both FTP and Telnet while providing high security by encrypting all transferred traffic between the hosts.

5.9.4 Other Application Standards. There are many other applications and therefore application standards. These include *Voice over IP* (VoIP; see Chapter 34 in this *Handbook*), *peer-to-peer applications* (P2P; see Chapter 35), and *service-oriented architecture* (SOA) and Web service applications (see Chapters 21, 30, and 31), among many others. Most applications have serious security issues. Application security has become perhaps the most complex aspect of network security (see Chapters 38, 39, and 40).

5.10 CONCLUDING REMARKS. It is impossible to understand information security without a strong knowledge of networking. This chapter is designed to give you a working overview of networking. It is likely to be sufficient if you run into basic networking questions while reading other chapters in this *Handbook*. However, to work in security, you will need a much stronger knowledge of networking. The books and other resources cited in Section 5.11 are a good start in that direction.

This chapter provides a broad overview of local area network (LAN) concepts, basic terms, standards, and technologies. These topics are important to give the information security professional a better understanding of the terms that might be used to describe a particular network implementation and its products. The chapter also is written with an eye to what information security professionals need to know; for a more complete

6 · 2 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

overview of the topic, the reader is referred to general LAN texts, such as those listed in Section 6.10.

6.1 OVERVIEW. There are a number of ways to describe a LAN, and each will provide a glimpse as to implementation and product differences as well as points of security exposures. This section introduces various terms and perspectives as a basis for the discussion in the following sections.¹

6.1.1 LAN Characteristics. One way of describing LANs is to describe the characteristics that distinguish a *local* network from other types of networks. The most common characteristics are:

- Small geographic scope (the two most distant stations may be up to 5 kilometers [km] or so apart)
- Fast speed (data rates well in excess of 1 million [mega] bits per second [Mbps] and up to 1 billion [giga] bits per second [Gbps])
- Special media (common use of coaxial cable and optical fiber, as well as twisted pair)
- Private ownership

This type of network, then, has a very different look and feel than the Internet or some other public or private wide-area networks (WANs). More people have access to the LAN infrastructure than to the infrastructure of just about any WAN. LAN users can easily “spy” on each other by sniffing packets, something that is generally very difficult on the Internet. A single user can bring the LAN to a standstill.

The corporate LAN is generally the users’ primary access to the Internet. The users on the LAN are behind the corporate firewall and router; some studies suggest that they are responsible for 80 percent of security incidents.

Other LANs include hotel networks, which are often used by criminals as handy sources of confidential information available on unprotected systems temporarily hooked up to these Internet-access services.

Often the success of these attacks is due to users’ lack of education and awareness, such as choosing poor passwords, not maintaining up-to-date virus signature files, or computers attached to the LAN without firewalls. Sometimes the attacks are more sophisticated, such as using a packet sniffer to learn another user’s password or taking steps to degrade network performance.

6.1.2 LAN Components. In general, there are four basic components required to build a LAN, providing their own vulnerabilities and exposures from a security perspective:

1. **Computers.** These are the basic devices that are connected on the network. Read “computer” very broadly; the term can include personal computers (PCs), minicomputers, mainframes, file servers, printers, plotters, mobile devices (e.g., smartphones and tablets), communications servers, and network interconnection devices. It can also include protocol analyzers.
2. **Media.** These are the physical means by which the computers are interconnected. LAN media include unshielded twisted pair (UTP), coaxial cable (coax), optical fiber, and wireless (radio) devices. The wireless media have connection points

throughout an area where devices can attach to the network, and every place is a potential connection point in a wireless environment.

3. **Network interface card (NIC).** This is the physical attachment from the computer to the LAN medium. Older NICs are internal cards; the only item that is actually seen is the physical attachment to the LAN, often an RJ-45 jack. An increasing number of adapters use the universal serial bus (USB) slots on modern computers. Although NICs range widely in price depending on their capabilities, intended use, and vendor, an internal 1 Gbps Ethernet NIC for a desktop personal computer (PC) could be purchased for less than \$7, a USB Ethernet adapter for about \$14, and a wireless USB adapter for less than \$13 at the time of writing in January 2013.
4. **Software.** The three components above provide physical connectivity. Software—often called a *network operating system* (NOS)—is necessary for the devices to actually take advantage of the resource sharing that the LAN can provide. The NOS can support many types of services such as file sharing, print sharing, client/server operation, communications services, and more.

While the LAN needs to be examined in a holistic fashion, each of these components at each attached node also may require examination.

6.1.3 LAN Technology Parameters. One final way of discussing the specific operation of the LAN is to describe the technology:

- **Physical topology.** The physical layout of the medium.
- **Logical topology.** The logical relationship of the LAN nodes to each other.
- **Media Access Control (MAC) Standard.** The specification describing the rules that each node follows to determine when it is its turn to transmit on the medium.
- **Use of the Logical Link Control (LLC) protocol.** Defines the frame format employed above the MAC layer, and additional services.
- **Use of higher-layer protocols.** Defines the node-to-node communicating protocols and additional higher-layer applications.

6.1.4 Summary. It does not matter how a LAN is classified or described. It is essential, however, that the LAN be understood from a variety of perspectives to be able to apply a network-security examination.

6.2 LAN TOPOLOGY. WANs typically use some sort of switched technology, such as traditional circuit switching, packet switching (e.g., X.25), or fast packet switching (e.g., frame relay or asynchronous transfer mode [ATM]). Indeed, point-to-point lines typically connect the network switches so that there is a single data transmission on the line at one time.

Historically, LANs have been broadcast networks, meaning that every LAN station hears every transmission on the medium. LAN topologies, then, have to support the broadcast nature of the network and provide full connectivity between all stations.

The *topology* of a network is used to describe two issues. The *physical topology* describes how the LAN stations are physically connected so that they can communicate with each other. The *logical topology* describes how the broadcast nature of the LAN is actually affected, and, therefore, how stations participate in the process of obtaining

6 · 4 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

permission to transmit on the medium. There are three common topologies found in LANs: star, ring, and bus.

6.2.1 Network Control. Since LANs are broadcast networks, it is imperative that only a single node be allowed to transmit at any one time. All LANs use a *distributed access-control* scheme, meaning that all nodes follow the same rules to access the network medium and no one LAN node controls the other nodes' access. In this way, LAN nodes can come online and offline without bringing the network down.

This description is *not* meant to suggest that there are no critical elements in a LAN. Indeed, if a central hub, switch, or transmitter fails, the LAN will crash. Distributed control *does* suggest, however, that all nodes (user stations) follow the same access rules, and failure of a single *node* will not bring the LAN down. The access-control scheme is defined by the MAC protocol.

6.2.2 Star Topology. In a *star topology* (see Exhibit 6.1), all devices on the LAN are interconnected through some central device. Since LANs use distributed access-control schemes, all communication is from one node to another, and the central device merely provides a pathway between pairs of devices.

Physical star topologies have a tremendous advantage over other topologies in that they greatly ease network administration, maintenance, reconfiguration, and error recovery. Disadvantages include the single point of failure.

6.2.3 Ring Topology. In a *ring topology*, the nodes are connected by a set of point-to-point links that are organized in a circle (see Exhibit 6.2). Stations connect to

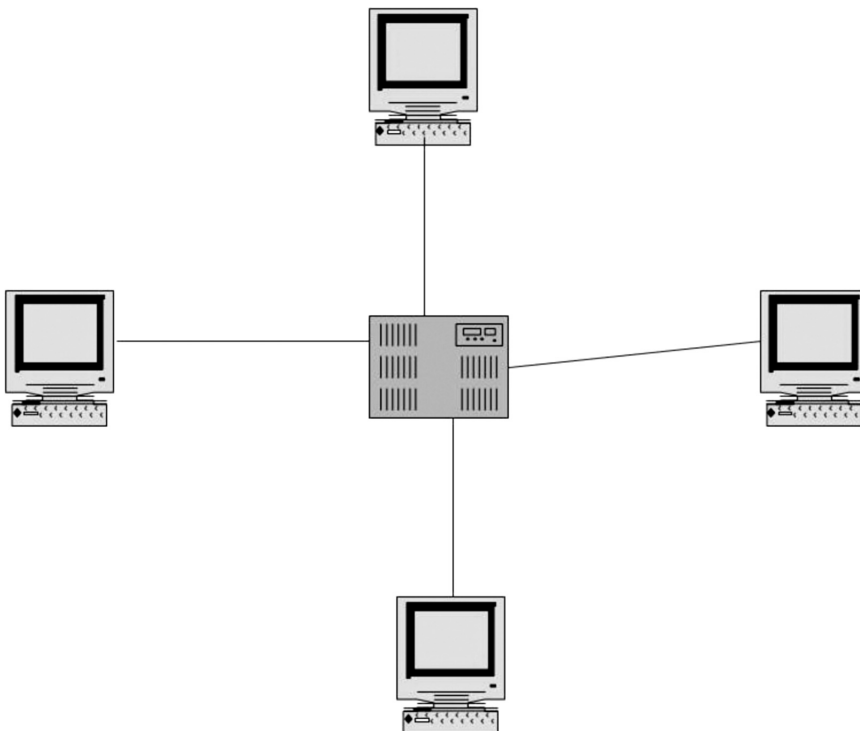

EXHIBIT 6.1 Star Topology

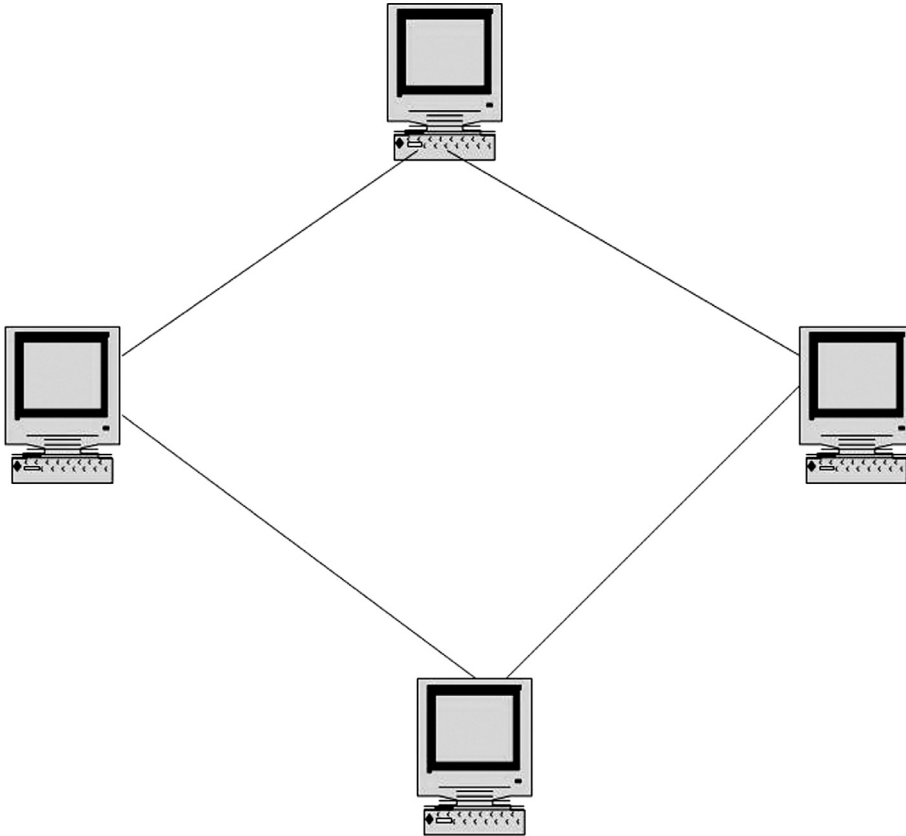

EXHIBIT 6.2 Ring Topology

the medium using *active taps* that are actually bit repeaters; a bit is read from the input line, held for a single bit time, then transmitted out to the output line.

A station transmits a message on the network by sending out a bit stream on its outgoing link; thus, rings are unidirectional in nature. Since all of the other stations see the bits one at a time, the intended receiver has no prior warning about an incoming message. For this reason, the transmitter is responsible for removing the message from the ring when the bits come back around. The MAC scheme ensures that multiple stations do not transmit at the same time.

In addition, a ring is a *serial broadcast* network. Because a station sends a message one bit at a time, every other station will see the message as it passes through but each will be receiving a different part of the message at any point in time.

Rings are a common physical LAN topology. However, unlike stars, they have multiple points of failure: if one link or one active tap fails, the integrity of the ring is destroyed. If the probability of failure of a single element is p and there are n elements, then the probability of failure $P\{F\}$ of the LAN is

$$P\{F\} = 1 - (1 - p)^n$$

As the number of elements rises, the probability of network failure rises exponentially. This problem is of such a critical nature that nearly all ring products use a star-wiring scheme or have some sort of redundancy built in for just this eventuality.

6 · 6 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

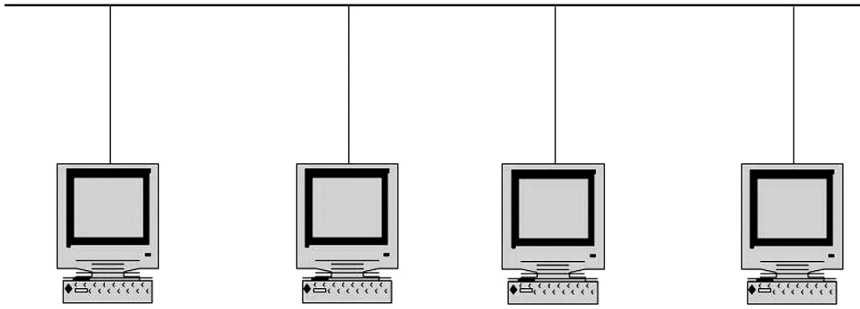

EXHIBIT 6.3 Bus Topology

6.2.4 Bus Topology. In a *bus topology* (see Exhibit 6.3), all devices are connected to a single electrically continuous medium; for this reason, this topology is also called a common cable or shared medium network. Nodes attach to the medium using a *passive tap*, one that monitors the bit flow without altering it. This is similar to the operation of a voltmeter; it measures the voltage on a power line without changing the available voltage.

Bus networks are analogous to the way appliances are connected to an alternating current (AC) power line. All of the devices draw power from the same source, even if they are on different physical segments of the power distribution network within the building. In addition, the operation of the devices is independent of each other; if the coffeepot breaks, the toaster will still work.

A bus is a *simultaneous broadcast* network, meaning that all stations receive a transmitted message at essentially the same time (ignoring propagation delay through the medium). Most home and business LANs employ a *baseband bus* where direct current (DC) signals are applied directly to the bus by the transmitter without any modification. In addition, transmissions on a baseband bus are broadcast bidirectionally and cannot be altered by the receivers. Bus LAN technologies are employed on cable television systems. For example, they employ a *broadband bus* where the signals are modulated (i.e., frequency shifted) to certain frequencies for transmission in one direction or another.

Buses are the oldest LAN topology and are generally limited in the type of medium that they can use. They do not usually suffer from single-point-of-failure problems.

6.2.5 Physical versus Logical Topology. A distinction was made above between the *physical* and *logical* topology of a LAN. *Physical* topology describes how the stations are physically positioned and attached to each other whereas the *logical* topology describes how the signals propagate and the logical operation of the network.

In all of today's commonly used LANs, the logical topology differs from the physical topology. The most common LAN configuration today is a *star-wired bus* (see Exhibit 6.4). This type of network has a star topology where all stations are physically attached with point-to-point links to a central device. This central device contains a bus that interconnects all of the I/O ports in such a way that when one station transmits a message, all stations will receive it. Since this acts exactly like a simultaneous broadcast, or bus, network, we categorize this configuration as a physical star, logical bus.

Another common configuration is a *star-wired ring* (see Exhibit 6.5). In this configuration, the bits will travel in logical order from station A to B, C, A, and so forth,

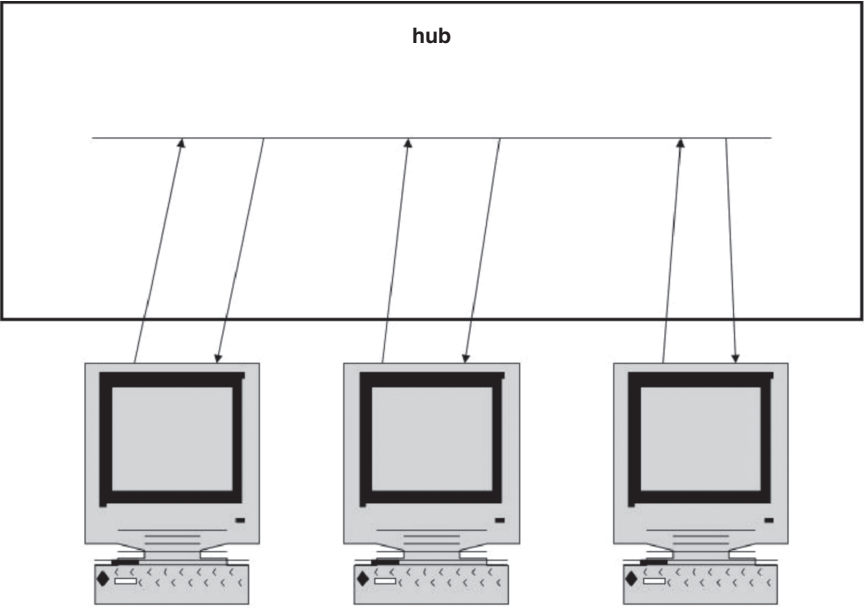

EXHIBIT 6.4 Star-Wired Bus

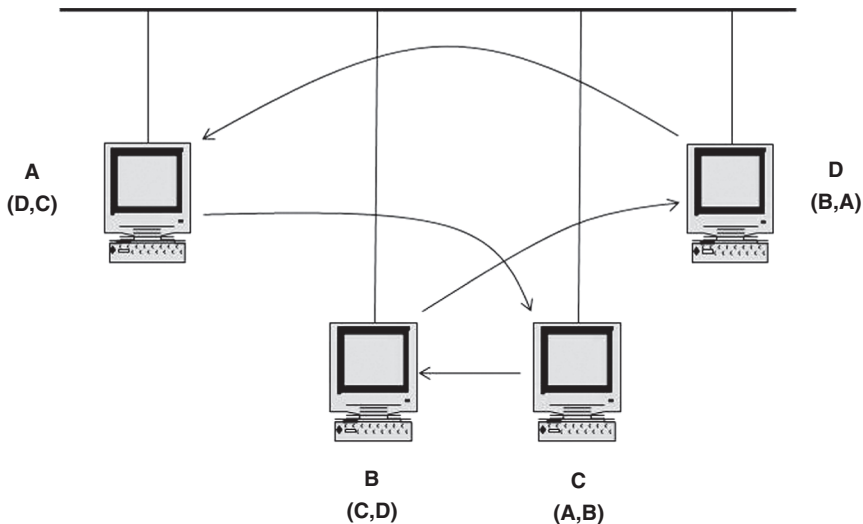

EXHIBIT 6.6 Bus-Wired Ring (The station identifier is shown above the station ID of the predecessor and successor stations in the logical ring.)

which matches the serial broadcast operation of a ring. We call this a physical star, logical ring.

Although uncommon today, another hybrid technology is the *bus-wired ring* (see Exhibit 6.6). In this configuration, nodes are passively attached to a single cable, forming a physical bus. Each station maintains a table specifying the address of predecessor and successor stations, thus forming a logical ring.

6.3 MEDIA. The next paragraphs discuss the three primary types of LAN media currently in use. Due to their relatively high speed, small geographic size, and protected environments, a number of media types can be employed with LANs.

6.3.1 Coaxial Cable. Coaxial cable (coax) is the original LAN medium. It gets its name from the physical composition of the cable itself (see Exhibit 6.7). At the center of the cable is a conductor, usually made of copper, which is surrounded by an insulator that, in turn, is surrounded by another conductor that acts as an electrical shield. Since the shield completely surrounds the central conductor and the two have a common axis, the shield prevents external electrical noise from affecting signals on

EXHIBIT 6.7 Coaxial Cable

EXHIBIT 6.8 Unshielded Twisted Pair

the conductor and prevents signals on the conductor from generating noise that affects other cables.

Coaxial cables vary in size from $\frac{1}{4}$ –1 inch (6.35–25.4 mm), depending on the thickness of the conductor, shield, and insulation. Applications for coax range from cable television to LANs. Speeds in excess of several hundred Mbps at distances of several hundred to several thousand meters can be achieved. Coaxial cable also has a high immunity from electromagnetic and radio frequency interference. However, it is easy to *tap*.

Coaxial cable is only seen in physical bus LANs such as Ethernet. The original Ethernet specification, in fact, called for a thin coaxial cable; a later version that employed thin (CATV) coax was dubbed CheaperNet. Coax is not typically found in star or ring networks.

Coaxial cable is easy to wiretap.²

6.3.2 Twisted Pair. The medium enjoying the largest popularity for LAN applications today is twisted pair. Twisted pair cable consists of two insulated copper conductors that are twisted around each other (see Exhibit 6.8). This is typically 22- to 26-gauge (i.e., 0.025"/0.644 mm to 0.016"/0.405 mm) wire, the same as is used for telephone wiring. Twisting the conductors around each other minimizes the effect of external electrical radiation on the signal carried on the wire; if external voltage is applied to one wire of the pair, it will be applied equally to the other wire. The twisting, then, effectively eliminates the effect of the external noise. As the number of twists per inch increases, the noise reduction characteristics improve; unfortunately, so does the overall amount of cable and the cost. Most twisted pair for telephony applications has 10 to 15 twists per foot.

The type of twisted pair cable shown in Exhibit 6.8 is called *unshielded twisted pair* (UTP) because the wire pair itself is not shielded. The data-carrying capacity of UTP is generally indicated by its *category*:

Level 1 (sometimes called Category 1, or Cat 1) cable is older 0.4 MHz cable used for some telephone and modem applications, but is generally unsuited for data applications.

Level 2 (sometimes called Category 2, or Cat 2) cable is 4 MHz cable used for legacy data terminal systems, such as IBM 3270 BISYNC.

Category 3 (Cat 3) cable has a maximum bandwidth of 16 MHz and is rated for 10 Mbps over a wire segment of 100 m (although speeds of 100 Mbps can often be achieved). Cat 3 cable is rated up to 16 Mbps and is primarily used today for telephones.

Category 4 (Cat 4) cable, with a maximum bandwidth of 20 MHz, was used for IBM's 16 Mbps Token Ring networks. It is not commonly seen today.

6 · 10 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

Category 5 (Cat 5) cable has a maximum bandwidth of 100 MHz and is rated for voice or data at speeds up to 100 Mbps over a wire segment of 100 meters. Cat 5e is rated for full-duplex and 1 gigabit (Gbps) Ethernet. These are the most common LAN cables in use today.

Category 6 (Cat 6) cable is rated to 250 MHz over a wire segment between 15 and 100 meters in length. Cat 6 is intended for use for very-high-speed broadband applications at data rates up to 10 Gbps. Cat 6a cable is a variant of Cat 6, rated to 500 MHz and 10 Gbps.

Category 7 (Cat 7) cable is rated up to 600 MHz and uses four pair. Each pair of wires in the cable sheath, and the sheath itself, are shielded to prevent electromagnetic interference at data rates up to 10 Gbps. Cat 7a is rated up to 1,000 MHz and 10 Gbps data rates.

UTP is commonly found in physical star-wired bus and ring LANs; it is never used in a physical bus and rarely in a physical ring. As with coaxial cable, it is easy to wiretap. In addition, many LANs using UTP also make connections through *patch panels*, which are frequently unprotected because the technicians installing the connections are unaware of the security issues of providing centralized access to dozens or hundreds of connections.

Another twisted pair variant is *shielded twisted pair* (STP), where each cable pair is surrounded by a metallic shield that provides the same function as the outer conductor in coaxial cable. STP was only used in the IBM Token Ring, a star-wired ring.

6.3.3 Optical Fiber. Optical fiber is a thin flexible medium that acts as a wave-guide for signals in the 10^{14} - to 10^{15} -Hz range, which includes the visible light spectrum and part of the infrared spectrum. Optical fiber is a great medium for digital communications; it is essentially immune to any type of radio or magnetic interference and very difficult (using highly specialized equipment) to tap surreptitiously. Theoretically able to achieve data rates on the order of trillions of bits per second, optical fiber has been shown to reach data rates of 100 Gbps over a 4,350-mile (7,000-km) fiber; the practical limit is usually due to the electronics performing optical-electrical conversion.

In WAN applications, this speed limit is exceeded in one of two ways.

1. An optical switch can terminate optical fiber without any electrical-optical conversion.
2. Dense wave division multiplexing (DWDM) allows 100 or more 10 Gbps bit streams to be carried on a single-fiber strand simultaneously. These technologies may well eventually find their way to the LAN.

The electronics are a critical part of any optical fiber system. The incoming electrical signal to be transmitted on the fiber is converted to an optical signal by the transmitter. Common optical sources are a *light-emitting diode* (LED) or *injection laser diode* (ILD). LEDs are less expensive than ILDs but are limited to lower speeds. The optical signal is received by a device called a *photodiode*, which essentially counts photons and converts the count to an electrical signal. Common photodiodes include the *positive-intrinsic-negative* (PIN) *photodiode* and *avalanche photodiode* (APD). The PIN is less expensive than the APD but is limited to lower speeds.

The physical and transmission characteristics of optical fiber are shown in Exhibit 6.9. At the center of an optical fiber cable is the *core*, a thin, flexible medium capable of carrying a light signal. The core is typically between 2 and 125 micrometers

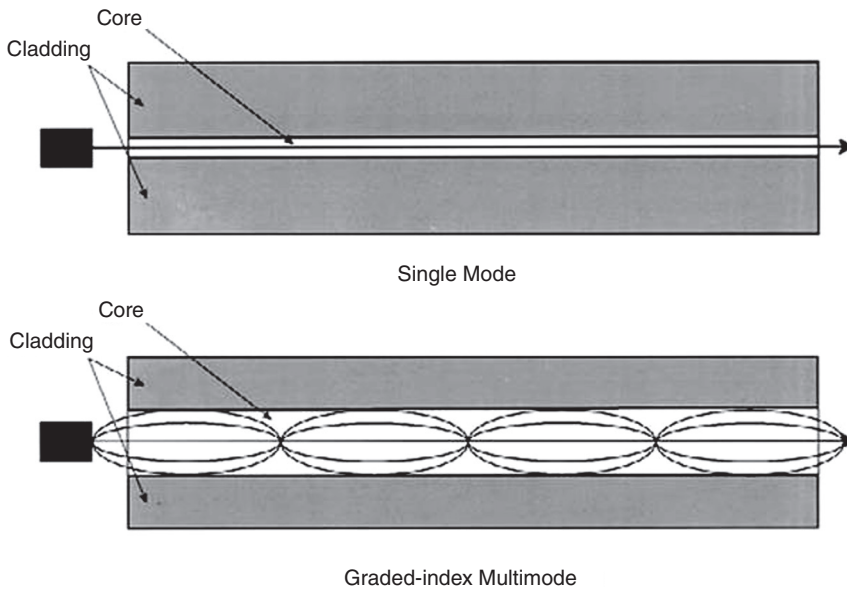

EXHIBIT 6.9 Optical Fiber Cable

(μm), or microns, in diameter and may be made from a variety of glass or plastic compounds. Surrounding the core is a layer called the *cladding*. The optical characteristics of the cladding are always different from the core's characteristics so that light signals traveling through the core at an angle will reflect back and stay in the core. The cladding may vary in thickness from a few to several hundred microns. The outermost layer is the *jacket*. Composed of plastic or rubber, the jacket's function is to provide the cable with physical protection from moisture, handling, and other environmental factors.

Two types of optical fiber cable are used for voice and data communications, differentiated by their transmission characteristics (see Exhibit 6.9). *Multimode fiber* (MMF) has a core diameter between 50 and 125 μm . Because this diameter is relatively large, light rays at different angles will be traveling through the core. This phenomenon, known as *modal dispersion*, has the effect of limiting the bit rate and/or distance of the cable. MMF cable is generally limited to a maximum cable length of 2 km. *Single-mode fiber* (SMF) eliminates the multiple path problem of MMF by using a thin core with a diameter of 2 to 8 μm . This thin-core cable results in a single propagation path so that very high bandwidths over large distances (up to 10 km) can be achieved.

SMF is the most expensive type of fiber and is usually used for long-haul data and telecommunications networks. MMF is commonly used on LANs; it is less expensive but can still handle the required data rates and distances.

Optical cable is extremely difficult to wiretap, but it's easy to cut. Such cables should be protected by shielded conduits, not placed in accessible locations such as next to a baseboard on the floor of a public corridor—in a hospital!

6.3.4 Wireless Media. Wireless LANs use radio signals to interconnect LAN nodes. Wireless LANs are increasingly common in environments where:

- It is difficult to install new wiring (e.g., in a building with asbestos in the walls).
- There are mobile users (e.g., in a hospital or car rental agency).

6 · 12 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

- Right-of-ways for wiring are hard to obtain (e.g., campus environments that span roadways).
- A temporary network is necessary (e.g., at a conference or meeting).
- Residential areas have no other networking facilities.
- Conference centers, hotels, and colleges and universities need wide and easy network access.

Wireless LANs generally employ infrared, spread spectrum, or microwave communications technology. *Infrared* (IR) is used for a variety of communications, monitoring, and control applications. It is also used for such non-LAN applications as home entertainment remote control, building security intrusion and motion detectors, medical diagnostic equipment, and missile guidance systems. For wireless LANs, the most common IR communications band uses signals with a wavelength in the range 800 to 1,000 nanometers (nm, or 10^{-9} m). *Diffused IR* operates at data rates between 1 to 4 Mbps at distances up to 200 feet, and can be used for stationary or mobile LAN nodes. *Directed Beam IR*, which requires line-of-sight, operates at data rates from 1 to 10 Mbps at distances up to 80 feet. IR systems are limited to a single room because the signals cannot pass through walls.

Spread spectrum is a wireless communications technology in the region of 2.4 or 5 gigahertz (GHz, or billions of cycles per second), where the actual frequency of the transmitted signal is deliberately varied during transmission. Originally, the frequency shifting was for security purposes to prevent monitoring of the communications channels. Two types of spread spectrum technology are used in LANs:

1. In *frequency hopping spread spectrum* (FHSS),³ the transmitter sends the signal over a set of radio frequencies, hopping from frequency to frequency at split-second intervals in what appears to be a random sequence. The sequence is not random, however, and the receiver changes frequencies in synchronization with the transmitter. FHSS can support data rates from 1 to 3 Mbps up to a distance of 330 feet (100 m).
2. In *direct sequence spread spectrum* (DSSS), each bit in the original data stream is represented by multiple bits in the transmitted signal, spreading the signal across a wide frequency range. One result of DSSS is that the system can achieve a greater bandwidth than the original signal. DSSS can support data rates in excess of 20 Mbps up to a distance of 1,000 feet (300 m).

Another modulation scheme used in wireless LANs is *orthogonal frequency-division multiplexing* (OFDM). OFDM is a variant of frequency division multiplexing and uses a forward error-correction scheme and orthogonal subcarriers in order to minimize frequency crosstalk and bit errors.

Wireless access points can be purchased for less than \$100, making this an attractive alternative to even UTP-based LANs in many scenarios.

Microwave LANs refers to communications in the area of 1, 5, and 19 GHz. Electromagnetic energy with a frequency higher than 1 GHz and data rates up to 20 Mbps can be maintained for distances up to 130 feet. One major disadvantage of microwave is that Federal Communications Commission (FCC) licensing is required for many of these frequencies.

6.3.5 Summary. In the early 1980s, coaxial cable was the most commonly used LAN medium. Twisted pair, used for telephony applications, was not used in LANs because high speeds could not be achieved. Optical fiber technology was still in its infancy and was very expensive. All of this changed by the early 1990s, when the electronics to drive twisted pair had dramatically improved, and optical fiber technology had greatly matured. It is rare to see coaxial cable used in a LAN today; instead, UTP (less costly than coax) or optical fiber (higher speeds than coax) are more often employed. Wireless LANs are a viable alternative to wire-based networks, yet more difficult to secure.⁴ However, growth in wireless network access to the Internet outstripped fixed broadband subscriptions by the late 2000s; in 2011, rates of growth for wireless subscriptions were 200 to 300 percent of the rates of growth for fixed subscriptions.⁵

6.4 MEDIA ACCESS CONTROL. As mentioned, LANs are broadcast networks connecting peer devices, all having equal access to the medium. These characteristics place two requirements on the protocol that controls access to the network:

1. There can be only one station transmitting at any given time since multiple transmitters would result in garbled messages.
2. All stations must follow the same rules for accessing the network since there is no master station.

The schemes controlling access to the network medium are called *media access control* (MAC) protocols. Although many different LAN MAC schemes have been introduced in working products, the most common ones are essentially variants of two approaches: *contention* and *distributed polling*. These schemes will be discussed below, along with reference to appropriate Institute for Electronics and Electrical Engineers (IEEE) LAN standards.

6.4.1 Contention. A contention network can be compared to a group of people sitting around a conference table without a chairperson. When someone wants to speak, it is necessary first to determine whether anyone else is already speaking; if someone else is speaking, no one else can begin until that person has stopped. When a person detects silence at the table, he or she starts to talk. If two people start to talk at the same time, a *collision* has occurred and must be resolved. In the human analogy, collisions are resolved in one of two ways: Either both speakers stop and defer to each other (“polite backoff”) or both continue speaking louder and louder until one gives up (a “rudeness algorithm”).

The contention scheme used in LANs is similar to the polite backoff situation, and is called *carrier sense multiple access with collision detection* (CSMA/CD). CSMA/CD is one of the oldest LAN MAC schemes in use today, used originally in Ethernet and becoming the basis of the IEEE 802.3 standard (to be described). Although there have been other contention schemes used on LANs, CSMA/CD is the one that has survived and thrived in the marketplace.

CSMA/CD works on logical bus networks. When a station is ready to transmit, it first listens to the network medium (“carrier sense”). If the station detects a transmission on the line, it will continue to monitor the channel until it is idle. Once silence is detected, the station with a message to send will start to transmit. Stations continue to monitor the channel during transmission so that if a collision is detected, all transmitters stop transmitting.

6.14 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

CSMA/CD networks employ a *backoff scheme* so that the first collision does not bring the network down. Without a backoff scheme, all transmitters would detect a collision and stop transmitting; after again hearing silence on the line, however, all stations would once again start transmitting and would again collide with each other. The backoff scheme causes stations to make a random decision whether to transmit or not after silence is detected on the channel after a collision has occurred.

CSMA/CD uses a backoff scheme called *truncated binary exponential backoff*. Although this name is a mouthful, it actually describes the process very precisely. When a station is ready to transmit and detects silence on the line, it will attempt to send a message with a probability of 1 (i.e., 100 percent likelihood that it will transmit); this probability is called the *persistence* of the MAC scheme.⁶ If a collision occurs, the station will stop transmitting and again wait for silence on the line. When silence is again detected, the station will transmit with a probability of $\frac{1}{2}$ (i.e., there is a 50 percent chance that it will transmit and a 50 percent chance that it will not). If two stations were involved in the collision and they both back off to a $\frac{1}{2}$ -persistent condition, then there is a 50 percent chance that one will transmit and one will defer at the next transmission opportunity, a 25 percent chance that both will defer at the next opportunity, and a 25 percent chance that both will collide again.

If a station collides again, its persistence is again cut in half, now to $\frac{1}{4}$. All stations involved in the collision(s) drop their persistence and each station independently determines whether it will transmit at the next occurrence of silence or not.

As long as collisions occur, the persistence is continually cut in half until the station either successfully transmits or has 16 unsuccessful attempts to transmit the message. After 16 failed attempts, the station gives up.⁷ After the station successfully transmits or has 16 unsuccessful attempts, the station's persistence returns to 1 and the operation continues as before.

Wireless LANs also use a form of contention, but it is generally not CSMA/CD because collision detection is not practical in a wireless environment. Instead, the stations still employ CSMA—they listen for an idle channel—but they do not necessarily transmit when the channel is idle. Instead, they wait to see if the channel remains idle for some period of time in an attempt to stave off a collision. This is a form of *CSMA with collision avoidance* (CSMA/CA).

6.4.2 Distributed Polling. Imagine that the same group of people is sitting around the same conference table, still without a chairperson. One person at the table has a microphone and can say anything to anyone in the room. Everyone in the room, of course, will hear the message. The rule here is that the only person who is allowed to speak is the one with the microphone; furthermore, the person will hold on to the microphone only while he or she has something to say and can hold on to it only for some maximum amount of time. When the first person is done talking or the time limit is reached, the microphone is passed to the next person at the table. Person 2 can now speak or immediately pass the microphone on to person 3. Eventually, the first person at the table will get the microphone back and get another opportunity to talk.

The scheme just described is implemented in LANs with a scheme called *token passing*. This is the basis for the IBM Token Ring and represents the second most commonly used LAN MAC algorithm. Token passing, in one variant or another, is the basis for the IEEE 802.4 and 802.5 standards, as well as for the Fiber Distributed Data Interface (FDDI).

Token passing requires a logical ring topology. When a station has data to send to another station, it must wait to receive a bit pattern representing the *token*. Tokens are

sent in such a way that only one station will see it at any given time; in this way, if a station sees the token, it has temporary, exclusive ownership of the network.

If a station receives the token and has no data to send, it passes the token on. If it does have data to send, it generates a *frame* containing the data. After sending the frame, the station will generate and send another token.

A *token ring* network is a logical ring implemented on a physical topology that supports a serial broadcast operation (i.e., a star or a ring). Each station receives transmissions one bit at a time and regenerates the bits for the next station. A station transmitting a frame will send the bits on its output link and receive them back on its input link. The transmitter, then, is responsible for removing its message from the network. When finished transmitting, the station transfers control to another station by sending the bits comprising a token on its output link. The next station on the ring that wants to transmit *and* sees the token can then send its data frame. Token rings (standardized in 802.5 and FDDI) are the most common implementation of token passing.

A *token bus* network (as specified in 802.4) is conceptually similar to the token ring, except that it is implemented using a simultaneous broadcast topology (i.e., a bus). In this physical topology, all stations hear all transmissions. A station that wants to send data to another will address a frame to the intended receiver on the network, as in a CSMA/CD bus. When done transmitting, the station will address a token to the next station logically in the ring; while all stations will hear the token transmission, only the one station to which it is addressed will pick it up. After receiving a token, a station may or may not transmit data, but it is, in any case, responsible for passing the token to the next station in the logical ring. Eventually, the token will return to the first station.

6.5 LAN PROTOCOLS AND STANDARDS. The Open Systems Interconnection (OSI) Reference Model continues to be the standard framework with which to describe data communications architectures, including those for LANs. The basic LAN protocol architecture maps easily to the OSI model, as discussed in this section.

6.5.1 OSI Model versus LAN Model Architectures. Although the LAN protocol architecture can be related to the OSI model, there is not a perfect one-to-one mapping of the protocol layers (see Exhibit 6.10). The OSI Physical Layer is analogous to a LAN Physical Layer (PHY). Both specify such things as:

- Electrical characteristics of the interface
- Mechanical characteristics of the connector and medium
- Interface circuits and their functions
- Properties of the medium
- Signaling speed
- Signaling method

Most LAN physical layer specifications actually comprise two sublayers. The lower sublayer describes physical layer aspects that are specific to a given medium; the higher sublayer describes those aspects that are media-independent.

The OSI Data Link Layer, responsible for error-free communication between any two communicating devices, is represented by two sublayers in a LAN. The lower sublayer is the MAC, which deals with issues of how the station should access the

6 · 16 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

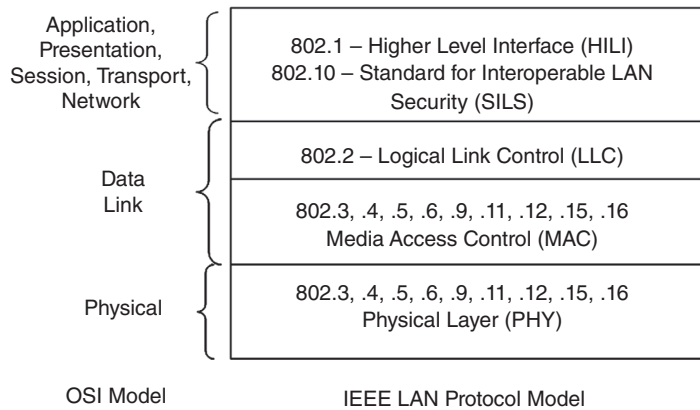

EXHIBIT 6.10 IEEE versus LAN Protocol Models

network medium. The MAC is responsible for error-free communication over the PHY and specifies such things as:

- Framing
- Addressing
- Bit-error detection
- Control and maintenance of the MAC protocol
- Rules governing medium access

The upper sublayer is called the Logical Link Control (LLC). The LLC protocol is responsible for maintaining a logical connection between two communicating LAN stations. The LLC specifies such rules as:

- Frame sequencing
- Error control
- Establishment and termination of a logical connection
- Addressing of higher layer services

Recalling that the main functions of the network layer are routing and congestion control, there are two reasons that no LAN protocol layer acts strictly like the OSI Network Layer:

1. There is no need for a routing algorithm in a broadcast network because all stations receive all transmissions; the address of the intended receiver is included in the transmission itself.
2. Congestion control is also not an issue in a broadcast network; a broadcast network must be limited to a single transmitter at a time, and this is accomplished by the MAC layer.

There are no standards for LANs corresponding to the upper four layers of the OSI model. Even in the less organized 1980s, end-to-end protocols as such were not required in a LAN environment because the end-to-end communication was limited to nodes on the LAN, and for that the MAC guaranteed error-free communication.

Only when LAN interconnection, via WAN and LAN access to the Internet, gained popularity did other end-to-end protocols become necessary. IP (and other network layer protocols) grew in demand as well. Those protocols are associated with the communications software as part of a network operating system (NOS), and these will be discussed later.

6.5.2 IEEE 802 Standards. Although they are not directly related to security, it is useful to be familiar with the standards describing LANs, the most common of which are the IEEE 802 standards. The IEEE Computer Society formed the Project 802 Committee in February 1980 to create standards for LANs as part of its more general work on standards for microprocessors; no other organization was making any similar standardization efforts. Originally, there was to be a single LAN standard, operating at a speed between 1 and 20 Mbps. The standard was divided into three parts: PHY, MAC, and a high-level interface (HILI) to allow other protocol suites to have a common protocol boundary with the LAN. The original MAC was based on the Ethernet standard, but other MAC schemes were quickly added and, over the years, the 802 committee has addressed many LAN schemes. They all have in common an interface to a single LLC protocol that provides a common interface between the HILI and any MAC.

A description of the Project 802 working groups (WG) and their status as of October 2012 follows.⁸

802.1—High-Layer LAN Protocols Working Group. Provides the framework for higher-layer issues, including protocol architecture, security, end-to-end protocols, bridging, internetworking, network management, and performance measurement.

802.2—Logical Link Control Working Group. Provides a consistent interface between any LAN MAC and higher-layer protocols. Depending on the options employed, the LLC can provide error detection and correction, sequential delivery, and multiprotocol encapsulation. The 802.2 standard is described in more detail in Section 6.5.6. This WG has been *disbanded*.⁹

802.3—Ethernet Working Group. Defines the MAC and PHY specifications for a CSMA/CD bus network. This specification is discussed in more detail in Section 6.5.3. (The 802.3 CSMA/CD standard is based on Ethernet, described in Section 6.5.4.)

802.4—Token Bus Working Group. Defines the MAC and PHY specifications for a token-passing bus based on work originally done at General Motors as part of the Manufacturing Automation Protocol (MAP). Well suited for factory floors and assembly lines, MAP never achieved widespread use. This WG has been disbanded.

802.5—Token Ring Working Group. Defines the MAC and PHY specifications for a token-passing ring. Although this WG is currently disbanded, the specification is discussed in more detail in Section 6.5.5 for historical purposes.

802.6—Metropolitan Area Network (MAN) Working Group. Defines the MAC and PHY specifications for a MAN. In particular, the 802.6 standard defines a MAC and PHY called Distributed Queue Dual Bus (DQDB), which was one of the MACs employed with the Switched Multimegabit Data Service (SMDS) and Connectionless Broadband Data Service (CBDS). Introduced in the early 1990s, neither service remains in use today. This WG has been disbanded.

6 · 18 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

802.7—Broadband Technology Advisory Group (BBTAG). Advises other 802 subcommittees about changes in broadband technology and their effect on the 802 standards. This WG has been disbanded.

802.8—Fiber Optics Technology Advisory Group (FOTAG). Advises other 802 subcommittees about changes in optical fiber technology and their effect on the 802 standards. This WG has been disbanded.

802.9—Integrated Services LAN (ISLAN) Working Group. Defines the MAC and PHY specifications for integrated voice/data terminal access to integrated services networks, including ISLANs and MANs, and Integrated Services Digital Networks (ISDN). The only practical implementation was deployed in IsoEthernet products, described in the IEEE 802.9a standard. This WG has been disbanded.

802.10—Security Working Group. Defines procedures for providing security mechanisms on interconnected LANs, including cryptography and certificates. This WG has been disbanded.

802.11—Wireless LAN (WLAN) Working Group. Defines MAC and PHY specifications for “through the air” media. The original 802.11 standard defined operation at 1 or 2 Mbps using the 2.4-GHz range and DSSS or FHSS spread spectrum technology; nominal maximum distances were 330 feet (100 m). The most common variants today are:

- 802.11b—Data rates up to 11 Mbps at a nominal maximum distance up to 460 feet (140 m) on a frequency of 2.4 GHz using DSSS.
- 802.11g—Data rates up to 54 Mbps at a nominal maximum distance up to 460 feet (140 m) on a frequency of 2.4 GHz using DSSS or OFDM.
- 802.11n—Data rates up to 150 Mbps at a nominal maximum distance up to 820 feet (250 m) on a frequency of 2.4 or 5 GHz using OFDM.

Future 802.11 standards are expected that will provide data rates up to 866.7 Mbps on a frequency of 5 GHz using OFDM.

802.12—Demand Priority Working Group. Describes one of the MAC and PHY specifications originally proposed for 100 Mbps LAN speeds and dubbed *100BASE-VG/AnyLAN*. Largely unused, and the WG has been disbanded.

802.13. (This number was never assigned to a WG because it was felt that the *13* would hamper products in the marketplace.)

802.14—Cable Modem Working Group. Originally intended to describe LANs for cable TV systems. This WG has been disbanded.

802.15—Wireless Personal Area Network (WPAN) Working Group. Defines a MAC and PHY for a short distance wireless network between portable and mobile devices such as PCs, personal digital assistants (PDAs), cell phones, pagers, and other communications equipment.

802.16—Broadband Wireless Access (BBWA) Working Group. Defines the MAC and PHY for high-speed wireless network access over relatively short distances. BBWA standards address the “first-mile/last-mile” connection in wireless metropolitan area networks, extending the reach of residential broadband services such as cable modem or digital subscriber line (DSL).

802.17—Resilient Packet Ring (RPR) Working Group. Defines standards to support the development and deployment of RPR local, metropolitan, and wide

area networks for resilient and efficient transfer of data packets at rates scalable to many gigabits per second. This WG is currently in *hibernation*.¹⁰

802.18—Radio Regulatory Technical Advisory Group (RR-TAG). On behalf of other 802 WGs using radio-based communication, this TAG monitors, and actively participates in, ongoing national and international radio regulatory activities.

802.19—Wireless Coexistence Working Group. Develops and maintains policies defining the responsibilities of 802 standards developers to address issues of coexistence with existing standards and other standards under development.

802.20—Mobile Broadband Wireless Access (MBWA) Working Group. Defines the specification for a packet-based wireless interface that is optimized for IP-based services. The goal is to enable worldwide deployment of affordable, ubiquitous, always on, and interoperable multivendor mobile broadband wireless access networks that meet the needs of business and residential end user markets. This WG is currently in hibernation.

802.21—Media Independent Handover Services Working Group. Developing standards to enable handover and interoperability between heterogeneous network types including both 802 and non-802 networks.

802.22—Wireless Regional Area Networks (WRAN) Working Group. Developing a standard for a radio-based PHY, MAC, and air interface for use by license-exempt devices on a noninterfering basis in the spectrum allocated to broadcast television.

802.23—Emergency Services Working Group. This working group was created to define an IEEE 802 framework for LANs that would comply with applicable civil authority requirements for communications systems. This working group has been disbanded.

802.24—Smart Grid Technology Advisory Group. This TAG was created to provide liaison between the 802 committee and the smart grid industry and regulatory bodies, and to provide coordination and collaboration amongst 802 working groups related to smart grids.

6.5.3 IEEE 802.3 CSMA/CD Standard. The original IEEE 802.3 standard, first published in 1985, describes the PHY and MAC for a CSMA/CD bus network operating over thick coaxial cable. Today, an 802.3 network implementation can employ any of a number of media types, including UTP and optical fiber. Without question, star-wired UTP implementations are the most popular.

The 802.3 committee anticipated the different media types that might be used, and they developed a nomenclature to identify the actual physical implementation, using the format:

[speed (Mbps)][signaling type][segment length (m) or media type]

The original 802.3 specification, for example, operated at 10 Mbps, used baseband (digital) signaling and limited a single coaxial cable segment to a length of 500 m (1,640 feet); the cable was designated 10BASE5. In fact, the largest distance between two 802.3 stations could be 2.8 km (9,200 feet), so repeaters might be used to interconnect several 500-m coaxial cable segments.

6 · 20 **LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN**

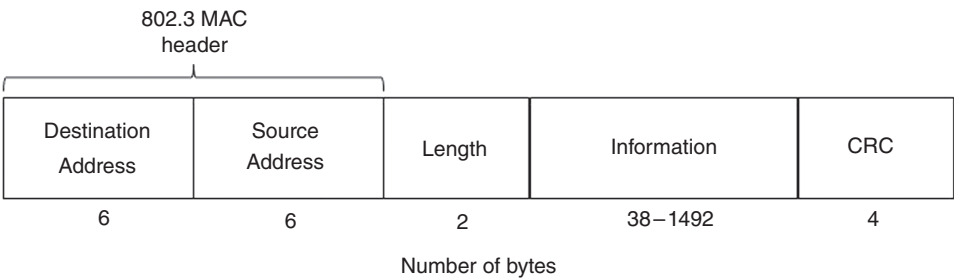

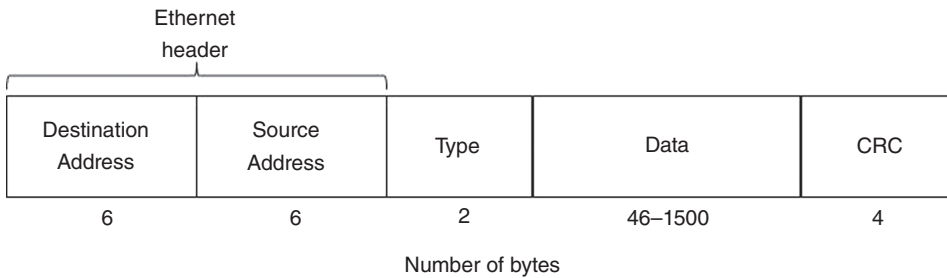

EXHIBIT 6.11 IEEE 802.3 Frame Format

A less expensive version, called *CheaperNet*, was later introduced that operated over thin coaxial cable segments limited to 185 m (610 feet); this PHY is denoted 10BASE2.

In the mid-1980s, AT&T introduced a product called StarLAN, which operated at 1 Mbps over UTP. Although this product has long been relegated to obscurity, it was the first to break the 1-Mbps barrier on UTP. Subsequent versions of 802.3 that employ UTP all use a star topology where each network node connects directly back to a central hub. The first 10-Mbps version of 802.3 was denoted 10BASE-T, the *T* indicating use of the UTP medium (which structured wiring standards say is limited to a distance of 100 m, or 330 feet). The 10-Mbps optical fiber version of 802.3 is 10BASE-F. Today, of course, 100-Mbps and 1-Gbps versions (i.e., 100BASE-T and 1000BASE-T) are available. Full-duplex Ethernet takes advantage of the point-to-point links in a star configuration and effectively doubles the line speed by allowing both stations to transmit at the same time.

Exhibit 6.11 shows the format of an IEEE 802.3 MAC frame, primarily for reference purposes. The fields and their functions are:

- **Preamble.** Used for clock synchronization; employs 7 repetitions of the 8-bit pattern 10101010. (8 binary bits = 1 byte = 1 octet)
- **Start frame delimiter (SFD).** The bit pattern 10101011 denotes the actual beginning of the frame. 1 octet.
- **Destination address (DA).** 48-bit MAC address of the station that should receive this frame. An all-1s address in 48 binary bits (ff-ff-ff-ff-ff-ff in hexadecimal) is the *broadcast address*, indicating that all stations should receive this message.
- **Source address (SA).** 48-bit MAC address of the station sending this frame.
- **Length.** Number of octets in the LLC data field, a value between 0 and 1500. 2 octets.
- **LLC Data.** Data from LLC (and higher layers). This field contains a 3-octet LLC Header, 5-octet 802.2 Subnetwork Access Protocol (SNAP) header, and 38 to 1492 octets of higher layer data.
- **PAD.** Additional octets to ensure that the frame is at least 64 octets in length; this minimum is required by CSMA/CD networks as part of the collision detection mechanism.
- **Frame check sequence (FCS).** Remainder from CRC-32 calculation used for bit error detection. 4 octets.

**EXHIBIT 6.12** Ethernet II Frame Format

6.5.4 Ethernet II. The IEEE's CSMA/CD standard is based on the Ethernet specification developed at Xerox's Palo Alto Research Center (PARC) in the mid-1970s. When Xerox first decided to market Ethernet, there was no OSI model or any LAN standards or products. Given that environment, Xerox sought industry support for this new specification. The Ethernet specification has been jointly distributed (and marketed) by Digital Equipment Corporation (DEC, now Compaq), Intel, and Xerox (hence sometimes known as *DIX Ethernet*). While the 802.3 standard is based on Ethernet II, the two are not exactly the same.

Exhibit 6.12 shows the format of an Ethernet MAC frame, primarily for purposes of comparison to the IEEE frame. The fields and their functions are:

- **Preamble.** Used for clock synchronization; employs the bit pattern 10101010 ... 10101011. 8 octets.
- **Destination address (DA).** 48-bit MAC address of the station that should receive this frame. An all-1s address (ff-ff-ff-ff-ff-ff) is the *broadcast address*, indicating that all stations should receive this message.
- **Source address (SA).** 48-bit MAC address of the station sending this frame.
- **Protocol identifier (PID).** Indicator of the protocol information transported in the Information field. Sample values include 2048 and 2054 to indicate the Internet Protocol (IP) and Address Resolution Protocol (ARP), respectively. 2 octets.
- **Information.** Protocol data unit from the protocol identified in the PID field. 46 to 1,500 octets. (It is the responsibility of the higher layer to ensure that there are at least 46 octets of data in the frame.)
- **Frame check sequence (FCS).** Remainder from CRC-32 calculation used for bit error detection. 4 octets.

The point in comparing the frame formats of Ethernet and 802.3 is primarily of historical purposes because today's implementations are 802.3 and not Ethernet. That said, it is interesting to note that the two specifications are, in fact, different. It is a minor thing, perhaps, and was a common misnomer in the industry to refer to *IEEE 802.3 Ethernet* (even the IEEE 802.3 committee is now known as the *Ethernet Working Group*), but it was an important difference to both a network administrator and a security professional.

In particular, in years past, if one LAN device only understood Ethernet encapsulation, it would not be able to communicate successfully with another LAN device that only understood IEEE 802.3 encapsulation. Both devices, however, can share the same

6 · 22 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

medium backbone because the electronics are the same. A NetWare server running the Internetwork Packet Exchange (IPX) network layer protocol over IEEE 802.3 frames, for example, could easily share the network with a UNIX host running IP over Ethernet, but it maintained some immunity from attack by an IP host for the NetWare server because the two networks could not cross-communicate.

6.5.5 IEEE 802.5 Token-Ring Standard. The IEEE 802.5 token-ring standard was based on the IBM product of the same name. Both the standard and the product date back to about 1985. It is described here for historical purposes.

The token ring has a logical ring topology, although it was built as a physical star. Designed to operate with STP or UTP cable, most implementations operated at speeds of 16 Mbps or higher. The 802.5 MAC was essentially the same as the token passing scheme described in Section 6.4.2. The fields of the MAC frame (see Exhibit 6.13) are:

- **Start delimiter (SD).** Marks the actual beginning of the transmission. Bit pattern JK0JK000, where J and K represent special symbols on the line.¹¹ 1 octet.
- **Access control (AC).** Indicates whether this transmission is a *token* (i.e., no data) or a *frame* (i.e., contains data). This field also contains information about the priority of this transmission. 1 octet.
- **Frame control (FC).** Indicates if this frame carries LLC (and higher-layer) data or MAC management information; if it is MAC-specific information, this field also indicates the MAC frame type. 1 octet.
- **Destination address (DA).** 48-bit MAC address of the station to which this frame is intended.
- **Source address (SA).** 48-bit MAC address of the station sending this frame.
- **Routing information field (RIF).** An optional field, used only in multiple-ring networks utilizing source routing *and* in which the intended receiver is on a different ring than the transmitter. In source routing, the transmitter can specify

the intended path of this frame, designating up to eight intermediate networks.¹² 0 to 18 octets.

- **Information (INFO).** Contains an LLC frame or MAC management information. No maximum length is specified by the standard, but the length of this field will be limited by the time required to transmit the entire frame, controlled by the *token holding time* parameter.
- **Frame check sequence (FCS).** Remainder from a CRC-32 calculation to detect bit errors in the frame. 4 octets.
- **End delimiter (ED).** Demarks the end of the transmission, with the bit pattern JK1JK1IE, where J and K are as described in the SD field. The I-bit indicates whether this frame is the last frame of a multiple-frame sequence and the E-bit indicates whether a bit error was detected by the receiver (E); these bits are cleared by the original sender when the frame returns to that station. 1 octet.
- **Frame status (FS).** The bit pattern AC00AC00; these bits indicate whether the frame's destination address was recognized by any station on the network (A) and whether this frame was successfully copied by the intended receiver (C). 1 octet.

As shown, a token comprises just three octets, the SD, AC, and ED fields. A station sends a frame whenever there is user data or MAC information to send. The station must wait until it receives a *token* before it can generate a *frame*.

The transmitting station is responsible for generating a new token after it transmits a single frame. Recall that the transmitted bits come back to the sender, and it is this station that removes the bits from the network. According to the original standard, the transmitter will send a token after sending all of the bits of the frame and must wait until it has seen at least the returning SA field to verify that it is, in fact, removing its own frame from the network. Optionally, early token release allows the transmitter to generate a new token immediately after finishing sending the bits from its frame, even if the SA field has not yet returned. This latter option was developed to improve performance in very large token ring environments, such as the American National Standards Institute (ANSI) FDDI standard.

Today, 802.5 token rings are primarily limited to IBM environments, and there is a lot to be found there. FDDI is more commonly found in multibuilding campus environments, used as a backbone to interconnect Ethernet/802.3 networks. FDDI is being phased out; the last FDDI product vendor dropped out of the marketplace in 1999.

6.5.6 IEEE 802.2 LLC Standard. The IEEE 802.2 LLC protocol was intended to provide a common interface between 802 LAN MACs and higher-layer applications. With the LLC, the underlying MAC scheme is transparent to the application just as the application is transparent to the MAC.

The LLC was designed to support any number of services, the most common being an unacknowledged connectionless service (primarily used in contention networks) and an acknowledged connection-oriented service (primarily used in token ring environments).

The LLC is loosely based on the Higher-layer Data Link Control (HDLC) bit-oriented protocol in both operation and frame format (see Exhibit 6.14). The LLC frame appears in the Information field of a MAC frame. The first two fields of the LLC header are the *Destination Service Access Point* (DSAP) and the *Source Service Access Point* (SSAP) fields, originally intended to identify the higher-layer services at the source

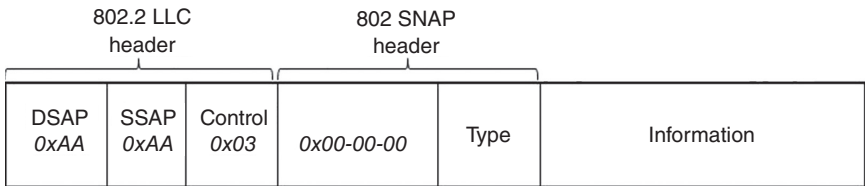

EXHIBIT 6.14 IEEE 802.2 LLC Frame Transporting SNAP Header (which in turn indicates IEEE organization and EtherType protocol identifiers)

and destination node. This is similar in concept to *ports* in the Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) but was never well implemented, and the DSAP and SSAP values are typically the same. The third field is the Control field, identifying the type of frame.

The Subnetwork Access Protocol (SNAP) is an IEEE 802 protocol that can be used to identify *any* protocol created by *any* agency, and is commonly used above the LLC layer. In this case, the SNAP header immediately follows the LLC header. Use of SNAP is indicated by the LLC fields when both DSAP and SSAP fields are set to a value of 170 (0xAA) and the Control field is set to a value of 3 (octal 03) to indicate that it is an Unnumbered Information frame.

The SNAP header has two fields. The 3-byte *Organizationally Unique Identifier* (OUI) field refers to the organization that developed either the higher-layer protocol or a way to refer to the protocol. The 2-byte *Type* field identifies the protocol using the Organization-defined number.

The Internet Protocol (IP) and Address Resolution Protocol (ARP) provide example uses of SNAP. The common format of a SNAP header encapsulating these protocols would be to set the OUI value to 0 (0x00-00-00) to identify IEEE/ISO as the organization. The Type field would then use the *EtherType* values of 2048 (0x08-00) and 2054 (0x08-06) to indicate use of IP and ARP, respectively.

6.5.7 Summary. This section has covered the important LAN standards governing what is most likely to be seen in the industry today. Table 6.1 summarizes some of the discussion about the most common LAN topologies, media, MAC schemes, and standards.

6.6 INTERCONNECTION DEVICES. LAN interconnection devices are used to attach individual LANs to each other in order to build a large enterprise network. They can also interconnect LAN components across a WAN and provide LAN access to the

Internet. Several types of such devices are used for LAN interconnections, including hubs, switches, bridges, and routers. The major distinction between these devices is the OSI layer at which they operate, and all are discussed in the next sections.

6.6.1 Hubs. *Hubs* are used to build physically star-wired LANs, using media that are basically point-to-point in nature (such as UTP and optical fiber). Note that it is the internal wiring of the hub that determines its *logical* nature, so that a logical bus or ring LAN can be physically star-wired.

So-called *Ethernet hubs* support 10, 100, and/or 1,000 Mbps Ethernet or 802.3 networks. Different hubs will have a different number of ports, generally ranging from 4 to 32. Hubs provide physical connectivity only; when a frame arrives on one port, the hub will broadcast the frame back out to all other ports, which simulates the broadcast bus environment. Multiple hubs can be interconnected to form reasonably large networks.

Token-ring hubs, generally called *multistation access units* (MAUs), look similar to Ethernet hubs but have different internal wiring. When an MAU receives a transmission on one port, it merely forwards that transmission, a bit at a time, to the next port sequentially on the MAU. In this way, it simulates the ring environment.

6.6.2 Switches. *Switches* are generally employed in the CSMA/CD environment and extend the capabilities of a hub. A switch operates at a combination of PHY and MAC layers. In addition to providing physical connectivity like a hub, a switch learns the MAC address of all stations attached to it. When a frame arrives on a switch port, the switch looks at the destination MAC address and places the frame on the port associated with that address (which might be the port leading to another switch).

Switches are used primarily to improve performance. Given the scenario described earlier, multiple stations can transmit simultaneously without collision. Furthermore, switches can operate in full-duplex mode, meaning that a single station can both transmit and receive at the same time. A 10 Mbps switched Ethernet LAN, for example, can achieve performance similar to that of a 100-Mbps hubbed Ethernet LAN. (This was a real boon in those environments where it is not viable to upgrade 10-Mbps NICs and wiring.)

There is a subtle security ramification to the use of switches versus hubs. In particular, if a user places a packet sniffer on a hubbed LAN, the sniffer will see every frame because the hub simulates the broadcast environment. A packet sniffer on a switched network will not be as effective; it will only pick up those frames that are specifically addressed to the LAN broadcast address. That said, many switches come with an administrative port that can be set to monitor all ports for troubleshooting purposes.

6.6.3 Bridges. A *bridge* provides a point-to-point link between the two LANs, usually those employing similar MAC schemes. Bridges operate at the MAC layer, and their operation is controlled by the MAC address.

Ethernet environments commonly employ *learning bridges*. In a very simple case, consider a bridge interconnecting two LANs, #1 and #2 (see Exhibit 6.15). When any LAN station sends a frame, both destination and source MAC addresses are included in the transmission. As frames appear on the networks, the bridge sees all of the source addresses and builds a table associating the MAC addresses with one LAN or the other, eventually learning the location of all of the network's stations. This process is sometimes called *backward learning* because the bridge learns the location of stations that transmit.

6 · 26 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

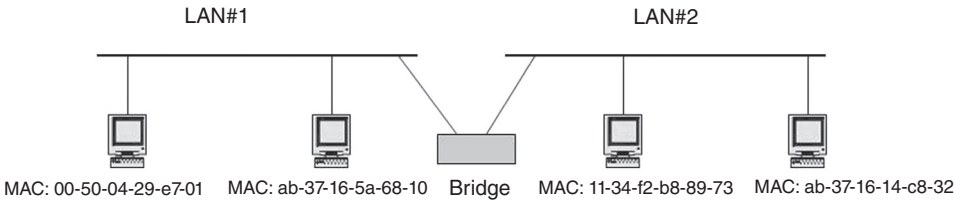

EXHIBIT 6.15 Two LANs Interconnected via a Bridge

A bridge is a simple frame store-and-forward device. Like all stations on the LAN, a bridge examines the destination address of any transmitted frames. If a transmission on LAN #1 contains a destination address of a station on LAN #2, the bridge will forward the frame. If a transmission contains an unknown destination address, the bridge will also forward the frame.

Although a bridge bases its decisions on the MAC address, it is not an intelligent device; that is, it knows that a station with a particular MAC address is in one direction or another, but it does not know precisely where that station is. Because bridges have to build tables containing all of the stations' addresses that they learn, bridges do not scale particularly well to large networks. Bridges also extend the *broadcast domain* (i.e., if a frame transmitted on LAN #1 is sent to the broadcast address, it will be forwarded to LAN #2).

6.6.4 Routers. A *router* is conceptually similar to a bridge in that it is also a store-and-forward device. A router, however, works at the Network Layer and is therefore a much more powerful device than a bridge. As Exhibit 6.16 shows, every LAN device has both a MAC (hardware) and Network Layer (software) address (in this case, IP is the sample Network Layer address). Because Network Layer addresses are hierarchical, the networks themselves have a network identifier number (the *NET_ID* in Exhibit 6.16). Network Layer addresses are well suited to environments where intermediate devices have to find a best route between networks.

Like a bridge, a router is considered to be just another station on a LAN to which it is attached. If the router sees a transmission on LAN #1 (with a *NET_ID* of 192.168.16.0) containing a destination address of a station on another network, it will route the packet to the correct destination network, even if that means going through another router to get there.

This example also demonstrates another major difference between bridges and routers. In a bridged environment, a station on LAN #1 sends a frame to some MAC address and has no knowledge of whether the intended destination is on the same LAN or not; the bridge will forward the frame if necessary, but this is all transparent to sender

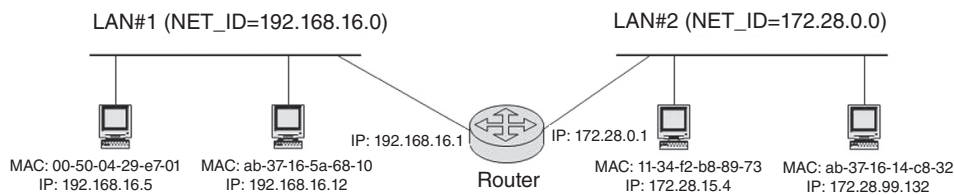

EXHIBIT 6.16 Two LANs Interconnected via a Router

and receiver. In a routed environment, however, the sender can tell if the receiver is on the same or different network merely by examining the destination network address. In fact, the router only gets involved if the packet has to leave the local network; that is why in an IP environment, for example, an address of a default gateway (router) has to be provided.

Routers also limit the broadcast domain. If a station on LAN #1 transmits a frame using the broadcast MAC address, the frame goes no further than the router.

Routers build their routing tables very differently than bridges. Whereas bridges learn the relative location of a station by observing a frame's source address, packets learn the Network Layer address by the use of routing protocols that allow groups of routers to exchange routing information.¹³

6.6.5 Summary. Hubs, switches, bridges, and routers are all commonly employed LAN interconnection devices. These are tools in the kit of everyone who works with LANs, as the building blocks of everything from small and intermediate-size local networks to large enterprise networks and the global Internet.

6.7 NETWORK OPERATING SYSTEMS. Just as an operating system manages computer resources, a *network operating system* (NOS) provides the software that controls the resources of a LAN. NOSs generally comprise software that provides at least these functions:

- *Hardware drivers* are the software that allows the NOS to communicate with the NIC.
- *Communications software* allows applications running on different LAN nodes to communicate.
- *Services* are the functional aspects of the NOS and the reason that people use a LAN in the first place. Sample services include file services (file sharing), print services (commonly shared printers), message services (email), communication services (LAN access to the Internet), and fax services (commonly shared facsimile).

NOSs are typically classified as being peer to peer or client/server. A *peer-to-peer* LAN allows any LAN node to communicate with any other LAN node, and any LAN node can provide services to other nodes. In a *client/server* (or *server-based*) environment, every node is either a client or a server. In this scenario, *servers* are special nodes that offer services to other servers or to clients, while *clients* are the ordinary end-user workstations. Clients can only communicate with a server.

When evaluating or investigating the security of a LAN, the software is the most common point of exposure, vulnerability, and exploitation, particularly for remote attacks.

Some sample NOSs that have had historical significance include:

AppleTalk. Apple Macs have come with integrated LAN capabilities since their inception in 1985. Originally using a scheme called LocalTalk, AppleTalk was a peer-to-peer network running over a 10-Mbps CSMA/CD LAN. The Network Layer protocol historically associated with AppleTalk was called the

Datagram Delivery Protocol (DDP). Apple dropped support for AppleTalk in 2009 and supports TCP/IP-based networking.

Microsoft Networking. Microsoft operating systems have come with LAN capabilities since Windows for Workgroups (WfW or Windows 3.11). Employing a nonroutable protocol called the Network Basic Input/Output System (NetBIOS) Extended User Interface (NetBEUI), Windows client systems (Windows 3.11 and later) can be easily used to build an inexpensive, simple peer-to-peer LAN for file and print sharing. NetBEUI is nonroutable because it does not provide an addressing mechanism to allow interconnected yet distinct NetBEUI subnetworks; if two NetBEUI networks are attached in any way, they will appear to be one large network. (This is why the hard drive of improperly configured Windows systems can be viewed from across the Internet.) Microsoft defined NetBIOS over TCP/IP (NBT) in the 1980s to support encapsulation of NetBIOS messages in TCP and UDP messages. Most Microsoft networking today relies more on TCP/IP than NetBEUI.

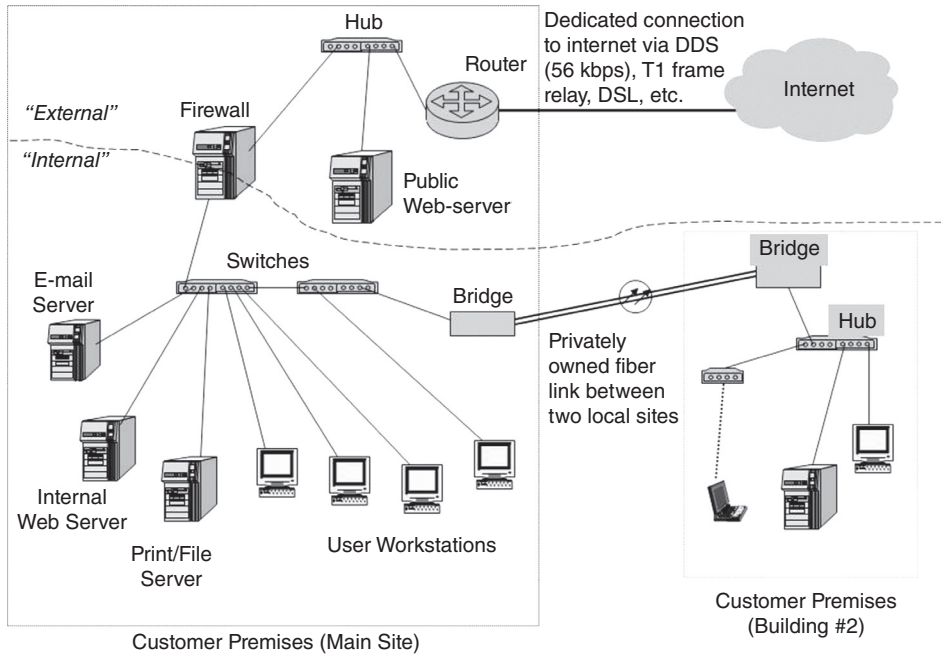

Microsoft Windows Server (including Windows NT Server, Windows Server 2003, Windows Server 2008, and Windows Server 2012). The NOS of choice for Windows network environments, Windows Server is Microsoft's client/server operating system. Client systems can run nearly any Windows operating system, from Windows XP or NT Workstation to Windows VISTA, Windows 7, or Windows 8. Clients on a Windows Server network themselves can form a peer-to-peer network. Microsoft networking is reliant on Active Directory and TCP/IP.

Novell NetWare. Novell offered one of the first PC-class networks in the early 1980s using a proprietary star-based LAN. By the 1990s, NetWare was the best-known client/server NOS and accounted for more than 70 percent of the NOS market. The Network Layer protocol associated with classical NetWare is the Internetwork Packet Exchange (IPX) protocol. By the turn of the century, Microsoft was eating dramatically into NetWare's popularity and TCP/IP was dominating as the protocol-of-choice. At around this time, Novell embraced Linux and TCP/IP, and NetWare has been replaced with the Open Enterprise Server.

UNIX and Linux. TCP/IP has been the network communications protocol for UNIX systems since 1984, allowing UNIX-based hosts to build client/server (and, ultimately, peer-to-peer) networks. TCP/IP has also been integral to Linux since its inception in 1991. With TCP/IP, any system can run server (daemon) software to provide services to other systems, so that any system can act as a client or server, depending on application.

6.8 SUMMARY. Exhibit 6.17 shows a possible network design that includes many of the elements that have been described in this chapter (and a few that have not). This network's router provides the interface to the Internet and is attached via some sort of dedicated connection, such as a point-to-point 56 Kbps or T1 (1.544 Mbps) leased line, frame relay, or digital subscriber line.

In this scenario, the router is physically located at the main site. From a security perspective, the organization may segment its network into an *external* and *internal* side, the internal being protected by a firewall.¹⁴ The external network includes the router, public Web server, and firewall. Those three systems are interconnected through

**EXHIBIT 6.17** LAN Scenario

a hub to which they each attach via a Cat 5 UTP cable. In this scenario, the hub could actually implement 10BASE-T or 100BASE-T Ethernet, or even a token ring.

The external and internal networks are connected through the firewall, which, in this case, will have two NICs. The two networks are separate and distinct; the firewall does not extend the broadcast domain of either network, and, in fact, these two networks would have different IP network identifiers.

The internal network at the main site is a collection of servers and user workstations that are interconnected via a set of switches. In this example, these are 8-port 100-Mbps Ethernet switches. Since there are more than 8 devices, the switches themselves need to be interconnected. There are several options for that:

- *Stackable* switches physically attach to each other, extending the switch's backplane to create a larger switch (in this case, a 16-port switch).
- An *optical fiber* link can be used to interconnect the switch, usually at backplane speeds in the 1+-Gbps range.
- A *UTP* link might be used to interconnect the switches via two of the 100-Mbps ports.

To connect the LAN in Building #2 with the LAN at the main site, a point-to-point connection between a pair of bridges would suffice. In this case, the buildings are several kilometers apart, necessitating use of optical fiber.

In Building #2, there is another hub-based LAN, with a laptop using wireless technology, communicating with an access node that is also attached to the hub.

This chapter has only skimmed the surface of LAN concepts, standards, and technologies. Their study is important to the security professional, however, because LANs are the basis of all networking. As a *network of networks*, the Internet comprises

6 · 30 LOCAL AREA NETWORK TOPOLOGIES, PROTOCOLS, AND DESIGN

millions of local networks. This chapter indicates many of the points of potential vulnerability or compromise in a system.

6. Since CSMA/CD transmits with a probability of 1, it is sometimes referred to as being 1-persistent.
7. As an aside, although the station can experience 16 collisions, the probability of transmission will never fall below 1/1024, or 2⁻¹⁰, since Ethernet and IEEE 802.3 do not allow more than 1,024 devices on the network. This is the source of the word “truncated” in the name of the scheme.

9. A WG is disbanded when it is considered that there is no more work for the IEEE to undertake in this topic area.
10. A WG will go into hibernation when there are no new projects to undertake. This status indicates a WG that has reached status quo.
11. The term “special symbol” requires explanation. The signaling scheme used in the token ring PHY standard is called Differential Manchester. In this signaling scheme, the signal is at a positive voltage for half of the bit time and at a negative voltage for the other half of the bit time, meaning that each bit has a sum total of 0 volts (resulting in what is sometimes called DC balancing). The J and K symbols are Differential Manchester code violations, where one symbol is at negative voltage for an entire bit time and the other at positive voltage for an entire bit

time. These code violations have the benefit of being able to indicate special events and can be used for synchronization. J and K symbols are always used in pairs to maintain DC balancing.

12. Source routing is a very rarely used option in IP and is, in fact, a security problem; firewall administrators routinely set up filters to block IP packets with source routing. Source routing in an 802.5 network, however, is a normal feature and is not considered to be a security threat because this information has no impact on the WAN.
13. In the IP environment, common routing protocols include the Border Gateway Protocol (BGP), Open Shortest Path First (OSPF), and Routing Information Protocol (RIP).
14. This is a very simplistic firewall design with the internal and external network. The focus of this diagram is on the LAN components, however, rather than the specific security architecture.

7.1 INTRODUCTION TO CRYPTOGRAPHY. The ability to transform data so that they are accessible only to authorized persons is just one of the many valuable services performed by the technology commonly referred to as encryption. This technology has appeared in other chapters, but some readers may not be familiar with its principles and origins. The purpose of this chapter is to explain encryption technology in basic terms and to describe its application in areas such as file encryption, message scrambling, authentication, and secure Internet transactions. This is not a theoretical

7 · 2 ENCRYPTION

or scientific treatise on encryption, but a practical guide for those who need to employ encryption in a computer security context.

Organizations around the world increasingly rely on cryptography to communicate securely and to store information safely. Typically, the algorithms used by the Department of Defense (DoD) organizations are employed and maintained for many years. For example, the Data Encryption Standard (DES) has been used in some form for over 20 years.¹

This chapter is a brief overview of cryptography and its practical applications to the needs of normal business users, as distinct from the needs of high-security government agencies. A thorough examination of the mathematics that are the foundation of these topics is beyond the scope of this chapter, but we provide suggested readings for further study.

7.1.1 Terminology. This list of basic terms will be helpful for readers as they continue through this chapter:

Algorithm—a finite list of well-defined instructions for accomplishing some task that, given an initial state, will terminate in a defined end state.

Cipher—the core algorithm used to encrypt data. A cipher transforms plaintext into ciphertext that is not reversible without a key.

Ciphertext—text in encrypted form, as opposed to the plain text. We show ciphertext in UPPERCASE throughout this chapter.

Codes—a list of equivalences (a *codebook*) allows the substitution of meaningful text for words, phrases, or sentences in an innocuous message; for example, “I will buy flowers for Mama tomorrow for her party at 7 pm” might be decoded to mean “Launch the attack on the mother ship next week on Sunday.”

Decrypt/Decipher—the process of retrieving the plaintext from the ciphertext.

Encrypt/Encipher—to alter plaintext using a secret code so as to be unintelligible to unauthorized parties.

Key—a word or system for solving a cipher or code.

Plaintext—the original message to be encoded or enciphered. We show plaintext in lowercase throughout this chapter.

The science of cryptology (sometimes abbreviated as *crypto*) is the study of secure communications, formed from the Greek words *κρυπτος* (*kryptos*), meaning “hidden,” and *λογος* (*logos*), “word.” More specifically, it is the study of two distinct, yet highly intertwined, fields of study: cryptography and cryptanalysis. Cryptography is “the science of coding and decoding messages so as to keep these messages secure.”² Cryptanalysis is the art and science of “cracking codes, decoding secrets, violating authentication schemes, and in general, breaking cryptographic protocols,”³ all without knowing the secret key. Systems for encrypting information are referred to as *cryptosystems*.

Systems for encrypting information may also be referred to as *ciphersystems*, from *cipher*, meaning “zero,” or “empty” (a word rooted in the Arabic *sifr*). Terms using cipher and crypto are interchangeable, with some authors preferring cipher to avoid the religious and cultural connotations of *crypt*, a word with the same root as “encryption.” Thus, encryption may be referred to as encipherment, decryption referred to as decipherment, and so on.

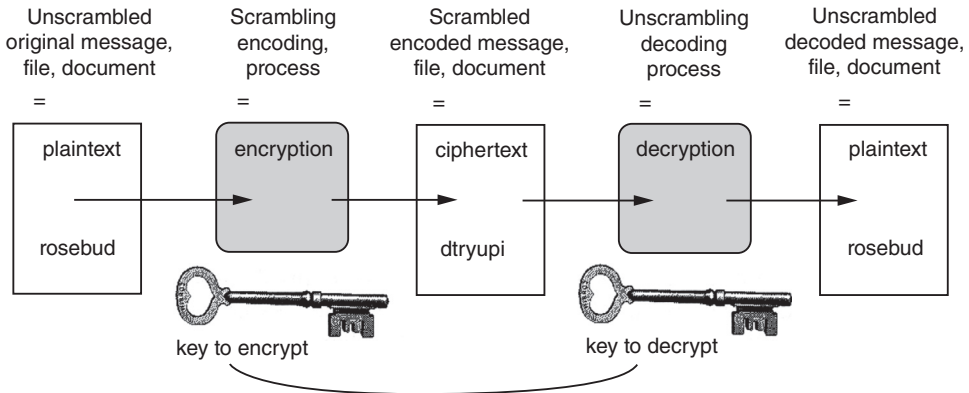

EXHIBIT 7.1 Diagram of Cryptographic Terms

The most obvious use of encryption is to scramble the contents of a file or message, using some form of shared secret as a *key*. Without the key, the scrambled data remain hidden and cannot be unscrambled or *decrypted*. The total number of possible keys for an encryption algorithm is called the *keyspace*. The keyspace is a function of the length of the key and the number of possible values in each position of the key. For a *keylength* of n positions, with each position having v possible values, then the keyspace for that key would be v^n . For example, with three positions and two values per position (e.g., 0 or 1), the possible keys would be 000, 001, 010, 011, 100, 101, 110, and 111 for a total keyspace of 8.

In cryptographic terms, the contents of a file before encryption are *plaintext*, while the scrambled or encoded file is known as *ciphertext* (see Exhibit 7.1). As a field of intellectual activity, cryptology goes back many millennia. Used in ancient Egyptian, China, and India, it was discussed by the Greeks and regularly employed by the Romans. The first European treatise on the subject appeared in the fourteenth century. The subject assumed immense historic importance during both world wars. The British success in breaking codes that the Germans used to protect military communications in World War II was a major factor in both the outcome of the war and in the development of the first electronic computer systems.

Since then, cryptography and computer science have developed hand in hand. In 1956, the United States National Security Agency (NSA), the U.S. Government department in charge of monitoring the worldwide flow of information, began funding improvements in computer hardware, pumping some \$25 million into Project Lightning. This five-year development effort, intended to produce a thousand-fold increase in computing power, resulted in over 150 technical articles. It also gave rise to more than 300 patent applications and succeeded in advancing the frontiers of hardware design. The NSA, based in Fort Meade, Maryland, was also involved in the creation of DES as the commercial encryption standard for much of the last 20 years. Today, the NSA is widely believed to have the world's largest collection of supercomputers and the largest staff of cryptanalysts.

7.1.2 Role of Cryptography. The central role of cryptography in computer security is ensuring the confidentiality of data. But cryptography can support other pillars of computer security, such as integrity and authenticity. This section looks at the different roles of cryptography.

7 · 4 ENCRYPTION

7.1.2.1 Confidentiality. The role of encryption in protecting confidentiality can be seen in a classic definition of encryption: “Encryption is a special computation that operates on messages, converting them into a representation that is meaningless for all parties other than the intended receiver.”⁴

Much of the literature on cryptography discusses the technology in terms of ensuring the confidentiality of messages, but this is functionally equivalent to protecting the confidentiality of data. The use of the term “message” reflects the traditional use to which cryptography has been put, both before and after the advent of computers. For example, Julius Caesar encrypted messages to Cicero 2,000 years ago, while today messages between a Web browser and a Web server are encrypted when performing a “secure” transaction.

When applying cryptography to computer security, it is sometimes appropriate to substitute the term “files” for “messages.” For example, hard drive encryption programs protect data files stored on a hard drive. However, data files take the form of messages when they are transferred from one computer to another, across a network, the Internet, or via phone lines. Practically speaking, data being transferred in this manner are exposed to a different set of dangers from those that threaten data residing on a computer in an office. Thus, the use of encryption to render files useless to anyone other than an authorized user is relevant both to files in transit and to those that reside on a server or a stand-alone computer, particularly when the latter is a laptop, notebook, or PDA.

7.1.2.2 Integrity. In the second half of the last century, following the advent of programmable computer systems, the ability of cryptography to transform data was applied in many new and interesting ways. As will be seen in a moment, many cryptographic techniques use a lot of mathematical calculation. The ability of computers to perform many calculations in a short period of time greatly expanded the usefulness of cryptography, and also inspired the development of ever-stronger ciphersystems.

Maintaining the integrity of data is often as important as keeping them confidential. When writing checks, people take pains to thwart alteration of the payee or the amount. In some cases, integrity is more important than confidentiality. Changing the contents of a company press release as it passes from the company to the press could have serious consequences. It is not only human actions that threaten data integrity; mechanical failures and logical errors can also change data. It is vital that such changes be detected, as was discussed in Chapter 4 of this *Handbook*, where it was observed that “[a]ll data movements and translations increase the likelihood of internal error, and for this reason parity checks and validity tests have become indispensable.”

That chapter covered the role of parity bits for error detection, the function of redundancy checks, and the use of checksums to provide a modification-detection capability. A type of cryptographic hash or checksum called a Message Authentication Code (MAC) can protect against intentional, but unauthorized, data modification as well as against accidental modification. A MAC is calculated by applying a cryptographic algorithm and a secret value, called the *key*, to the data. The data are later verified by applying the cryptographic algorithm and the same secret key to the data to produce another MAC; this MAC then is compared to the initial MAC. If the two MACs are equal, then the data are considered authentic (see diagram in Exhibit 7.2, which uses the public key cryptosystem, discussed later). Otherwise, an unauthorized modification is assumed (any party trying to modify the data without knowing the key would not know how to calculate the appropriate MAC corresponding to the altered data).

7.1.2.3 Authentication. In the context of computer security, authentication is the ability to confirm the identity of users. For example, many computers now ask users to log on before they can access data. By requesting a user name and password, systems attempt to assure themselves that only authentic users can gain access. However, this form of authentication is limited—it merely assures that the person logging on is someone who knows a valid user name and password pair. Cryptography plays a very important role in efforts to ensure stronger authentication, from encrypting the password data to the creation and verification of electronic identifiers such as digital signatures. These will be described in more detail later in this chapter, along with the differences between public key and private key cryptography, both of which may be used in these schemes.

Using a public key system, documents in a computer system can be electronically signed by applying the originator's private key to the document. The resulting digital signature and document then can be stored or transmitted. The signature can be verified using the public key of the originator. If the signature verifies properly, the receiver has confidence that the document was signed using the private key of the originator and that the message had not been altered after it was signed. Because private keys are known only to their owner, it is also possible to verify the originator of the information to a third party.

7.1.2.4 Nonrepudiation. An aspect of computer security that has increased greatly in significance, due to the growth in internetwork transactions, is nonrepudiation. For example, if someone places an electronic order to sell stocks that later increase

7 · 6 ENCRYPTION

in value, it is important to prove that the order definitely originated with the individual who placed it. Made possible by public key cryptography, nonrepudiation helps ensure that the parties to a communication cannot deny having participated in all or part of the communication.

7.1.3 Limitations. One role that cryptography cannot fill is defense against data destruction. Although encryption does not assure availability, it does represent a very valuable extra line of defense for computer information when added to physical security, system access controls, and secure channels of communication. Indeed, when computers are mobile, or data are being communicated over insecure channels, encryption may be the main line of defense. However, even though applied cryptography can provide computer users with levels of security that cannot be overcome without specialized knowledge and powerful computers, encryption of data should not be thought of as an alternative to, or substitute for, system access control. According to Seberry and Pieprzyk⁵, the role of cryptography is to protect “information to which illegal access is possible and where other protective measures are inefficient.”

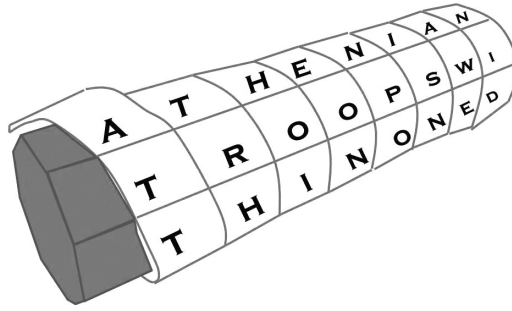

Encryption-based file access controls should be a third barrier after site and system access controls, if for no other reason than that encryption systems alone do little to prevent people deleting files.

7.2 BASIC CRYPTOGRAPHY. The aim of cryptography is to develop systems that can encrypt plaintext into ciphertext that is indistinguishable from a purely random collection of data. This implies that all of the possible decrypted versions of the data except one will be hopelessly ambiguous, with none more likely to be correct than any of the others. One of the simplest ways to create ciphertext is to represent each character or word in the plaintext by a different character or word in the ciphertext, such that there is no immediately apparent relationship between the two versions of the same text.

7.2.1 Early Ciphers. It is believed that the earliest text to exhibit the baseline attribute of cryptography, having a slight modification of the text, occurred in Egypt nearly 4,000 years ago. A scribe used a number of unusual symbols to confuse or obscure the meaning of the hieroglyphic inscriptions on the tomb of a nobleman named Khnumhotep II.⁶

It is also believed that the first effective military use of cryptography was a simple transposition cipher (see Section 7.3.3) by the Spartans, who “as early as 400 BCE employed a cipher device called the scytale for secret communication between military commanders.”⁷ The scytale was a cylindrical or tapered stick with a thin strip of leather or parchment wrapped around it spirally.⁸ The message to be hidden was written lengthwise with no blank spaces. When unraveled, the parchment appeared to hold nothing but random letters. To read the parchment, the recipient had to have a stick with exactly the same dimensions as the sender. The distribution of appropriate decoding scytales took place before the military commanders departed for the field.⁹ For example, a particular combination of stick and strip could allow the cleartext (shown in lowercase):

atheniantroopswithinonedaysmarchofromebereadynow

**EXHIBIT 7.3** Scytale in Use

to be broken into up to six rows of eight letters to be written across the rolled-up strip, in this way:

athenian
troopswi
thinoned
aysmarch
ofromebe
readynow

The message might appear on the scytale as shown schematically in Exhibit 7.3.

Reading the unwrapped strip without the stick would produce this ciphertext (shown in uppercase):

ATTAORTRHYFEHOISREEONMODNPOAMYISNRENAWECBONIDHEW

“The first attested use of [a substitution cipher] in military affairs comes from the Romans.”¹⁰ During that time, Julius Caesar encoded all his messages by simply replacing every letter with the letter three positions away. For example, the letter *a* would become the letter *d*, the letter *b* would become the letter *e*, and so on. Now called the Caesar cipher, this scheme is best-known of all the monoalphabetic algorithms (see Section 7.2.5).¹¹ Consider the Caesar cipher illustrated in the next comparison using the modern English alphabet, with the letters of the alphabet simply shifted three places.

Plaintext: abcdefghijklmnopqrstuvwxyz
Ciphertext: DEFGHIJKLMNOPQRSTUVWXYZABC

To encrypt a message, the sender finds each letter of the message in the plaintext alphabet and uses the letter below it in the ciphertext alphabet. Thus, the clear message:

Plaintext: beware the ides of march

is transformed into the encrypted message:

Ciphertext: EHZDUH WKH LGHV RI PDUFK

EXHIBIT 7.4 Code Wheels and the NSA Seal

This type of cipher is known as a *substitution cipher*. Although the Caesar cipher is relatively simple, substitution ciphers can be very powerful. Most examples of the Caesar cipher shift the alphabet three places, as shown, so that the ciphertext line begins with *d*, but some authors suggest Caesar might have used other numbers, so the term “Caesar cipher” is used for all ciphers that conform to this algorithm (an *algorithm* being a formula or recipe for solving a problem).

This level of encryption might seem rudimentary, but it is an important starting point for much that follows. For example, one way to visualize the Caesar cipher is as a pair of rings, one inside the other, as shown in Exhibit 7.4. Both circles contain the letters of the alphabet. If one is rotated relative to the other, the result is a cipher wheel, something well suited to automation. Eventually this happened, at first mechanically, then electrically, and today digitally. Automation facilitates repetition, and messages encrypted with a substitution cipher can be more difficult to decipher if multiple different substitutions are used. Thus, the code wheel earned a place in the seal of the NSA, the U.S. government agency most influential in the development of encryption.

7.2.2 More Cryptic Terminology. The key or password for the Caesar cipher presented in the last section is the number of places the alphabet has been shifted, in this case three. Because this key must be kept private in order for the message to remain protected, it must be delivered to the recipient for the message to be decoded, or decrypted, back to plaintext. That is why the Caesar cipher is described as a *private key* algorithm and also a *symmetrical encryption* algorithm, the same private key being used to encrypt and decrypt the message. Algorithms of this type can be defeated by someone who has the key, an encrypted message, and knowledge of the algorithm used. This might sound like a statement of the obvious; however, as will be seen later in this chapter, there are encryption algorithms that use keys that can be openly exchanged without rendering the encrypted data accessible. Knowledge of the algorithm used can often be derived, or reverse-engineered, by analysis of its output.

Another seemingly obvious fact is that when a private key cipher is used in an effort to achieve confidentiality, one problem is swapped for another. The problem of exchanging messages while keeping the contents from unintended recipients is replaced by the problem of exchanging keys between sender and receiver without disclosing the keys. This new problem is known as the *key-exchange problem*. The key-exchange problem will be examined in more detail later.

7.2.3 Basic Cryptanalysis. “The first people to understand clearly the principles of cryptography and to elucidate the beginnings of cryptanalysis were the Arabs.”¹² By the fifteenth century, they had discovered the technique of letter frequency distribution analysis and had successfully decrypted a Greek message on its way to the

Byzantine Emperor.¹³ In 1492, a man known as al-Kalka-shandi described this technique in an encyclopedia. He also described several cryptographic techniques, including substitution and transposition ciphers.¹⁴

Returning to the Caesar cipher, consider how this code could be broken using the science of cryptanalysis. When examined for a length of time, this particular code is fairly transparent. As soon as several letters are identified correctly, the rest fall into place. For example, because “the” is the most common three-letter word in the English language, testing “XLI” against “the” reveals that each letter of plaintext has a fixed relationship to the ciphertext: a shift of three to the right.

If that difference is applied to the rest of the message, the result is a piece of plaintext that is intelligible and thus assumed to be the correct solution to the problem. However, even in this simple example several sophisticated processes and assumptions are at work; they deserve closer attention before looking at more complex codes. First, the test of “the” against “XLI” assumes that the plaintext is English and that the attacker has some detailed knowledge of that language, such as the frequency of certain words. Second, it is assumed that the ciphertext follows the plaintext in terms of word breaks. Typically, this is not the case. Ciphertext usually is written in blocks of letters of equal length to further disguise it, as in:

Ciphertext: EHZDU HWKHL GHVRI PDUFK

When the recipient of the message decrypts it, the result, while not exactly easy reading, is nevertheless entirely intelligible:

Plaintext: bewar ethei desof march

Also note the convention of ignoring the case of individual letters and placing all plaintext in lowercase while all ciphertext is in capitals.

7.2.4 Brute Force Cryptanalysis. The next thing to note about the Caesar cipher is that, using the English alphabet, there are 26 possible keys. This means that someone intercepting the encrypted message could mount a standard form of attack known as *brute force cryptanalysis*. This method runs possible keys through the decryption algorithm until a solution is discovered. Statistically speaking, the correct key is reached after testing only half of all possible keys. In Exhibit 7.5, a spreadsheet table details a brute force attack on the Caesar ciphertext. In the example, the plaintext appears in line 6, Key #3.

Note that three items of information are required for this attack, and all three of them are relevant to encryption on personal computers:

1. A knowledge of the encryption algorithm used
2. The number of possible keys
3. The language of the plaintext

Using a computer in an office is somewhat different from sending messages on the field of battle (at least on a good day). Unlike an enemy spy, someone who is attempting to gain unauthorized access to data already has a fairly good idea of which algorithm is being used. (There are relatively few in use, and they often are directly associated with particular applications). This takes care of the first item. The primary obstacle to a brute force attack is the second item, number of keys. In the case of the Caesar

EXHIBIT 7.5 Brute Force Attack on the Caesar Cipher

cipher, the number of possible keys is relatively small, so the work involved in carrying out the attack can be completed very quickly, which is highly significant. Time is often the most important factor in practical cryptanalysis. Being able to decrypt messages within 24 hours is of little use if the information pertains to events that are measured in minutes, such as orders to buy and sell stock, or to launch air raids. If the cipher consisted entirely of random letter substitutions, like this:

Plaintext: abcdefghijklmnopqrstuvwxyz
 Ciphertext: UTWFRAQYSEDCKJVBXGZIPHLNM

The number of possible keys (the *keyspace*) is now $26!$, or $\sim 4.03 \times 10^{26}$, which looks even more daunting when written out:

403,291,461,126,606,000,000,000,000

Imagine a brute force attack using a computer that can perform 1 million decryptions per microsecond (considerably more number crunching than the average personal computer can perform). Using a single processor, it could take over 10 million years to execute a brute force attack on this code. Fortunately for the code breaker, there are other ways of cracking substitution ciphers, as discussed in a moment. The point is that, while brute force attacks are possible, they are not always practical.

Although it is true that by the central limit theorem of statistics, the most likely number of trials required to hit on the correct key is one-half the total keyspace, the average reduction by a factor of 2 is negligible in the face of computational periods measured in years and the difficulty of identifying cleartext in the morass of incorrect decryptions.

Functionally, brute force attacks depend on knowing which encryption algorithm is behind the ciphertext. Practically, they depend on the feasibility of successes within an appropriate time frame. They also depend on the third item of information in the list above: knowledge of the language of the plaintext. The solution to the Caesar cipher in Exhibit 7.5 tends to jump out because it is closer to plain English than any of the other solutions. However, without knowing what constitutes plaintext, a brute force attack will, at best, be inefficient, and, at worst, unsuccessful. This part of cryptanalysis, recognizing a positive result, is less amenable to automation than any other. The difficulty is compounded by encryption of purely numerical results where the correct cleartext can be impossible to determine without extensive additional knowledge.

7.2.5 Monoalphabetical Substitution Ciphers. Both the Caesar cipher and the random substitution cipher shown are examples of monoalphabetic ciphers. This means that one letter of ciphertext stands for one letter of plaintext. This renders such codes susceptible to an attack quite different from brute force. Suppose a customs officer attempts to discover when and how an illegal weapons shipment will be entering the country. The following message is intercepted:

YZYGJ KZORZ OYXZR RKZRK XUXRJ XRZXU YKQQQ

The person who encoded this text clearly substituted new letters for the original letters of the message. To the experienced code breaker or cryptanalyst, the task of deciphering this message is quite a simple one. First count how many times each letter occurs in the text. This produces a list like this:

Ciphertext: R Z X Y K J U O G
Frequency: 6 6 5 4 4 2 2 2 1

Note that the last three letters are discounted as they are merely filling out the five-letter grouping. Next refer to a table of frequencies, which shows the relative frequency with which the letters of the alphabet occur in a specific language or dialect of that language. One such list is shown in Exhibit 7.6. This list was created for this example and proposes that the most commonly used letters in English in descending order of frequency are *e, t, r*, and so on. The actual order is more likely to be *e, t, a, i, o, n, s, h, r, d, l, u*, the order of keys on the English Linotype machine from the nineteenth century, although the precise order of frequencies can vary according to the region of origin or subject matter of the text.

Assuming that the original message is in English, a list that matches code letters to plaintext letters is easily derived.

Ciphertext: R Z X Y K J U O G
Frequency: 6 6 5 4 4 2 2 2 1
Plaintext: e t r i n o a h s

The result is:

Ciphertext: YZYGJ KZORZ OYXZR RKZRK XUXRJ XRZXU YKQQQ
Plaintext: itiso nthet hirte enten raro retrainqq

This is readable as “it is on the thirteen ten rare ore train.” Although this example obviously was contrived to make a point, it clearly illustrates an important cryptographic

tool that can quickly decipher something that at first seems to be very forbidding. The encryption in the previous example could have been based on a simple substitution cipher. For example, after using the password “TRICK” followed by the regular alphabet minus the letters in the password for the plaintext, the ciphertext is the alphabet written backward:

Plaintext: TRICKABDEFGHJLMNOPQSUVWXYZ
Ciphertext: ZYXWVUTSRQPONMLKJIHGFEDCBA

Frequency analysis also works if the substitution is entirely random, as in the example shown earlier, the key for which is entirely random. The specialized tools, such as frequency tables, that are required to break codes point out a basic trade-off: If a basic level of protection is needed, it is easy to get but also easy to break, at least for an expert. The qualification “for an expert” is important because users of encryption need to keep its role in perspective. The salient questions are: Who can gain from decrypting the data, and what means do they have at their disposal? There is no point investing in powerful encryption hardware or software if those likely to attempt to read your files are not particularly sophisticated, dedicated, or well equipped. For example, a person who mails a postcard knows it can be read by anyone who sees it. Envelopes can be used to prevent this, hardly the ultimate in confidentiality, but widely used and relatively successful nonetheless.

7.2.6 Polyalphabetical Substitution Ciphers. Even when the plaintext uses a wider range of letters than the contrived example, substitution ciphers can be cracked by frequency analysis. A powerful technique is to concentrate on the frequency of two-letter combinations, which are known as *digraphs*, the most common of which in English is “TH.” One way to counter frequency analysis is to use multiple substitutes for the more frequent letters. This cannot be done with a straightforward alphabetic coding. However, if using numbers for letters, it is possible to assign multiple numbers to some letters, such as 13 17 19 23 for E, which would help dilute the natural frequency of this letter. It would appear that supplying multiple substitutions, known as *homophones*, in proportion to the frequency of each letter would effectively

counter frequency analysis. However, some of the underlying structure of the plaintext still survives, notably digraphs, which the cryptanalyst can use to crack the code.

In Europe during the Middle Ages, advances in cryptography were being made by the Papal States and Italian city-states to protect diplomatic messages. Then, in 1379, an Italian man named Gabriele de Lavinde created the first European manual on cryptography. “This manual, now in the Vatican archives, contains a set of keys for 24 correspondents and embraces symbols for letters, nulls, and several two-character code equivalents for words and names.”¹⁵ The nomenclature described by Lavinde’s manual “was to hold sway over all Europe and America for the next 450 years.”¹⁶

Several other notable advances emerged in Europe during the period of Lavinde’s manual. First, in 1470, Leon Battista Alberti published the first description of a cipher disk.¹⁷ Next, in 1563, Giambattista della Porta provided the first example of a digraphic cipher in which two letters are represented by one symbol.¹⁸

One method of decreasing the extent to which the structure of the plaintext is reflected in the ciphertext is to encrypt multiple letters of the plaintext. For example, “AR” might be encrypted as “CM.” This is the theory behind what is known as the Playfair cipher, which was invented in 1854 by a British scientist, Sir Charles Wheatstone, but that was named after his friend Baron Playfair who fought for its adoption by the British Foreign Office.¹⁹ Although the Playfair cipher remained in use through both world wars, it does not do enough to disguise the plaintext and cannot withstand a concerted frequency analysis.

7.2.7 The Vigenère Cipher. A particularly important technique in the evolution of polyalphabetic ciphers has its roots in the sixteenth century. In 1586, Blaise de Vigenère published a square encryption/decryption table, named after him as the Vigenère Square, and descriptions of the first plaintext and ciphertext autokey systems.²⁰ The Vigenère cipher involves a table of letters, like the one shown in Exhibit 7.7, that are used with a key to provide different monoalphabetic substitutions as the encryption proceeds through the plaintext. Thus, each letter of the ciphertext has a different relationship with the plaintext, like this:

```
Key:          doomsdaydoomsdaydoomsdaydoomsday
plaintext:    sellentireportfolionowandbuygold
ciphertext:   VSZXWQTGJIAZVGYWCMBFPFBOJIKUKLQ
```

The message is enciphered by looking at the row in the table that begins with the first letter of the key. Then go along that row until the column headed by the first letter of the plaintext. The ciphertext substitution is the letter at that intersection in the table. Thus, row d, column s, yields V. Then proceed to the second letter, and so on. Note that the first time the letter *e* is encrypted the cipher is S, but the second time it is W. The two *l*s in sell are encoded as Z and X, respectively, and so on.

Does this cipher completely obscure the structure of the plaintext? Stallings notes: “If two identical sequences of plaintext letters occur at a distance that is an integer multiple of the keyword length, they will generate identical ciphertext sequences.”²¹ This means that the cryptanalyst can determine the length of the keyword. Once this is done, the cipher can be treated as a number of monoalphabetic substitutions, that number being equal to the key length. Frequency tables are again brought into play, and the code can be cracked. The cryptographer’s response to this weakness is to use a longer key so that it repeats less often. In fact, one technique, *autokey*, invented by

Vigenère, is to form the key from the plaintext itself, together with one code word, like this

plaintext:    sellentireportfolionowandbuygold
ciphertext:   VSZXWQTGJIAZVGYWCMDBFPFBOJILUKLQ
```

This system is very powerful, but it still can be attacked by statistical analysis based on frequencies, because the letters of the plaintext and key share roughly the same frequency distribution. The next level of defense is to use a keyword that is as long as the plaintext but bears no statistical relationship to it. This approach, which is of great cryptographic significance, was not hit upon until the twentieth century arrived, bringing with it binary code and global warfare.

7.2.8 Early-Twentieth-Century Cryptanalysis. The advent of modern cryptography began with the invention and development of the electromagnetic telegraph system and the introduction of the Morse code. Samuel Morse brought a system of dots and dashes that allowed near real-time long-distance communication. He envisioned this system as a means of secure communications. It would be up to others to devise systems to encrypt telegraphic communications. Anson Stager, the supervisor

of the U.S. Military Telegraph during the Civil War, devised 10 ciphers for the Union Army that were never broken by the Confederacy.²²

The use of telegraphic ciphers and codes continued into the two world wars. In fact, one of the most famous early successes of cryptanalysis prompted the entrance of the United States into World War I. When the war first started, the German transatlantic telegraph cable had been cut by the British, forcing all of Germany's international communications to route through the United Kingdom before being sent on to the Swedish or American transatlantic lines.²³ In 1917, "British cryptographers deciphered a telegram from German Foreign Minister Arthur Zimmermann to the German Minister to Mexico, von Eckhardt."²⁴ It promised Mexico ownership over territory that belonged to the United States (e.g., California), if Mexico joined the German cause and attacked the United States. The British informed President Wilson of their discovery, giving him a complete copy of the telegram, thus resulting in the United States declaring war on Germany.²⁵ That telegram has become famous in the history of cryptanalysis as the Zimmermann Telegram.

World War II saw several Allied victories over the Axis powers by use of advanced cryptographic systems. Few of these victories are more widely known and celebrated than the cracking of the German Enigma cipher machine, described next:

Following the decryption of the Zimmerman Telegram during World War I and the effects that weak ciphers had on that war's outcome, Germany was looking for an unbreakable cipher and was interested in leveraging automation and the use of machinery to replace traditional paper and pencil techniques. The Enigma machine consisted of a basic keyboard, a display that would reveal the cipher text letter, and a scrambling mechanism such that each plain text letter entered as input via the keyboard was transcribed to its corresponding cipher text letter. The machine was modular in design and multiple scrambling disks were employed to thwart attempts at frequency analysis.²⁶

A British cryptanalysis group, with the help of a group of Polish cryptanalysts, first broke the Enigma early in World War II, and some of the first uses of computers were for decoding Enigma ciphers intercepted from the Germans. Breaking Enigma was a major victory for the Allies, and in order to keep exploiting it, they kept the fact that they had cracked it a secret.²⁶

Thus far, the encryption schemes or devices described have encrypted messages consisting of words and nothing more. However, the emergence of the computer, even in its initial rudimentary form, revolutionized cryptology "to an extent even greater than the telegraph or radio."²⁷ Most cryptologic advances since World War II have involved, or made use of, computers. In the last few decades, cryptographic algorithms have advanced to the point where computing them by hand would be unfeasible, and only computers can do the required mathematics.²⁸ Relying on computers has broadened the kind of information that can benefit from encryption. Computers use a unique language that transforms all information stored into bits, each a 1 or a 0.²⁹ "This, in effect, means that plaintext is binary in form, and can therefore be anything; a picture, a voice, an email or even a video—it makes no difference, a string of binary bits can represent any of these."³⁰

7.2.9 Adding up XOR. In 1917, an engineer at AT&T, Gilbert Vernam, was working on a project to protect telegraph transmissions from the enemy. At that time, teletypewriters were used, based on a version of Morse code called Baudot code, after its French inventor. In Baudot code, each character of the alphabet is allotted five units, each of which is either an electrical current or absence of current, known as a

7 · 16 ENCRYPTION

mark or a space. For example, the letter *a* is represented by *mark, mark, space, space, space*. In binary terms, each unit constitutes a bit that is either 0 or 1 (the five-bit code for *a* would be 11000). This system of pulses allowed teletype machines to convert text to and from telegraph signals using a keyboard and punched paper tape for input (a hole represents a mark because it allows the reading device to make electrical contact and create a pulse, whereas a space is represented by leaving the paper intact). Anyone with a suitable machine could intercept and read the transmission.

The 32 possible combinations (2^5) in this code were assigned to the 26 letters plus six “shunts” that did various things like shift to capitals or go down to the next line. Vernam’s brilliant idea was to use a tape of random characters in Baudot code as a key that could be electromechanically added to the plaintext. Kahn describes the method of addition like this:

If the key and plaintext pulses are both marks or both spaces, the ciphertext pulse will be a space. If the key pulse is a space and the plaintext pulse is a mark, or vice-versa (in other words, if the two are different), the ciphertext will be a mark.³¹

Today, this is known as Exclusive-Or, sometimes referred to as bit-wise XOR or just XOR for short (see Exhibit 7.8). XOR is widely used in computerized encryption schemes. Consider what happens when encoding the letter *a* using *B* as the key:

Plaintext: 1 1 0 0 0 (=a)
Key: 1 0 0 1 1 (=B)
Ciphertext: 0 1 0 1 1

In the first column, $1 + 1 = 0$, as indicated in Exhibit 7.8. To decipher the encrypted character, simply perform the same operation, but add the ciphertext to the key:

Ciphertext: 0 1 0 1 1
Key: 1 0 0 1 1 (=B)
Plaintext: 1 1 0 0 0 (=a)

At the time of its discovery, the significance of this method lay in its capacity for automation. The operator could feed the plaintext and key tapes into the teletype machine, and it would transmit an encrypted message with no further human input. No offline preparation was required. Furthermore, as long as the receiver had the key tape, the teletype at the receiving end automatically printed out plaintext. This made Vernam’s system the first to integrate encryption into the communication process, an essential feature of encryption systems for today’s computer-based communications.

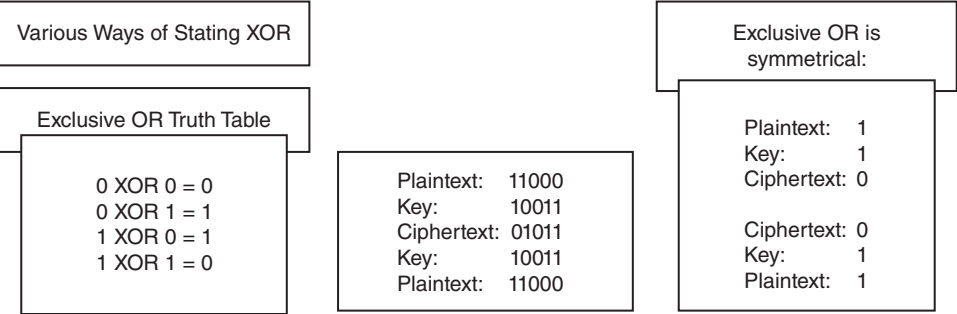

EXHIBIT 7.8 Diagram of XOR

7.3 DES AND MODERN ENCRYPTION. Although the use of XOR predated computers, the fact that it worked so well with binary code ensured that it would become an essential item in the modern cryptographer's toolkit. And so the focus of this chapter turns to modern cryptography and two of the most widely used cryptosystems today. The first is Data Encryption Standard (DES) and the second is Rivest, Shamir, Adleman (RSA).

7.3.1 Real Constraints. As the preceding overview of the evolution of encryption suggests, major advances, which are few and far between, often are linked with the individuals who made them, such as Vigenère, Playfair, and Vernam, none of whom had the benefit of computers. Today's computerized encryption schemes typically employ a number of classic techniques that, when combined, eliminate or minimize the shortcomings of any single method. Several techniques will be discussed here, including transposition and rotors, that point the way to the most widely used encryption scheme to date: DES. First, however, consider the practical problems encountered by Vernam's otherwise brilliant scheme.

Vernam proposed a key that was a long series of random characters. This was coded on a loop of paper tape that eventually repeated (the tape held about 125 characters per foot). The length of the key made cryptanalysis of intercepted messages extremely difficult, but not impossible, because eventually the key repeated. With sufficient volume of ciphertext, the code would yield to frequency analysis. (Bear in mind that during time of war, or even military exercises, hundreds of thousands of words may be encrypted per day, providing a solid basis for cryptanalysis.)

7.3.2 One-Time Pad. Several improvements then were suggested to avoid the impracticality of simply creating longer and longer key tapes. Another AT&T engineer, Lyman Morehouse, suggested using two key tapes of about eight feet in length, containing some 1,000 characters, to generate over 999,000 combinations of characters that could be fed into the encryption process as the key. This was an improvement in terms of practicality and security, but, as Major Joseph Mauborgne of the U.S. Army Signal Corps pointed out, heavy message traffic encrypted in this way still could be decoded. It was Mauborgne who realized that the only unbreakable cipher would use keys that are, as Kahn puts it "endless and senseless."³² Thus he came up with what we know as the one-time system, the one unbreakable encryption scheme.

The one-time system sometimes is referred to as a *one-time pad*,³³ because this is the way it has been deployed by intelligence agents in the field. The agent is issued a pad that aligns columns and rows of entirely random characters, as shown in Exhibit 7.9. The first letter of the plaintext is encrypted using the appropriate ciphertext from row 1, the second letter is encrypted from row 2, and so on. The result is ciphertext that contains no statistical relationship to the plaintext. When the message is encrypted the pad is destroyed. The recipient, who has a copy of the pad, uses it to reverse the process and decrypt the message.

The one-time pad essentially is a polyalphabetic substitution cipher, but with the same number of alphabets as there are characters in the message, thus defeating any kind of frequency analysis. A brute force attack is defeated by the fact that every possible result is as statistically significant as every other. As Kahn points out, a four-letter group of ciphertext could just as easily yield *kiss*, *fast*, *slow*, or any other possible four-letter combination.

7 · 18 ENCRYPTION

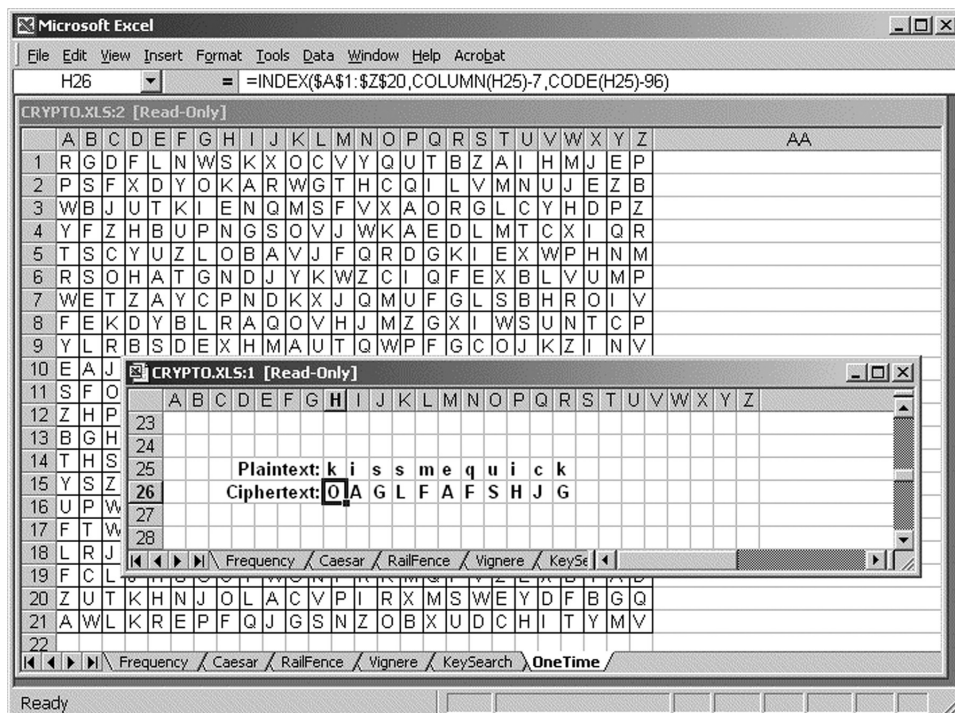

EXHIBIT 7.9 One-Time Pad

So why is the unbreakable one-time system not in universal use? Well, it remains a favorite of intelligence agents in the field who have an occasional need to send short messages. However, for large-scale commercial or military encryption, it fails to solve the key size problem that Vernam's system brought to light. The key has to be as large as the total volume of encrypted information, and there is a constant demand for new keys. Furthermore, both sender and receiver have to hold and defend identical copies of this enormous key.

7.3.3 Transposition, Rotors, Products, and Blocks. A completely different technique from substitution is *transposition*. Instead of substituting ciphertext characters for plaintext, the transposition cipher rearranges the plaintext characters. The simplest example is referred to as *rail fence*. For example, to encrypt "sell entire portfolio now and buy gold" each character is written on alternate lines, like this:

```
sletrprfloadugl
elnietooinwnbyod
```

which results in this ciphertext:

```
SLETRPRFLOADUGLELNIEOTOINWNBOD
```

So far, this does not present a serious challenge. More challenging is the next transposition into rows and columns that are numbered by a key (in this case, 37581426)

so that the first set of ciphertext characters are under 1, the second under 2, and so on:

Key:	3	7	5	8	1	4	2	6
Plaintext:	s	e	l	l	e	n	t	i
	r	e	p	o	r	t	f	o
	l	i	o	n	o	w	a	n
	d	b	u	y	g	o	l	d

Ciphertext: EROGTFALSRLDNTWOLPOUIONDEEIBLONY

Although more complex, this transposition will still yield to cryptanalysis because it retains the letter frequency characteristics of the plaintext. The analyst also would look for digraphs and trigraphs while playing around with columns and rows of different length. (Kahn describes French code breakers during World War I literally cutting text into strips and sliding them up and down against each other to break German transposition ciphers.)

What makes transposition difficult to decipher is additional stages of encryption. For example, if the previous ciphertext is run through the system again, using the same key, all semblance of pattern seems to disappear.

Key:	3	7	5	8	1	4	2	6
Plaintext:	e	r	o	g	t	f	a	l
	s	r	l	d	n	t	w	o
	l	p	o	u	i	o	n	d
	e	e	i	b	l	o	n	y

Ciphertext: TNILAWNNESLEFTO0OLOILODYRRPEGDUB

The development of increasingly complex multiple-transposition ciphers pointed out the positive effects of multiple stages of encryption, which also apply to substitution ciphers. The prime examples of this are the rotor machines used by the Germans and Japanese in World War II. Some of the insights gained during the attack on German codes, such as Alan Turing's 1940 work on the application of information statistics to cryptanalysis, were considered so important that they remained classified for more than 50 years.

Although they eventually were defeated by Allied cryptanalysts, electromechanical systems such as Enigma were not only the most sophisticated precomputer encryption systems, but the effort to crack them was also a major catalyst in the development of computer systems themselves. When people started applying computer systems to code making rather than code breaking, they quickly hit on the idea of chopping plaintext into pieces, or blocks, for easier handling. The term "block cipher" is used to describe ciphers that encrypt one block (e.g., 8 bytes of data) at a time, one block after another. Another result of computerizing the encryption process is a class of ciphers known as *product ciphers*. A product cipher has been defined as "a block cipher that iterates several weak operations such as substitution, transposition, modular addition/multiplication [such as XOR], and linear transformation."³⁴

The mathematics of product ciphers are beyond the scope of this chapter, but it is useful to note that "[n]obody knows how to prove mathematically that a product cipher is completely secure . . . [A] product cipher should act as a 'mixing' function

which combines the plaintext, key, and ciphertext in a complex nonlinear fashion.”³⁵ The parts of the product cipher that perform the rounds of substitution are referred to as *S-boxes*. The product cipher called Lucifer has two of these S-boxes, while DES encryption has eight S-boxes. The ability of a product cipher to produce truly random, nonlinear ciphertext depends on careful design of these S-boxes.

Examples of modern product ciphers include Lucifer (developed by IBM), DES (developed by IBM/NSA), LOKI (Brown, Pieprzyk, and Seberry), and FEAL (Shimizu and Miyaguchi). A class of product ciphers called *Feistel ciphers* operates on half of the ciphertext at each round, then swaps the ciphertext halves after each round. Examples of Feistel ciphers include Lucifer and DES, both of which are commercial systems, the subject of the next section of this chapter.

7.3.4 Data Encryption Standard. Traditionally, the primary markets for code makers and computer makers have been the same: governments and banks. After World War II, computers were developed for both military and commercial purposes. By the mid-1960s, the leading computer maker was IBM, which could see that the growing role of electronic communications in commerce would create a huge market for reliable encryption methods. Over a period of years, mathematicians and computer scientists, including Horst Feistel at the IBM research lab in Yorktown Heights, New York, developed a cipher called Lucifer that was sold to Lloyds of London in 1971 for use in a cash-dispensing system.³⁶

The U.S. National Security Agency (NSA) was in close touch with the Lucifer project, making regular visits to the lab (the constant flow of personnel between the NSA, IBM, and the mathematics departments of the major American universities tended to ensure that all new developments in the field were closely monitored). At roughly the same time, the National Bureau of Standards (NBS) was developing standard security specifications for computers used by the federal government. In 1973, the NBS invited companies to submit candidates for an encryption algorithm to be adopted by the government for the storage and transmission of unclassified information. (The government handles a lot of information that is sensitive but not sufficiently relevant to national security to warrant classification.)

IBM submitted a variation of its Lucifer cipher to the NBS, and after extensive testing by the NSA, this cipher was adopted as the nation’s Data Encryption Standard (DES). The acronym actually refers to a document published as Federal Information Processing Standards Publication 46, or FIPS PUB 46 for short. This was published on January 15, 1977, and DES became mandatory for all “federal departments and agencies, for any . . . nonnational-security data.”³⁷ The federal mandate also stated that commercial and private organizations were to be encouraged to use DES.³⁸ As a result, DES became widely used, especially in the banking industry.³⁹ The heart of DES is the Data Encryption Algorithm (DEA), which is described in a publication of the American National Standards Institute, titled *American National Standard for Information Systems—Data Encryption Algorithm—Modes of Operation*, 1983, referred to as ANSI X3.106-1983.

7.3.5 DES Strength. DES became, and remained, the de facto standard for commercial encryption until the late 1990s, when doubts about its strength relative to the rapid advances in computer hardware and software led to a quest for an eventual replacement. However, DES is still widely deployed, so more detailed discussion of its use is needed before discussing its replacement. The first thing to note is that the only

known method of deciphering data encrypted with DES without knowledge of the key is the use of brute force. This involves the computerized comparison of plaintext data with encrypted versions of the same data, using every possible key until both versions of the data match. With DES, the number of possible combinations is about 70 quadrillion. That is a very big number, and trying all those combinations within anything less than years requires relatively expensive hardware (or the carefully orchestrated application of large amounts of cheap hardware).

Technically speaking, the DEA is a combined substitution/transposition cipher, a product cipher that operates on blocks of data 64 bits, or 8 bytes, in length. Using 56 bits for the key produces a keyspace of 2^{56} , or 72,057,594,037,927,940, a number in the region of 70 quadrillion. A diagram of DES is shown in Exhibit 7.10.

The difficulty of attacking DES can be increased fairly easily if double or triple encryption is used, but despite this, there has always been something of a cloud over DES. At the time the DEA was approved, two Stanford University professors who are preeminent in twentieth-century cryptography, Martin Diffie and Whitfield Hellman, pointed out that the algorithm, as approved by the NBS, would be increasingly vulnerable to attack as computer equipment increased in power and came down in cost.

7.3.6 DES Weakness. As the author George Sassoon writes, “Although both the U.S. Department of Commerce and IBM deny it vigorously, everyone in the know insists that the NSA enforced a halving of the DES key length to ensure that they themselves could break the ciphers even if nobody else could.” Although the NBS dismissed such criticisms, and the NSA flatly denied that they were behind any attempts to weaken the cipher, this opinion received some support from the NSA in 1986 when the agency announced it would no longer certify the DEA for nonclassified use, less than 10 years after the DES was approved. This move was prompted by the rapid development of parallel computers, which achieve amazing processing capabilities by using hundreds or even thousands of multiple processors, working in parallel. These machines offer enormous power at considerably less cost than traditional supercomputers. Perhaps the NSA could see the inevitability of something like the EFF DES Cracker, which was built in 1998 for less than \$250,000 and broke a DES-encrypted message in fewer than three days.

The original Lucifer cipher used data blocks of 128 bits and a key of 112 bits. If this had been adhered to in the DEA, the difference in the number of possible key combinations would have been staggering. Although 2^{56} , the current keyspace, is a number greater than 7 with 16 zeroes behind it, 2^{112} is greater than 5 with 33 zeroes behind it. The practical consequence of this weakness in the DEA meant that the demand for stronger algorithms remained, and promising new ones emerged, such as Bruce Schneier’s Blowfish.

There are still some positive aspects to DES that make it viable for some commercial uses. As was mentioned earlier, the cryptographic weakness of DES can easily be strengthened by double encryption, which doubles the difficulty of decryption, taking the task well into the realm of supercomputers and purpose-built, massively parallel machines. The fact that DES has been a standard for so long means that DES now is available in many forms, such as single-chip implementations that can be inserted into ROM sockets and integrated into all manner of hardware, such as expansion cards, PCMCIA cards, and smart cards.

7.4 PUBLIC KEY ENCRYPTION. Even with a longer key, the DEA still would have a major weakness, one that it shares with all of the other private key encryption

7 · 22 ENCRYPTION

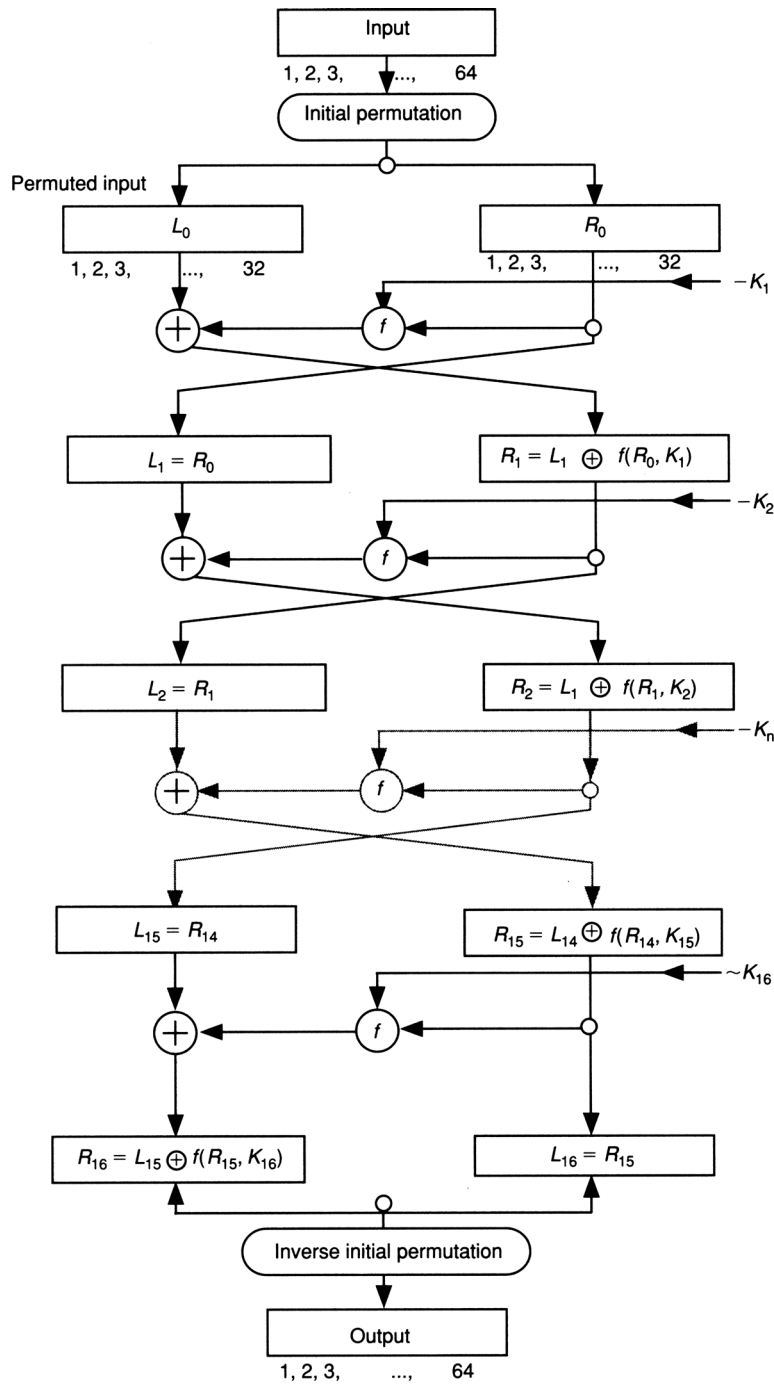

EXHIBIT 7.10 Diagram of DES

systems mentioned so far. That weakness is the need to keep the key secret. In this section we examine this problem, and the “public key” solutions that are now available.

7.4.1 Key-Exchange Problem. When password-protected data are sent from one place to another, either electronically or by hand, the need to transmit the password to the recipient presents serious obstacles. In cryptography, these are known collectively as the *key-exchange problem*. This is the way it is described by the Crypt Cabal⁴⁰:

If you want your friends to be able to send secret messages to you, you have to make sure nobody other than them sees the key. . . . [This is] one of the most vexing problems of all prior cryptography: the necessity of establishing a secure channel for the exchange of the key. To establish a secure channel, one uses cryptography, but private-key cryptography requires a secure channel!

So, even when using very powerful private key systems, such as DES, password or key distribution is a major problem. After all, the reason for encrypting valuable information in the first place is because it is assumed someone is trying to steal it or tamper with it. This implies a motivated and skilled adversary. Such an adversary is likely to use every opportunity to discover the password that will unlock the information. The password is perhaps most at risk from such an adversary when it is passed from one person to another. Although it sounds like the stuff of Bond movies, it actually is a very real and practical problem that had to be faced in many areas of legitimate organized activity, from businesses to public institutions, even when a powerful DEA-based computerized encryption system became available.

Suppose an encrypted file of sensitive accounting data needs to get to the head office. How does the recipient know the password needed to access the file? The sender could make a phone call. But will it be overheard? How is the identity of the person at the other end to be verified? A courier could be dispatched with a sealed envelope. The password could be encrypted. But all of these channels present problems. How to guarantee that the courier is honest or that the envelope will arrive intact? And if the password is encrypted, it will need a password itself, which will have to be transmitted. The recipient of the file can be provided with the password before the message is encrypted, but this is no guarantee that the password will not be intercepted. There are ways of making matters more difficult for the attacker, but the ideal solution would be to use a key that was useless to the attacker. This possibility is diagrammed in Exhibit 7.11.

7.4.2 Public Key Systems. A public key encryption system offers encryption that does not depend on the decryption key remaining a secret. It also allows the receiver of keys and messages to verify the source. The first published description of a public key cryptosystem appeared in 1976, authored by Stanford University professor Martin Hellman and researcher Whitfield Diffie. Ralph Merkle independently arrived at a similar system.

Ralph Merkle first proposed the idea of public key cryptography in 1974, and Martin Hellman and Whitfield Diffie brought the same idea to the public forum in 1976.⁴¹ The idea was considered a seminal breakthrough, “for it had not occurred to anyone else in the long history of cryptology that the deciphering key could be anything other than the inverse of the enciphering key.”⁴² The Diffie-Hellman system employs a form of mathematics known as modular arithmetic. “Modular arithmetic is a way of restricting the outcome of basic mathematical operations to a set of integers with

7 · 24 ENCRYPTION

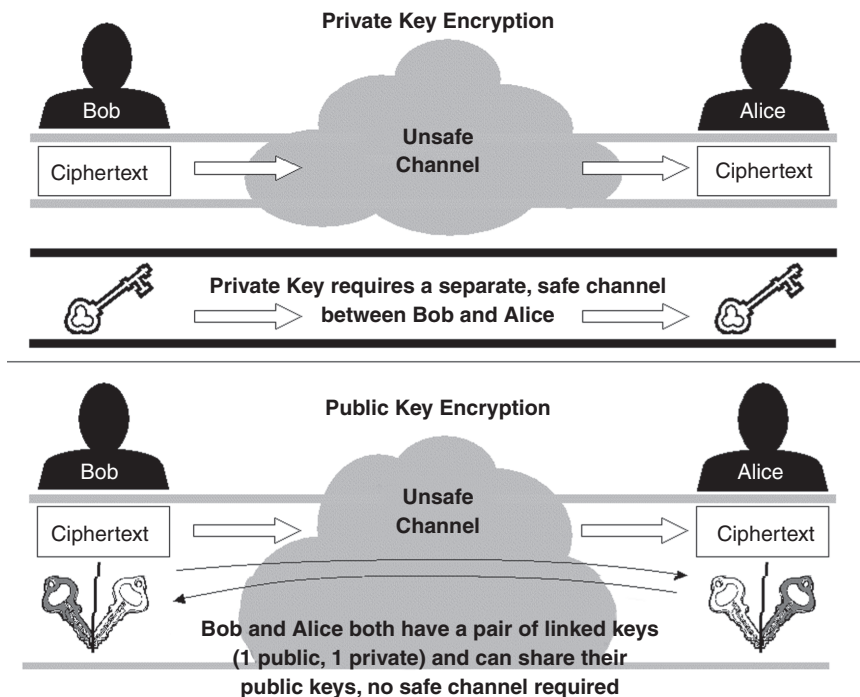

EXHIBIT 7.11 Comparison of Private and Public Key Encryption

an upper bound.”⁴³ An excellent example of this mathematical principle is found by examining a military clock:

Consider a clock on military time, by which hours are measured only in the range from zero to 23, with zero corresponding to midnight and 23 to 11 o'clock at night. In this system, an advance of 25 hours on 3 o'clock brings us not to 28 o'clock, but full circle to 4 o'clock (because $25 + 3 = 28$ and $28 - 24 = 4$). In this case, the number 24, an upper bound on operations involving the measurement of hours, is referred to as a modulus. When a calculation involving hours on a clock yields a large number, we subtract the number 24 until we obtain an integer between 0 and 23, a process known as modular reduction. This idea can be extended to moduli of different sizes.⁴⁴

The Diffie-Hellman protocol allows two users to exchange a symmetric key over an unsecure medium without having any prior shared secrets. The protocol has two publicly known and widely distributed system parameters: p , a large prime integer that is 1,024 bits in length,⁴⁵ and g , an integer less than p . The two users wishing to communicate are referred to as Alice and Bob for simplicity's sake. They proceed in this way.

First, Alice generates a random private value a , and Bob generates a random private value b . Both a and b are [less than p]. Then they derive their public values using parameters p and g and their private values. Alice's public value is $g^a \bmod p$ and Bob's public value is $g^b \bmod p$. They then exchange their public values. Finally, Alice computes $g^{ab} = (g^b)^a \bmod p$, and Bob computes $g^{ba} = (g^a)^b \bmod p$. Since $g^{ab} = g^{ba} = k$, Alice and Bob now have a shared secret key k .⁴⁶

This protocol introduced a concept to cryptography known as the discrete log problem. “The discrete log problem is stated as follows: given g , p , and $g^x \bmod p$,

what is x ?”⁴⁷ It is generally accepted throughout the mathematical and cryptologic communities that the discrete log problem is difficult to solve, difficult enough for algorithms to rely on it for security.⁴⁸

An algorithm to perform public key encryption was published in 1977 by Ronald Rivest of MIT, Adi Shamir of the Weizmann Institute in Israel, and Leonard Adleman of the University of Southern California. These three men formed the RSA Data Security Company, which was granted an exclusive license to the patent that MIT obtained on their algorithm. A large number of companies licensed software based on this algorithm, from AT&T to IBM and Microsoft. The RSA algorithm is currently at work in everything from online shopping to cell phones. Because it resolved the secret key dilemma, public key cryptography was hailed by many as a revolutionary technology, “representing a breakthrough that makes routine communication encryption practical and potentially ubiquitous,” according to the Sci.Crypt FAQ, which states:

In a public-key cryptosystem, E_K can be easily computed from some public key X , which in turn is computed from K . X is published, so that anyone can encrypt messages. If decryption D_K cannot be easily computed from public key X without knowledge of private key K , but readily with knowledge of K , then only the person who generated K can decrypt messages.⁴⁹

The mathematical principles that make this possible are beyond the scope of this chapter. Somewhat more detail can be found in the RSA Laboratories’ “Frequently Asked Questions About Today’s Cryptography,” which is distributed by RSA Data Security, the company that markets products based on the RSA algorithm. In brief, public key encryption is possible because some calculations are difficult to reverse, something pointed out by Diffie and Hellman, who first published the idea of public key encryption. Here is how RSA describes the calculations that make it possible (with minor clarification from the author):

Suppose Alice wants to send a private message, m , to Bob. Alice creates the ciphertext c by exponentiating:

$$c = m^e \bmod n$$

where e and n are Bob’s public key. To decrypt, Bob also exponentiates:

$$m = c^d \bmod n$$

where d is Bob’s private key. Bob recovers the original message, m ; the relationship between e and d ensures that Bob correctly recovers m . Because only Bob knows d , only Bob can decrypt.

This is diagrammed in Exhibit 7.12, which follows the scenario described. The lower part of the diagram uses numbers taken from an example given by Stallings. These numbers are much smaller than the actual numbers used by RSA. The point is that, given the ciphertext (c) and the public key (e, n) and knowledge of the algorithm, it is still impractical to decipher the message (m). This is because n is created by multiplying two prime numbers (normally represented as p and q) and e is derived from n combined with the secret key, d . To break the cipher, you need to factor a large number into a pair of prime numbers. How large? More than 150 digits in length (that is digits, not bits).

This cryptanalysis is very hard to do in a meaningful period of time, even with a very powerful computer. Large networks of computers have successfully factored

7 · 26 ENCRYPTION

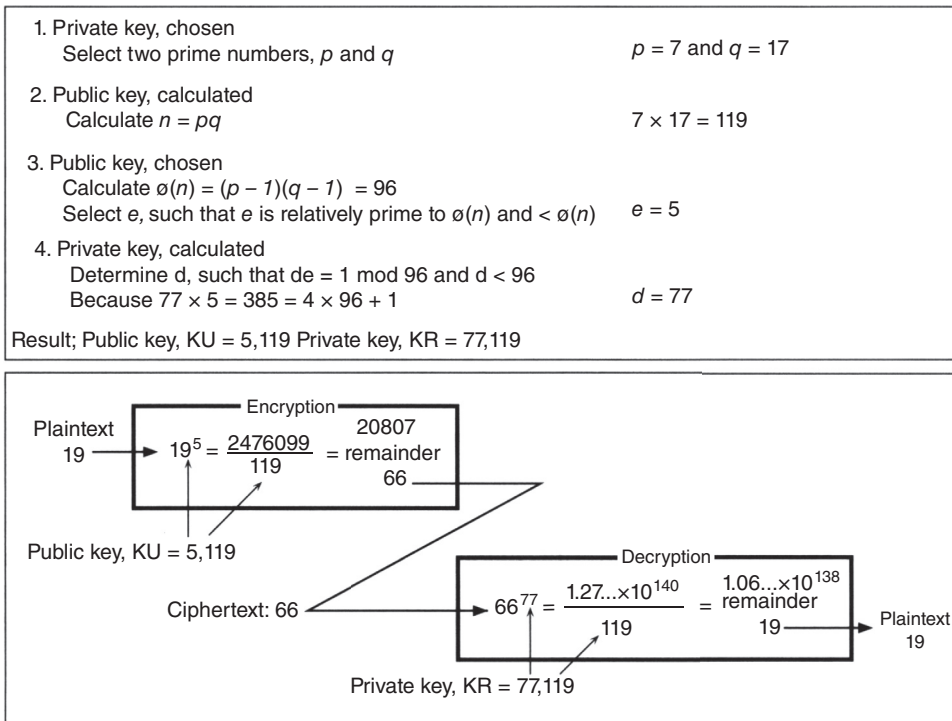

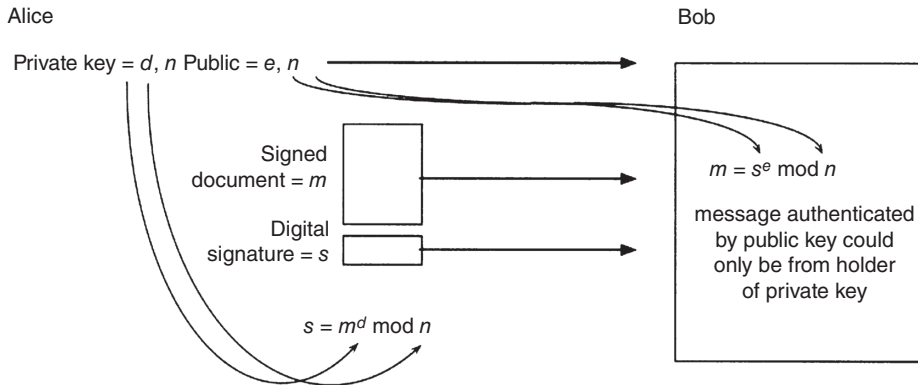

Exhibit 7.12 Public Key Diagram

a 100-digit number into two primes, but the RSA algorithm can use numbers even bigger if computer power and factoring algorithms start to catch up to the current implementations.

7.4.3 Authenticity and Trust. The point of the public key cryptosystems is to provide a means of encrypting information that is not compromised by the distribution of passwords, but public key encryption does not solve all problems associated with key exchange. Because the keys are considered public knowledge, some means “must be developed to testify to authenticity, because possession of keys alone (sufficient to encrypt intelligible messages) is no evidence of a particular unique identity of the sender,” according to Sci.Crypt FAQ.⁵⁰

This has led to key-distribution mechanisms that assure listed keys are actually those of the given entities. Such mechanisms rely on a *trusted authority*, which may not actually generate keys but does employ some mechanism which guarantees that “the lists of keys and associated identities kept and advertised for reference by senders and receivers are ‘correct.’”⁵¹ Another approach has been popularized by the program called Pretty Good Privacy, or PGP. This is the “Web of trust” approach that relies on users to distribute and track each other’s keys and trust in an informal, distributed fashion.

Here is how RSA can be used to send evidence of the sender’s identity in addition to an encrypted message. First, some information is encrypted with the sender’s private key. This is called the *signature* and is included in the message sent under the public key encryption to the receiver. The receiver can “use the RSA algorithm *in reverse* to

**EXHIBIT 7.13** Authentication with RSA

verify that the information decrypts sensibly, such that only the given entity could have encrypted the plaintext by use of the secret key.”⁵²

What does “decrypts sensibly” mean? The answer involves something called a *message digest*, which is “a unique mathematical ‘summary’ of the secret message.”⁵³ In theory, only the sender of the message could generate his or her valid signature for that message, thereby authenticating it for the receiver. Here is how RSA describes authentication, as diagrammed in Exhibit 7.13.

Suppose Alice wants to send a signed document m to Bob. Alice creates a digital signature s by exponentiating: $s = m^d \bmod n$, where d and n belong to Alice’s key pair. She sends s and m to Bob. To verify the signature, Bob exponentiates and checks that the message m is recovered: $m = s^e \bmod n$, where e and n belong to Alice’s public key.

7.4.4 Limitations and Combinations. As mentioned earlier, many products use RSA today, including Microsoft Windows, Lotus Notes, Adobe Acrobat, Netscape Navigator, Internet Explorer, and many more. In most of these examples, RSA is used for its authentication capabilities rather than for large-scale data encryption. That is because public key systems have one very noticeable downside: They are slow. This is balanced by the fact that they are harder to break. According to RSA, DES generally is at least 100 times as fast as RSA when implemented in software. In hardware, DES is between 1,000 and 10,000 times as fast, depending on the implementations. RSA may narrow the gap in coming years as more specialized chips are developed. However, public key algorithms are unlikely to ever match the performance of private key ciphers such as DES. Fortunately, there is a simple solution: Use a fast private key algorithm for the data encryption, but use a public key system to handle the key exchange and authentication, as diagrammed in Exhibit 7.14.

The private key encryption system might be DES or a system such as RC2 and RC4, both of which are available from RSA Data Security, or Schneier’s Blowfish, which is freely available. Just as there are other private key systems besides DES, there are other public systems besides RSA. One method, called SEEK, is patented, trademarked, and marketed by Cylink of Sunnyvale, California. This method uses an alternative algorithm for public key distribution. Cylink manufactures a range of DES encryptors that use SEEK for key distribution.

7.5 PRACTICAL ENCRYPTION. The primary market for encryption systems and devices is communications. However, the development of Internet commerce has

7 · 28 ENCRYPTION

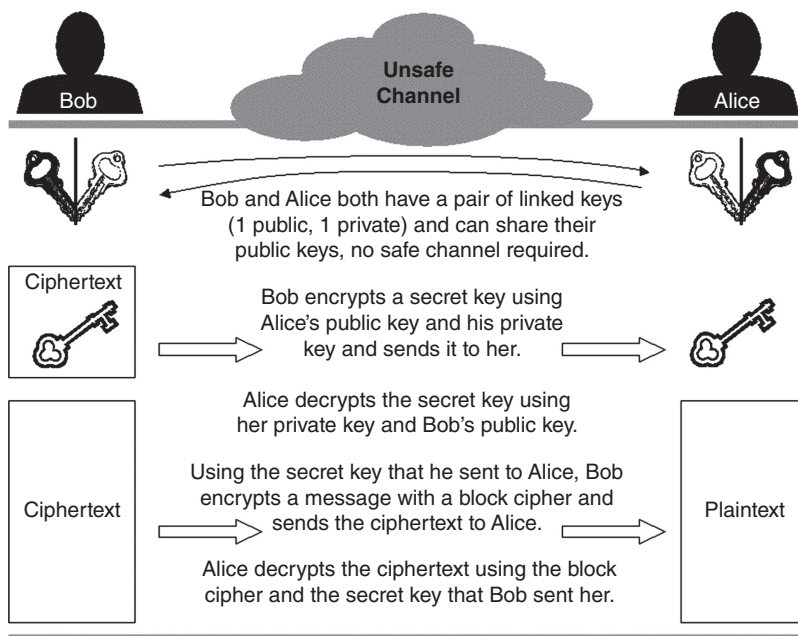

EXHIBIT 7.14 Combining Public and Private Key Encryption

resulted in a number of new and interesting crypto components that have considerable value for computer security.

7.5.1 Communications and Storage. If you look at the commercial products on the National Institute of Standards and Technology (NIST)'s list of approved DES implementations, most are designed to protect information when it is being communicated, not when it is sitting on a machine for local use. This is understandable when you look at the development of computing, which has spread outward from "fortress mainframe." Centralized data storage facilities lend themselves to physical access control. Encrypting data that stays behind walls and locked doors may be overkill in that scenario, particularly when there is a performance penalty involved.

Encryption was reserved for data in transit, between computers, across wires. This philosophy was extended to file servers on networks. File encryption on the server was not considered a priority as people assumed the server would be protected. Data encryption on stand-alone machines and removable media is a relatively recent development, particularly as more and more confidential data are packed into physically smaller and smaller devices. There are now many products with which to implement file encryption.

7.5.2 Securing the Transport Layer. One of the most visible examples of encryption at work in computer security today is the security icon people see in their Web browser; see Exhibit 7.15 for examples of Netscape Navigator and Microsoft Internet Explorer. This is an example of something called transport layer security, which uses protocols that go by the name of SSL and TLS.

7.5.2.1 Popular Protocols. SSL stand for Secure Sockets Layer, the software encryption protocol developed by Netscape and originally implemented in Netscape

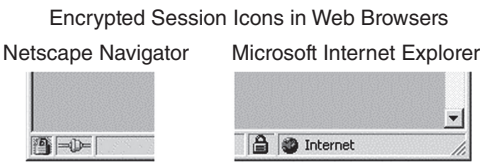

EXHIBIT 7.15 SSL 3.0 in Action

Secure Server and the Netscape Navigator browser. SSL is also supported by Microsoft Internet Explorer and a number of other products. TLS stands for Transport Layer Security, the name given to an Internet standard based on SSL, by the IETF (as in Internet Engineering Task Force, RFC 2246). There are minor differences between SSLv3.0 and TLSv1.0 but no significant differences as far as security strength is concerned, and both protocols interoperate with each other.

The TLS is a protocol, a standardized procedure for regulating data transmission between computers. It is actually composed of two layers of protocol. At the lowest level is the TLS Record Protocol, which is layered on top of some reliable transport protocol, typically the TCP in TCP/IP, the set of protocols that run the Internet. The TLS Record Protocol provides connection security that is both private (using symmetric cryptography for data encryption) and reliable (using a message integrity check). Above the TLS Record Protocol, encapsulated by it, is the TLS Handshake Protocol. This allows the server and client to authenticate each other, a major role for TLS in various forms of e-commerce, such as Internet banking. The TLS Handshake Protocol can also negotiate an encryption algorithm and cryptographic keys before any application protocol sitting on top of it, such as HTTP, transmits or receives its first byte of data (see Exhibit 7.16).

7.5.2.2 Properties of TLS. In providing connection security, the TLS Handshake Protocol delivers three basic properties. The identity of the parties can be

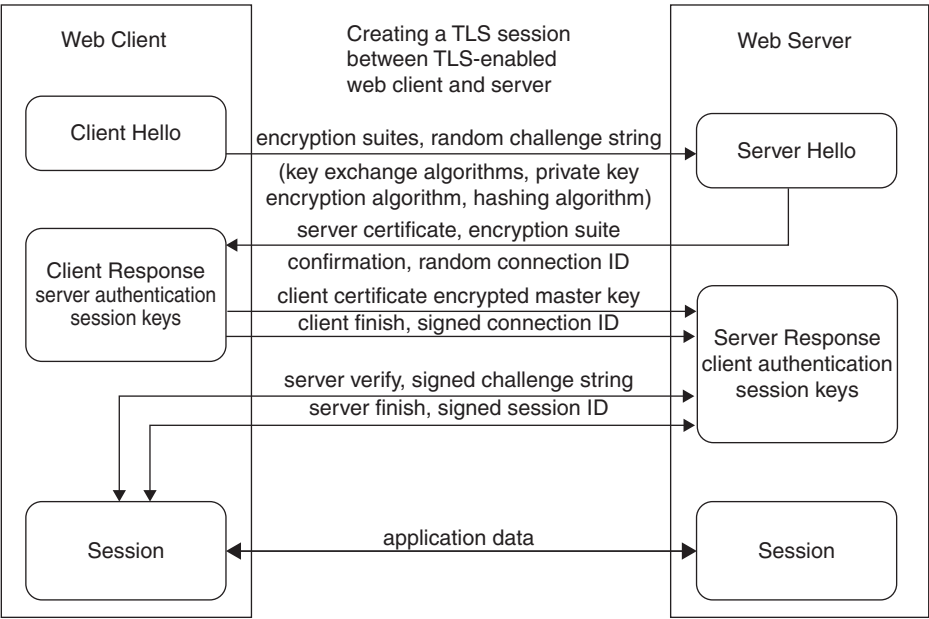

EXHIBIT 7.16 Creating a TLS Session

authenticated using public key cryptography (such as RSA). This authentication can be made optional, but typically it is required for at least one of the parties (e.g., the Yahoo! Travel server authenticates itself to the user's browser client, but the user's client does not authenticate itself to the Yahoo! Travel server, a distinction discussed in a moment).

The second and third basic properties of the TLS Handshake Protocol are that a shared secret can be securely negotiated, unavailable to eavesdroppers, even by an attacker who can place itself in the middle of the connection; and the protocol's negotiation is reliable. In the words of RFC 2246: "no attacker can modify the negotiation communication without being detected by the parties to the communication."

TLS can use a variety of encryption algorithms. For the symmetric encryption that is part of the Record protocol, DES or RC4 can be used. The keys for this symmetric encryption are generated uniquely for each connection and are based on a secret negotiated by another protocol (such as the TLS Handshake Protocol). The record protocol includes a message integrity check using a keyed MAC, with secure hash functions such as SHA and MD5, used for MAC computations. The encryption suite to be used for a specific connection is specified during the initial exchange between client and server, as shown in Exhibit 7.16.

7.5.2.3 Tested in the Real World. TLS/SSL has been widely used and extensively tested in the real world, and thoroughly probed by real cryptographers. Some of the caveats and limitations noted by these and other experts follow. The first is that neither a good standard nor a good design can guarantee a good implementation. For example, if TLS is implemented with a weak random number seed, or a random number generator that is not sufficiently random, the theoretical strength of the design will do nothing to protect the data that are thus exposed to potential compromise. (Although beyond the scope of this chapter, Pseudo-Random Number Generators, or PRNGs, play a vital part in many cryptographic operations, and they are surprisingly difficult to create; unless they closely simulate true randomness, an attacker will be able to predict the numbers they generate, thus defeating any scheme that relies on their "random" quality.)

The second major caveat is that, if clients do not have digital certificates, the client side of the TLS session is not authenticated. This presents numerous problems. Most of today's "secure" Web transactions, from airline tickets booked at Yahoo Travel to shares traded at most online brokerages, represent a calculated risk on the part of the vendor. Although the client doing the buying is assured, by means of the merchant certificate, that the merchant at www.amazon.com really is Amazon, the merchant has no digital assurance that the client computer belongs to, or is being operated by, the person making the purchase. Of course, there are other assurances, such as the match between the credit card that the purchaser supplies and the other personal details that go along with it, such as billing address. But the merchant is still risking a charge-back and possibly other penalties for a fraudulent transaction.

In the case of larger and more sensitive financial transactions, the need to be assured of the client's identity is greater. A digital certificate is a step in the right direction, but it is a step many merchants have not yet taken, for several reasons. The first is the cost of issuing certificates to customers, and the second is the difficulty of getting those certificates onto their systems. Some merchants have decided that the cost and effort are worth it. For example, the Royal Bank of Scotland took this approach with its online banking system back in 1998.

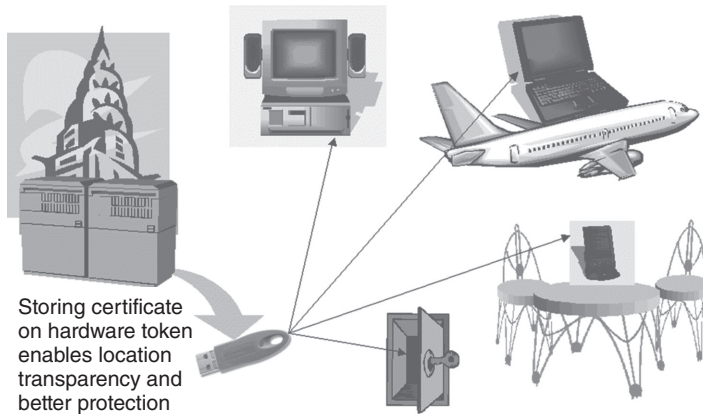

EXHIBIT 7.17 Using a Hardware Token for Digital Signatures

There are other issues. The user needs to protect the certificate, even from such threats as hardware failure (user reformats the drive, loses the certificate) or unauthorized use (a family member uses the computer and thus has access to the certificate). Furthermore, the user needs to be able to move the certificate, for example, onto a laptop computer so that the bank account can be accessed while traveling. The obvious answer is to place the certificate on a robust removable medium (see Exhibit 7.17). Such media are generically referred to as hardware tokens. A standard for tokens has not yet emerged. Smart cards are an obvious choice, but card readers need to be deployed. There are alternatives, such as putting the certificate on a floppy disk or on a small key fob that plugs into a USB port.

7.5.2.4 Cost of Secured Transactions. For companies looking to perform highly secure transactions today, using SSL without client-side authentication is proving acceptable in the short term, at least for some categories of transaction. Even then it can be costly, in terms of either dollars or processing power. Although TLS is an open standard, and Netscape has provided crucial parts of the technology royalty free, there is still the question of which algorithms to use. Some algorithms are more expensive than others, and not always in obvious ways. For example, you have to license RC4, whereas DES is free, but RC4 is optimized for a 32-bit processor and DES is not.

Furthermore, research shows that the amount of “hits” that a Web server can handle drops dramatically when those hits require TLS (and it drops a whole lot more when processing client authentication as well as server authentication). The answer here may be specialized hardware. Several companies, such as IBM and Rainbow Technologies, make crypto-coprocessor cards that relieve the server’s CPU of the specialized math processing involved in crypto. They are cheaper than adding another server to keep up with the very demanding task of providing secure Web transactions.

7.5.3 X.509v3 Certificate Format. Another example of encryption widely used in computer security today is X.509. This is not a rocket ship but a standard for digital certificates, described earlier in this chapter. The International Telecommunication Union’s Telecommunication Standardization Sector (ITU-T)’s X.509 standards document states: “Virtually all security services are dependent upon the identities of the communicating parties being reliably known, i.e. authentication.” Consider how this affects Web transactions. The preceding section described how SSL can encrypt

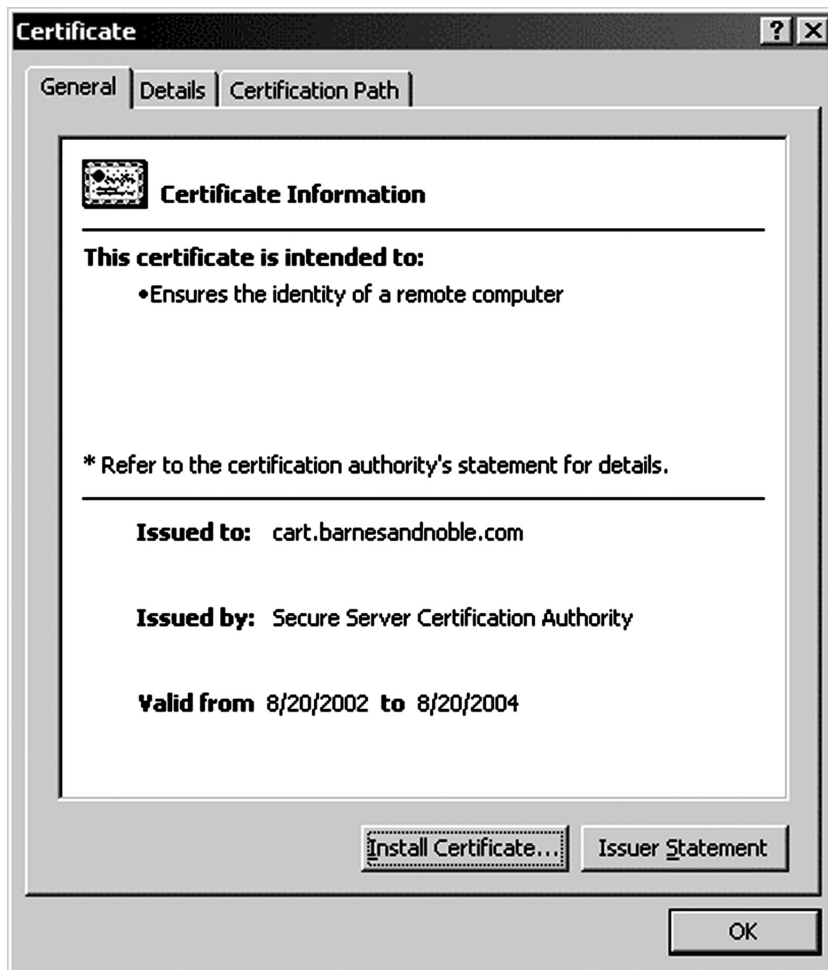

EXHIBIT 7.18 Digital Certificate

Web pages sent from Web server to Web client, and vice versa, but it cannot assure the identity of the parties involved. The X.509 standard helps to address this problem, which negatively impacts the profitability of Web-based businesses.

When a Web user asks for assurance that the bn.com Web site is actually Barnes & Noble, it can be provided by way of a digital certificate (see Exhibit 7.18). This means that an entity, known as a certificate authority (CA), has taken considerable pains to reliably identify, and consequently certify, the merchant as the rightful owner of an encryption key. This key is the public half of a uniquely and mathematically related public/private key pair, such that a message encrypted with the public key can only be decrypted with the corresponding private key.

Individuals, as well as merchants, can have a public/private key pair. A bank might then access that public key, and use it, plus the bank's private key, to encrypt the account details it sends to customers over the Web. Only the customer with the right private key can decrypt this information, using the bank's public key. At the same time, customers know the statement information can only have come from the bank (otherwise the bank's public key would not work to decrypt it). Customers also know,

EXHIBIT 7.19 X.509 Certificate Format

Version	Identifies the Certificate Format
Certificate Serial Number	Number that is unique within the issuing CA
Signature Algorithm Identifier	Identifies the algorithm used to sign the certificate, together with any necessary parameters
Issuer	X.500 name of the issuing CA
Validity Period	Pair of dates between which the certificate is valid
Subject	X.500 name of the holder of the private key corresponding to the public key certified by the certificate
Subject Public Key Information	Public key for the subject, plus an identifier for the algorithm with which this public key is to be used

thanks to an encrypted message digest (a digital fingerprint of the message contents), that the data they get from the bank has not been altered. Thus, it is very difficult for either party to claim that it never took place. In this way, digital certificates can enhance confidentiality, integrity, and nonrepudiation.

7.5.3.1 ISO/IEC/ITU 9594-8 a.k.a. X.509. The management of public keys is the task of Public Key Infrastructure (PKI), of which the X.509 standard is an important part. For example, an organization’s employees can perform secure business communications over the Internet, such as contract negotiation, using PKI. To engage in a secure transaction with someone, it is necessary to find and access the other person’s public key, and vice versa. The answer is to publish public keys in the form of a digital certificate, then use some form of directory to locate them. In order for different systems to interoperate, standards for directories have been developed, notably X.500. This standard applies such elements of directory standardization as a hierarchical naming convention:

Country, Organization, Common Name.
So Fred Jones of Megabank might have the X.500 name:
[Country = US, Organization = Megabank, Inc., Common Name = Fred Jones]

A means of locating digital certificates to verify identities was a logical extension of the standard, thus X.509 was developed, officially known as ITU-T X.509 (formerly CCITT X.509) and also ISO/IEC/ITU 9594-8. In X.509 there is a definition of a basic certificate format, which consists of seven fields shown in Exhibit 7.19.

The certificate format has evolved considerably since 1988. The original format is now referred to as X.509v1. When X.500 itself was revised in 1993, two more fields were added to support directory access control, resulting in the X.509v2 format.⁵⁴ X.509v2 added unique identifiers for the issuer and the subject, optional bit strings used to make the issuer and subject names unambiguous in the event that the same name is later reassigned to different entities. Suppose that Fred Jones, whose assigned X.500 name was given earlier, is an executive vice president of Megabank, but is then hired away by a competitor. Megabank deassigns his name, but if a different Fred Jones, a programmer, then comes to work for Megabank, he is effectively reassigned the same X.500 name:

[Country = US, Organization = Megabank, Inc., Common Name = Fred Jones]

7 · 34 ENCRYPTION

This poses authorization problems for any access control lists attached to X.500 data objects, due to the difficulty of identifying all of the access control lists that grant privileges to a particular user’s name. The unique identifier field added in X.509v2 provides somewhere to put a new value whenever a name is reused. In fact, a better solution is to use a better distinguisher in the X.500 name, such as:

[Common Name = Fred Jones, Employee Number = 1000002]

In 1993, when the Internet Privacy Enhanced Mail (PEM) RFCs were published, they included specifications for a public key infrastructure based on X.509v1 certificates. Attempts to deploy PEM, however, revealed deficiencies in the Version 1 and 2 certificate formats. Consequently, ISO/IEC/ITU and ANSI X9 developed the X.509v3 format, which greatly extends the capabilities of the format by providing extension fields and broader naming options in X.509v3.

7.5.3.2 Extending the Standard. Extensions were added in Version 3 to address problems discovered while implementing Version 1 and 2 certificates. These can be seen in the diagram in Exhibit 7.20. Particular extension field types may now be specified in standards or defined and registered by any organization or community. Each extension field is assigned a type by means of an object identifier, registered in the same way that an algorithm is registered. Although theoretically anyone can define an extension type, to achieve practical interoperability, common extension types need to be understood by different implementations. Thus, the most important extension types are standardized. But when X509v3 is used within a closed group—for example,

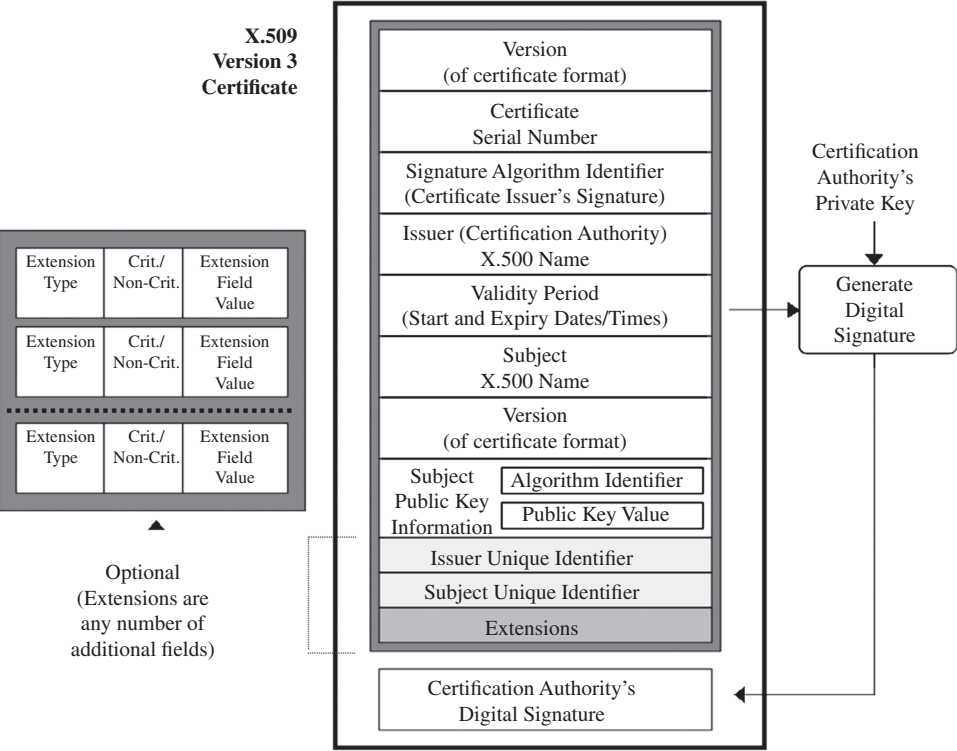

EXHIBIT 7.20 X.509v3 Certificate

a group of business partners—it is possible to define unique extension types to satisfy specific needs.

7.5.3.3 X.509 Sources, Issues, and CAs. Someone managing an e-commerce project does not necessarily need to know X.509 in detail but should at least read the Arsenault and Turner document (see Section 7.8, “Further Reading,” at the end of the chapter); it clearly describes not only X.509 but the role it plays in PKI (which they define as “the set of hardware, software, people, policies and procedures needed to create, manage, store, distribute, and revoke certificates based on public-key cryptography”⁵⁵). Also very helpful are the presentations by VeriSign’s Warwick Ford, which NIST has online at its Web site. For the e-commerce developer who wants more detail, the next step is Ford’s book, coauthored with fellow VeriSign executive Michael Baum, *Secure Electronic Commerce*.⁵⁶ This documents other important aspects of X.509, such as the Certificate Revocation List, used to revoke certificates before they expire (e.g., if the private key has been compromised). A copy of the standard, available online, at the International Telecommunication Union (ITU) Web site (www.itu.int), is also valuable.

The extensions and improvements in the X.509v3 certificate format greatly increase its usefulness, but providing a uniform method of going beyond the standard does raise the specter of a lack of standardization. This is something that the IETF’s PKIX working group is addressing. And there are other issues to consider when evaluating X.509 as a security technology, many of which are raised by Ed Gerck of the Meta-Certificate Group. Articles at the group’s Web site point out that X.509 does not address “the level of effort which is needed to validate the information in a certificate.”⁵⁷ In other words, some security issues are beyond the scope of X.509, but they do need to be considered when deploying systems that rely on these certificates. For example, it does not make sense to rely on a digital certificate if the measures taken to assure the identity of the owner and user of the certificate are not commensurate with the risk involved in relying on the certificate. Furthermore, transactions that do not use certificates on both sides will remain inherently problematic.

These issues point to the importance of the role played by the CA. As mentioned earlier, CAs are the entities that issue and sign certificates. Each has a public key that is listed in the certificate. The CA is responsible for scheduling an expiration date and for revoking certificates when necessary. The CA maintains and publishes a Certificate Revocation List (CRL).

In other words, ensuring the validity of certificates entails a lot of maintenance. The CRL, for example, is crucial if certificates are compromised or found to be issued fraudulently. This happened in 2001 when a number of VeriSign certificates were found to be issued in error to someone posing as Microsoft. Because some computer users now rely on certificates to guarantee the authenticity of software upgrades and components, failure to check the revocation list before downloading certified code could result in malicious code attacks.

Problems with certificates have the potential for widespread impact because the authority in certificates is hierarchical, as shown in Exhibit 7.21. When a CA issues a certificate, it signs it with its own key. Anyone relying on certificates issued by that CA needs to know by what authority the CA is issuing that certificate. To simplify, there are two possible answers. The CA is self-certifying, that is, providing its own “root” key, or it is relying on another CA for the root key. Clearly, any compromise of the root key undermines all certificates that gain their authority from it.

See Chapter 37 of this *Handbook* for a more extensive discussion of PKI and CAs.

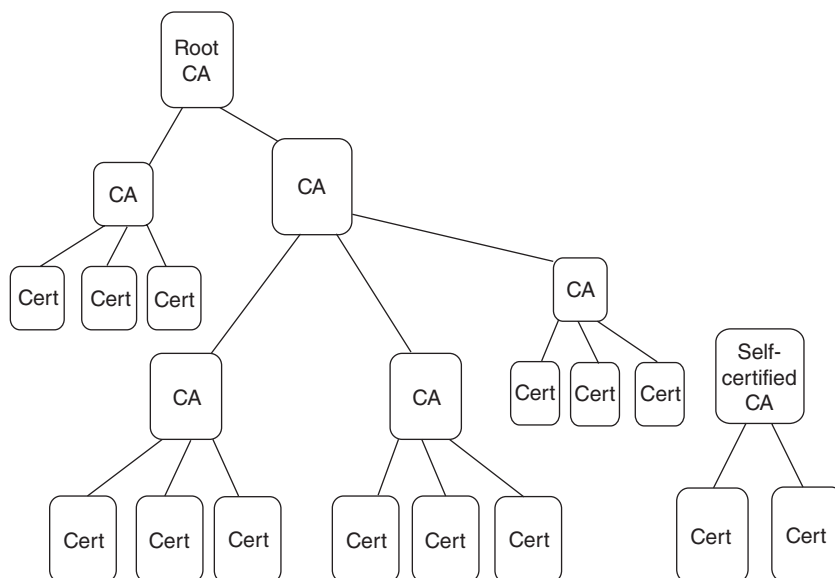

EXHIBIT 7.21 Certificate Authorities and the Root Key

7.6 BEYOND RSA AND DES. Cryptography research and development did not stop with the development of the RSA algorithms. Events in the last two decades of the twentieth century and the first decade of the twenty-first, and their implications, are discussed in this final section of the chapter, which concludes with some warnings on implementing encryption.

7.6.1 Elliptic Curve Cryptography. In 1985, Neal Koblitz from the University of Washington and Victor Miller of IBM independently discovered the application of elliptic curve systems to cryptography. When applied to public key cryptography, elliptic curve arithmetic has been found to offer certain advantages over first-generation public key techniques such as Diffie-Hellman and RSA.

The security of elliptic curve algorithms is based on the same principle as the Diffie-Hellman algorithm, the discrete log problem, as described in Section 7.4.2. The advantages to elliptic curve algorithms lie in the key size needed to achieve certain levels of security. As one scales security upward over time to meet the evolving threat posed by eavesdroppers and hackers with access to greater computing resources, elliptic curves begin to offer dramatic savings over the old, first-generation techniques.⁵⁸

Until 2010, public key systems used 1,024 bits or 2,048 bits for creating keys. NIST recommended that after 2010, these systems be upgraded to a system that can provide adequate security. One way of doing this would be to increase the key size that is used. However, systems that are in place today become increasingly cumbersome the larger the key size. The NSA is endorsing elliptic curve cryptography, stating on its Web site that it has implemented elliptic curve public key cryptography systems to protect both classified and unclassified information.⁵⁹ Elliptic curve systems offer a way to increase key size moderately when more security is required. Exhibit 7.22 shows the NIST recommended key size that RSA or Diffie-Hellman should use to protect the transportation of symmetric keys of various sizes as well as the corresponding elliptic curve key size.

EXHIBIT 7.22 NIST Recommended Key Sizes

80	1024	160
112	2048	224

256	15360	521

Source: National Security Agency, "The Case for Elliptic Curve Cryptography," www.nsa.gov/business/programs/elliptic_curve.shtml.

Thus, in order to use RSA to protect a 256-bit AES key, one should use a key of 15,360 bits, which is an order of magnitude larger than the key sizes currently in use throughout the Internet. However, an elliptic curve key would need to be only 521 bits. Elliptic curve algorithms can use smaller keys, because the math involved makes the inverse, or decryption, operations harder as the key length increases.⁶⁰

Another feature that makes elliptic curves appealing is the fact that they are more efficient than the current implementations of public key cryptography, which tend to be relatively slow, causing them to be used more as key distribution methods than data encryption methods. Exhibit 7.23 shows the ratio of Diffie-Hellman computations versus elliptic curve computations for each of the key sizes listed in Exhibit 7.22.⁶¹

7.6.2 RSA Patent Expires. On September 6, 2000, RSA Security released the RSA public key encryption algorithm into the public domain. This means that anyone can now create products that incorporate this algorithm (provided it is their own implementation and not one licensed from RSA). In effect, RSA Security waived its rights to enforce the patent for any development activities that include the RSA algorithm occurring after September 6, 2000. The U.S. patent for the RSA algorithm actually expired on September 20, 2000. The result has been an even broader use of public key encryption, at lower cost.

The RSA patent was always somewhat controversial, because it applied to a piece of mathematics, which is not what most people think of when they think of an invention. The owners of the patent were never able to expand protection beyond the United States. As a result, versions of public key encryption based on alternatives to the RSA algorithm were developed and marketed outside the country, by companies

like Ireland's Baltimore Technologies, Finland's F-Secure, and Israel's Algorithmic Research. Now encryption companies can dispense with the costly maintenance of multiple versions of their public key products (U.S. and non-U.S.). In addition, U.S. companies can develop and market RSA-based products. Large companies actually can "roll their own" public key encryption schemes for internal use, based on a proven, royalty-free algorithm.

7.6.3 DES Superseded. RSA Security, the company that tried to make the RSA algorithm synonymous with public key encryption, played a leading role in the other watershed crypto event of 2000, the naming of a successor to DES, the Data Encryption Standard. As noted earlier, projects like the EFF DES Cracker showed that a computer built for less than \$250,000 could decipher a DES-encrypted message in fewer than three days. In fact, this was part of the "DES Challenges" sponsored by RSA Security. DES Challenge I was won by Rocke Verser of Loveland, Colorado, who led a group of Internet users in a distributed brute force attack. The project, code-named DESCHALL, began on March 13, 1997, and was successfully completed some 90 days later. DES Challenge II consisted of two contests posted on January 13 and July 13, 1998. The first contest was cracked by a distributed computing effort coordinated by distributed.net, which met the challenge in 39 days. The second contest was the one solved by EFF's purpose-built DES Cracker.

The effect of these projects was to focus attention on the need for stronger encryption. Companies and government agencies wanting to archive sensitive data need it to remain secure for decades, not days. However, as predicted in the 1970s, advances in computer power rendered "obsolete" the DEA, the widely used private key algorithm that forms the basis of the DES. Of course, the term "obsolete" is relative in this context. DES is not obsolete when applications need to encrypt bulk data to keep it confidential for a limited period of time, and a lot of data falls into this category. As Exhibit 7.24 shows, there is a direct relationship among time, technology, and the degree of protection that any ciphersystem provides.

In 1997, the U.S. Government began the process of establishing a more powerful standard than DES, known as Advanced Encryption Standard (AES). This is a Federal Information Processing Standard (FIPS) Publication, FIPS 197, specifying "a

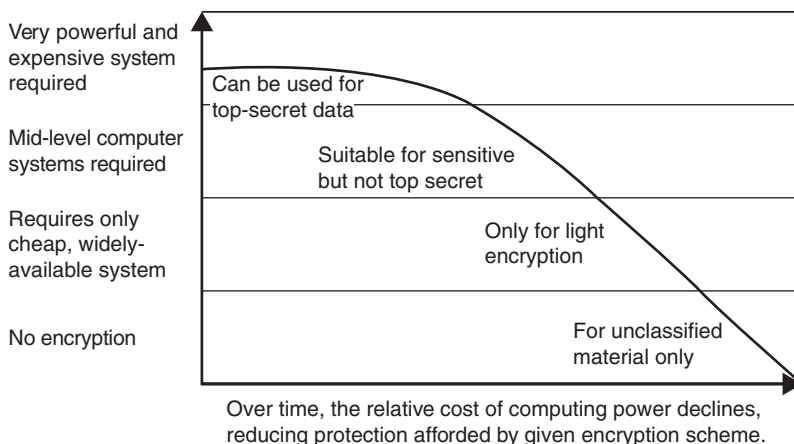

EXHIBIT 7.24 Relationship among Time, Technology, and Protection

cryptographic algorithm for use by U.S. Government organizations to protect sensitive (unclassified) information.” The government anticipated correctly that AES would be “widely used on a voluntary basis by organizations, institutions, and individuals outside of the U.S. Government—and outside of the United States—in some cases.”

In essence, a competition was held to find the best possible algorithm for the job, and the winner, chosen in October 2000, was Rijndael (pronounced “Rhine Doll”). This algorithm was developed specifically for the AES by two cryptographers from Belgium, Dr. Joan Daemen and Dr. Vincent Rijmen. Rijndael is a block cipher with a variable block length and key length. So far, keys with a length of 128, 192, or 256 bits have been specified to encrypt blocks with a length of 128, 192, or 256 bits. (All nine combinations of key length and block length are possible.) However, both block length and key length can be extended very easily in multiples of 32 bits. Rijndael can be implemented very efficiently in hardware, even on smart cards.

7.6.4 Quantum Cryptography. A new basis for computation will profoundly affect cryptographic strength in the coming decades. This section provides a brief and nontechnical summary of the science of quantum computation and quantum cryptography.

7.6.4.1 Historical Perspective. The entirety of this chapter has focused on the status of cryptography as it currently exists. The classic computer has been sufficient to perform the computations and processes required of AES, RSA, and all of the cryptographic systems and algorithms that have been explored since the advent of cryptography. Although modern computers are fundamentally the same as they were in the 1950s, the machines we use today are significantly faster.⁶² Even though the speed has increased, the primary task of computers has remained the same: “to manipulate and interpret an encoding of binary bits into a useful computational result.”⁶³ To push the bounds of computer performance ever forward, computer scientists’ goal has “been the reduction of size in the transistors used in modern processors.”⁶⁴

Early computers were constructed of gates and storage “bits” made of many thousands of molecules. The components of today’s processors are moving in the direction of a few hundred molecules. The computing industry has always known that miniaturization would reach a barrier below which circuits could not be built, because their fundamental physical behavior would change.⁶⁵

The components of modern computers are reaching this barrier; should transistors become much smaller, they will “eventually reach a point where individual elements would be no larger than a few atoms.”⁶⁶ Computer scientists are concerned about this continual shrinking, because at the atomic level, the laws of quantum mechanics will govern the properties and behavior of circuits, not the laws of classical mechanics.⁶⁷

The science of quantum mechanics is not fully understood by scientists; it was initially thought to be a major limitation to the evolution of computer technology.⁶⁸ It was not until 1982 that the scientific community saw any benefit from the unusual effects associated with quantum mechanics. That year, Richard Feynman theorized about a new type of computer that would harness the effects of quantum mechanics and use these effects to its advantage.⁶⁹ In 1985, David Deutsch of the University of Oxford published a “ground breaking theoretical paper describing how any physical process could be modeled perfectly (in theory) using a quantum computing system.”⁷⁰ He further argued that a quantum system would be able to execute tasks that no modern computer could perform, such as *true* random number generation.⁷¹ “After

Deutsch published this paper, the search began to find interesting applications for such a machine.”⁷²

7.6.4.2 Fundamentals. A “quantum” is “the smallest amount of a physical quantity that can exist independently, especially a discrete quantity of electromagnetic radiation.”⁷³ Quantum mechanics explains the physics and behaviors of particles, atoms, and energy.⁷⁴ The idea of a quantum computer is based on the phenomena that occur at the atomic and subatomic level, which are explained by quantum mechanics and defy all classical laws of physics.⁷⁵ These phenomena will be covered in more detail shortly; it is necessary at this point, however, to explain several fundamental differences between classical modern computers and the idea of a quantum computer.

Classical computers store and process information in units called bits, represented as a zero (0) or a one (1) in a computer’s transistors. Bits are then organized into bytes, a series of eight bits. Thus, the information stored on a computer is stored as individual bits grouped into bytes. Therefore, a document “comprised of n -characters stored on the hard drive of a typical computer is accordingly described by a string of $8n$ zeros and ones.”⁷⁶ It is important to emphasize that bits “can *only* exist in one of two distinct states, a ‘0’ or a ‘1’.”⁷⁷ This leads to the first difference between classical computers and quantum computers.

Quantum computers store and process information in units called quantum bits, referred to as “qubits.” “Qubits represent atoms, ions, photons or electrons and their respective control devices that are working together to act as computer memory and a processor.”⁷⁸ Similar to a classic bit, a qubit is represented as a 0 or a 1. Unlike a classic bit, a qubit can also exist in a *superposition* of both a 0 *and* a 1. In other words, it is possible for a single qubit to exist as a 0, a 1, or simultaneously as both a 0 *and* a 1. A qubit that is in two positions at once is said to be in its coherent state.⁷⁹ This can be explained more coherently with an example:

If a coin is flipped in a darkened room, the result of the coin being flipped is mathematically just as likely to be heads or tails. While the light is off, the coin is in a superposition—whereby it is both heads and tails at once, because an [observer] cannot see which it is. If [the observer] turns on the light, [he or she] “collapses” the superposition, and forces the coin to be either heads or tails by measuring it. Measuring something destroys the superposition, forcing it into being in just one classical state.⁸⁰

This coherent state leads to the phenomenon that would make a quantum computer exponentially more powerful than any computer to date; this is the phenomenon called “quantum parallelism.”⁸¹ Essentially, because a qubit in a coherent state holds two values at once, a single operation done on such a qubit would act on both values at the same time.⁸² “Likewise, a two-qubit system would perform the operation on four values and a three-qubit system on eight [values].”⁸³ To summarize, an operation done on a system of n qubits would act on 2^n values simultaneously.⁸⁴ Exhibit 7.25 shows this concept using a system containing three qubits, which represent eight states simultaneously.

“The very property that makes quantum computing so powerful also makes it very fragile and hard to control.”⁸⁵ In order to harness the power of quantum parallelism, scientists need to be able to read and measure the output from the operations performed on groups of qubits. Herein lies the problem of decoherence. When a qubit in the coherent state measurably interacts with the environment, it will immediately decohere and resume one of the two classical states, either a 0 or a 1, and it will no longer exhibit

its dual-state ability. In other words, simply looking at a qubit can cause it to decohere, and this makes measuring qubits directly impossible.⁸⁶

If scientists are unable to measure something directly, then they must find a way to measure indirectly, or a practical quantum computer will never be made. One possible answer lies in another property of quantum mechanics called entanglement. Entanglement is an obscure attribute that involves two or more atoms or particles. When certain conditions are met or certain forces are applied to two or more particles, then they can become entangled, whereby the particles exhibit opposite properties. The entangled particles will remain entangled, no matter the physical distance between them, and one entangled particle will always be able to communicate with its partner. Particles spin either up or down, and this spin is how scientists measure information about the particles. The property of coherence tells us that a particle will spin both up and down simultaneously until a scientist looks at it and measures it. "The spin state of the particle being measured is . . . communicated to the correlated particle, which simultaneously assumes the opposite spin direction to that of the measured particle."⁸⁷ Thus, entanglement could allow scientists to know the value of a qubit without actually looking at one. Scientists admit that entanglement is a difficult notion; they are still exploring the concept.⁸⁸ They also acknowledge that it could be years before a workable solution to the problem of measuring information in a quantum system is discovered.⁸⁹

7.6.4.3 Impacts. Although quantum computers, in theory, can perform any task that a classical computer can, this does not necessarily mean that a quantum computer will always outperform a classical computer. Multiplication is an often-cited example of something that would be done just as quickly on a classical computer as on a quantum computer.⁹⁰ From the early stages of quantum computing, scientists knew that to demonstrate the superior computing power, new algorithms would have to be designed to exploit the phenomenon of quantum parallelism. Such algorithms are complex and difficult to devise, but two are driving the development of this highly theorized field: Shor's algorithm and Grover's algorithm.⁹¹

Peter Shor of Bell Labs designed the first quantum algorithm in 1994. Shor's algorithm allows for rapid factoring of very large numbers into their prime factors. For example, scientific estimates state that it would take a modern computer 10^{24} years to

factor a 1,000-digit number; it would take a quantum computer about 20 minutes.⁹² The implications of this quantum algorithm on classic algorithms that depend on the difficulty of factoring for security, such as the widely used RSA algorithm, are immense. “The ability to break the RSA coding system will render almost all current channels of communications unsecure.”⁹³

Lov Grover, also of Bell Labs, invented the second quantum algorithm in 1996. Grover’s algorithm allows a quantum computer to search databases of all kinds much more quickly than any capability existing today. Grover notes that the greatest benefit is gained when his algorithm is used on an unsorted database.⁹⁴ On average, it takes a classical computer $n/2$ number of searches to find a specific entry in a database of n entries. Grover’s algorithm allows the same search to be done in the square root of n number of searches. For example, in a database of 1 million entries, it would take a computer today on average of 500,000 searches to find the right answer; it would take a quantum computer using Grover’s algorithm only 1,000 searches. This could have implications for symmetric key algorithms such as DES, because this algorithm would allow an exhaustive search of all possible keys to occur quite rapidly.⁹⁵

7.6.4.4 Current Status. Encouraged by the repercussions of quantum computing and the related algorithms on the security of information and cryptography, governments around the world are funding efforts to build a practical quantum computing system. The United States has many initiatives on-going. In 2001, the Defense Advanced Research Projects Agency (DARPA) of the Department of Defense launched a \$100 million effort that would last five years. In addition, the National Science Foundation has \$8 million in grant money for researching quantum capabilities. DARPA’s Quantum Information Science and Technology initiative will now exist indefinitely; it became a fully funded and permanent program in 2006.⁹⁶ A number of other governments, primarily within Europe and Asia, are involved in quantum computation research and development. In 2000, the European Commission launched a comprehensive research effort with \$20 million budgeted over three years. In Japan, the Ministry of Post and Telecommunications began an initiative in 2001 that will last 10 years with a total requested budget of \$400 million. There are several commercial enterprises also involved in quantum projects. This includes IBM, Bell Labs, the Japanese firms of Fujitsu, Ltd., NEC Corporation, and Nippon Telephone and Telegraph Corporation.⁹⁷ This list is by no means exhaustive, as there are universities and other organizations throughout the world with research efforts in full swing.

Because of the worldwide effort to understand quantum computing more thoroughly, several key advancements have been made. In 1998, researchers at Los Alamos National Laboratory and MIT were able to spread a qubit over three nuclear spins of certain types of molecules. According to the experiments, spreading the information (qubit) out made it more difficult to corrupt, or decohere. The researchers were able to accomplish this using a technique called nuclear magnetic resonance (NMR), which allows the manipulation and control of a nucleus’s spin. This technique allowed the researchers to use the property of entanglement to analyze indirectly the quantum information.⁹⁸

In 2000, researchers at IBM developed a five-qubit computer, also using the nuclei of a liquid. The nuclei were programmed by radio frequency pulses and then detected by NMR techniques. Using this technique, the team was able to find the period of a particular function, or the length of the shortest interval over which it repeats its values. This problem would take a classical computer several repeated cycles to compute; the team at IBM was able to do it in one step. In 2001, a combined group of scientists from

IBM and Stanford University demonstrated Shor's algorithm and were able to find the prime factors of 15. The seven-qubit computer correctly deduced that the prime factors were 3 and 5.⁹⁹

In February 2007, a Canadian company called D-Wave claimed to demonstrate the first commercial quantum computer. It is a "supercooled, superconducted niobium chip housing an array of 16 qubits."¹⁰⁰ D-Wave chose not to focus on cryptographic efforts when building the Orion, as the computer is called. Instead, Orion focuses its energy on solving pattern-matching problems and nondeterministic polynomial problems (NP-complete problems). NP-complete problems are decision problems that contain searching and optimization problems, and are used when someone needs to know if a certain solution for a certain problem exists. Examples of such problems include database searches, pattern matching, identifying diseases from symptoms, and finding matches for genetic material.¹⁰¹ The company's demonstrations were done via a television feed from a remote location, due to the sensitive nature of the machine and the difficulty in transporting equipment that is cooled to just above absolute zero. Despite the demonstrations and the claims of D-Wave, scientists are skeptical that Orion is actually performing quantum computations. Even the chief executive of D-Wave said that, although all evidence indicates that Orion is performing quantum computations, there is some uncertainty. Nevertheless, D-Wave announced plans to boost the Orion to 1,000 qubits by 2008.¹⁰²

In July 2007, scientists from NIST (United States) and the Rutherford Appleton Laboratory (United Kingdom) teamed up to explore magnetic quantum effects. This team reports having chained together "100 atoms of yttrium barium nickel oxide into a quantum spin-chain that, in effect, turn[ed] the 30-nanometer long magnetic molecule into a single element."¹⁰³ This discovery is an important step toward putting qubits onto solid-state circuits. Thirty nanometers is well beyond the atomic length scale, and it is unusual to see quantum coherence beyond the atomic level. However, the team did report stable coherent states at this size, which is large enough for the lithographic techniques used to create circuit boards and conductors of classical computers.¹⁰⁴

In April 2013, researchers "successfully transmitted a secure quantum code through the atmosphere from an aircraft to a ground station." The author continues,

"This demonstrates that quantum cryptography can be implemented as an extension to existing systems," says LMU's Sebastian Nauwerth. In the experiment, single photons were sent from the aircraft to the receiver on the ground. The challenge was to ensure that the photons could be precisely directed at the telescope on the ground in spite of the impact of mechanical vibrations and air turbulence. "With the aid of rapidly movable mirrors, a targeting precision of less than 3 m over a distance of 20 km was achieved," reports Florian Moll, project leader at the DLR's Institute for Communication and Navigation. With this level of accuracy, William Tell could have hit the apple on his son's head even from a distance of 500 m.

With respect to the rate of signal loss and the effects of air turbulence, the conditions encountered during the experiment were comparable to those expected for transmission via satellite. The same holds for the angular velocity of the aircraft. The success of the experiment therefore represents an important step towards secure satellite-based global communication.¹⁰⁵

Even with the advances just mentioned, skeptics believe that practical quantum computers that outperform classical computers are still years, or even decades, away. After conducting many hours of research on the topic of quantum computing, this author's opinion is that it is not a matter of *if* quantum computing will become a reality but a matter of *when*. That scientists have been able to demonstrate a few theoretical

7 · 44 ENCRYPTION

quantum computations on systems comprised of only a few qubits is highly promising. Yet scientists need to overcome many obstacles. Systems containing hundreds or thousands of qubits will be needed to perform useful computations. In addition, precise controls will be required to accomplish operations while avoiding decoherence; in fact, decoherence is perhaps the biggest obstacle to the creation of a quantum system. Until scientists can reliably measure information produced by qubits at work, it is unlikely that a practical quantum system will be built in the near future.¹⁰⁶

7.6.5 Snake Oil Factor. As encryption vendors and cryptographers come to grips with the implementation and extended testing of new algorithms, it is important to note these words from the AES competition requirements:

A complete written specification of the algorithm shall be included, consisting of all necessary mathematical equations, tables, diagrams, and parameters that are needed to implement the algorithm.

In other words, there is no secret about how the AES will make things secret, just as there is no secret about how DES works. This often strikes the crypto-novice as illogical. Why not keep the algorithm secret? Surely that will make any messages encrypted with it that much harder to decrypt. Not really. Any reliance on the secrecy of the algorithm inserts a weak link in the chain of security. Encrypting data does not guarantee that it will remain confidential. The keys must be kept secret, and the identity of persons requesting authorized access must be verified to ensure they are authentic, and so on. This is true of public key encryption as well as private key encryption.

This principle is known as Kerckhoffs' Principle, based on an 1883 publication by military cryptographer Auguste Kerckhoffs:

1. The system must be practically, if not mathematically, indecipherable;
2. It must not be required to be secret, and it must be able to fall into the hands of the enemy without inconvenience;
3. Its key must be communicable and retainable without the help of written notes, and changeable or modifiable at the will of the correspondents;
4. It must be applicable to telegraphic correspondence;
5. It must be portable, and its usage and function must not require the concurrence of several people;
6. Finally, it is necessary, given the circumstances that command its application, that the system be easy to use, requiring neither mental strain nor the knowledge of a long series of rules to observe.¹⁰⁷

There is no benefit to be gained by relying on an algorithm that has not been subject to open review, particularly when strong, reviewed algorithms exist. Beware of encryption vendors, or producers of any security products, that claim strength based on secret algorithms. Such claims are often a case of snake oil. (For more on bogus claims for crypto products, see Curtin's "Snake Oil FAQ," included in Section 7.8, "Further Reading," at the end of this chapter.)

7.7 STEGANOGRAPHY. Instead of scrambling data through cryptography, one can also insert data covertly into other data streams. *Steganography* (literally *covered writing* in Greek) generally uses the low-order bits of a data stream—typically an

image—to convey the cleartext. In today’s high-resolution representations of color images, modifying the least significant bits of a pixel makes a negligible change in color, at least to the human eye. The steganographic software can make the changes and then extract them from the modified image.¹⁰⁸

Such modified images are difficult to identify, but steganography detection tools, which rely on detecting abnormal patterns in the pixels of a carrier image, do exist.¹⁰⁹ For example, StegoHunt™ and StegoAnalyst software from Wetstone Technologies can identify and analyze steganographically modified data; StegoBreak can extract the cleartext from the carrier file.¹¹⁰

7.8 FURTHER READING. As stated at the outset, this chapter was not designed to be an extensive treatise on cryptography or a complete guide to the implementation of encryption technology. There are many resources available to help readers deepen their understanding of this fundamental area of information security.

8.1 INTRODUCTION. A computer security *incident* is some set of events that involves an attack or series of attacks at one or more sites. (See Section 8.4.3 for a more formal definition of the term “incident.”) Dealing with these incidents is inevitable for individuals and organizations at all levels of computer security. A major part of dealing with these incidents is recording and receiving incident information, which almost always is in the form of relatively unstructured text files. Over time, these files can end up containing a large quantity of very valuable information. Unfortunately, the unstructured form of the information often makes incident information difficult to manage and use.

This chapter presents the results of several efforts over the last few years to develop and propose a method to handle these unstructured computer security incident records. Specifically, this chapter presents a *tool* designed to help individuals and organizations record, understand, and share computer security incident information. We call the tool the *common language for computer security incident information*. This common language contains two parts:

1. A set of “high-level” incident-related terms
2. A method of classifying incident information (a taxonomy)

8 · 2 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

The two parts of the common language, the terms and the taxonomy, are closely related. The taxonomy provides a structure that shows how most common-language terms are related. The common language is intended to help investigators improve their ability to:

- Talk more understandably with others about incidents
- Gather, organize, and record incident information
- Extract data from incident information
- Summarize, share, and compare incident information
- Use incident information to evaluate and decide on proper courses of action
- Use incident information to determine effects of actions over time

This chapter begins with a brief overview of why a common language is needed, followed by a summary of how the incident common language was developed. We then present the common language in two parts: (1) incident terms and taxonomy and (2) additional incident information terms. The final section contains information about some practical ways to use the common language.

8.2 WHY A COMMON LANGUAGE IS NEEDED. When the first edition of this *Handbook* was published more than 30 years ago, computer security was a small, obscure, academic specialty. Because there were only a few people working in the field, the handling of computer security information could largely take place in an ad hoc way. In this environment, individuals and groups developed their own terms to describe computer security information. They also developed, gathered, organized, evaluated, and exchanged their computer security information in largely unique and unstructured ways. This lack of generalization has meant that computer security information has typically not been easy to compare or combine, or sometimes even to talk about in an understandable way.

Progress over the years in agreeing on a relatively standard set of terms for computer security (a common language) has had mixed results. One problem is that many terms are not yet in widespread use. Another problem is that the terms that are in widespread use often do not have standard meanings. An example of the latter is the term “computer virus.” We hear the term frequently, not only in academic forums but also in the news media and popular publications. It turns out, however, that even in academic publications, “computer virus” has no accepted definition.¹ Many authors define a computer virus to be “a code fragment that copies itself into a larger program.”² They use the term “worm” to describe an independent program that performs a similar invasive function (e.g., the Internet Worm in 1988). But other authors use the term “computer virus” to describe *both* invasive code fragments and independent programs.

Progress in developing methods to gather, organize, evaluate, and exchange computer security information also has had limited success. For example, the original records (1988–1992) of the Computer Emergency Response Team (now the CERT Coordination Center or CERT/CC) are simply a file of email and other files sent to the CERT/CC. These messages and files were archived together in chronological order, without any other organization. After 1992, the CERT/CC and other organizations developed methods to organize and disseminate their information, but the information remains difficult to combine or compare because most of it remains almost completely textual information that is uniquely structured for the CERT/CC.

Such ad hoc terms and ad hoc ways to gather, organize, evaluate, and exchange computer security information are no longer adequate. Far too many people and organizations are involved, and there is far too much information to understand and share. Today computer security is an increasingly important, relevant, and sophisticated field of study. Numerous individuals and organizations now regularly gather and disseminate computer security information. Such information ranges all the way from the security characteristics and vulnerabilities of computers and networks, to the behavior of people and systems during security incidents—far too much information for each individual and organization to have its own unique language.

One of the key elements to making systematic progress in any field of inquiry is the development of a consistent set of terms and taxonomies (principles of classification) that are used in that field.³ This is a necessary and natural process that leads to a growing *common language*, which enables gathering, exchanging, and comparing information. In other words, the more a field of inquiry such as computer security grows, the more a common language is needed to understand and communicate with one another.

8.3 DEVELOPMENT OF THE COMMON LANGUAGE. Two of the more significant efforts in the process of developing this common language for computer security incident information were (1) a project to classify more than 4,300 Internet security incidents completed in 1997,⁴ and (2) a series of workshops in 1997 and 1998 called the *Common Language Project*. Workshop participants included people primarily from the Security and Networking Research Group at the Sandia National Laboratories, Livermore, California, and from the CERT/CC at the Software Engineering Institute, Carnegie Mellon University, Pittsburgh, Pennsylvania. Additional participation and review came from people in the Department of Defense (DoD) and the National Institute of Standards and Technology (NIST).

These efforts to develop the common language were *not* efforts to develop a comprehensive dictionary of terms. Instead, the participants were trying to develop both a *minimum* set of “high-level” terms to describe computer security attacks and incidents, and a structure and classification scheme for these terms (a *taxonomy*), which could be used to classify, understand, exchange, and compare computer security attack and incident information.

Participants in the workshops hoped this common language would gain wide acceptance because of its usefulness. There is already evidence that this acceptance is taking place, particularly at incident response teams and in the DoD.

In order to be complete, logical, and useful, the common language for computer security incident information was based initially and primarily on theory (i.e., it was a priori or nonempirically based).⁵ Classification of actual Internet security incident information was then used to refine and expand the language. More specifically, the common language development proceeded in six stages:

1. Records at the CERT/CC for incidents reported to them from 1988 through 1995 were examined to establish a preliminary list of terms used to describe computer security incidents.
2. The terms in this list, and their definitions, were put together into a structure (a preliminary taxonomy).
3. This preliminary taxonomy was used to classify the information in the 1988 through 1995 incident records.
4. The preliminary taxonomy and classification results were published in 1997.⁶

8 · 4 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

5. A series of workshops was conducted from 1997 through 1998 (the *Common Language Project*) to make improvements to the taxonomy and to add additional terms.
6. The results of the workshops (the “common language for security incidents”) were first published in 1998.

A *taxonomy* is a classification scheme (a structure) that partitions a body of knowledge and defines the relationship of the pieces.⁷ Most of the terms in this common language for security incident information are arranged in such a taxonomy, as presented in the next section. *Classification* is the process of using a taxonomy for separating and ordering. As discussed earlier, classification of information using a taxonomy is necessary for computer security incident information because of the rapidly expanding amount of information and the nature of that information (primarily text). Classification using the common-language taxonomy is discussed in the final section of this chapter.

Our experience has shown that satisfactory taxonomies have classification categories with these six characteristics⁸:

1. **Mutually exclusive.** Classifying in one category excludes all others because categories do not overlap.
2. **Exhaustive.** Taken together, the categories include all possibilities.
3. **Unambiguous.** The taxonomy is clear and precise, so that classification is not uncertain, regardless of who is doing the classifying.
4. **Repeatable.** Repeated applications result in the same classification, regardless of who is doing the classifying.
5. **Accepted.** It is logical and intuitive, so that categories can become generally approved.
6. **Useful.** The taxonomy can be used to gain insight into the field of inquiry.

These characteristics were used to develop and evaluate the common-language taxonomy. A taxonomy, however, is merely an approximation of reality, and as such, even the best taxonomy will fall short in some characteristics. This may be especially true when the characteristics of the data being classified are imprecise and uncertain, as is typical for computer security incident information. Nevertheless, classification is an important, useful, and necessary prerequisite for systematic study of incidents.

8.4 COMPUTER SECURITY INCIDENT INFORMATION TAXONOMY. We have been able to structure most of the terms in the common language for security incident information into a taxonomy. These terms and the taxonomy are presented in this section. Additional terms that describe the more general aspects of incidents are presented in Section 8.5.

8.4.1 Events. The operation of computers and networks involves innumerable *events*. In a general sense, an event is a discrete change of state or status of a system or device.⁹ From a computer security viewpoint, these changes of state result from *actions* that are directed against specific *targets*. An example is a user taking action to log in to the user’s account on a computer system. In this case, the action taken by the user is to *authenticate* to the login program by claiming to have a specific identity and

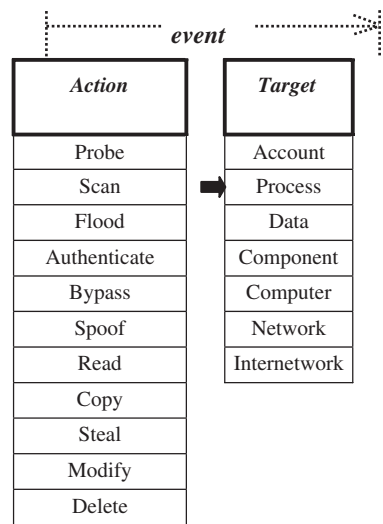

EXHIBIT 8.1 Computer and Network Events

then presenting the required verification. The target of this action would be the user’s *account*. Other examples include numerous actions that can be targeted toward:

- *Data* (e.g., actions to *read*, *copy*, *modify*, *steal*, or *delete*)
- *A process* (e.g., actions to *probe*, *scan*, *authenticate*, *bypass*, or *flood* a running computer process or execution thread)
- *A component, computer, network, or internetwork* (e.g., actions to *scan* or *steal*)

Exhibit 8.1 presents a matrix of actions and targets that represent possible computer and network events (although not all of the possible combinations shown are feasible). A computer or network event is defined as:

Event—action directed at a target that is intended to result in a change of state, or status, of the target.¹⁰

Several aspects of this definition are important to emphasize. First, in order for there to be an event, there must be an action that is taken, and it must be directed against a target, but the action does *not* have to succeed in actually changing the state of the target. For example, if a user enters an incorrect user name and password combination when logging in to an account, an authentication event has taken place, but the event was not successful in verifying that the user has the proper credentials to access that account.

A second important aspect is that an event represents a *practical* linkage between an action and a specific target against which the action is directed. As such, it represents the way people generally conceptualize events on computers and networks, and not all of the individual steps that actually take place during an event. For example, when a user logs in to an account, we classify the action as *authenticate* and the target as *account*. The actual action that takes place is for the user to access a process (e.g., a “login” program) in order to authenticate. Trying to depict all of the individual steps

8 · 6 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

is an unnecessary complication; the higher-level concepts presented here can describe correctly and accurately the event in a form well understood by people. In other words, it makes sense to abstract the language and its structure to the level at which people generally conceptualize the events.

By all means, supporting evidence should be presented so the evidence provides a complete idea of what happened. Stated another way, abstraction, conceptualization, and communication should be applied as close to the evidence as possible. For example, if a network switch is the target of an attack, then the target should normally be viewed as a computer or as a component (depending on the nature of the switch), and not the network, because assuming the network is the target may be an inaccurate interpretation of the evidence.

Another aspect of the definition of event is that it does not make a distinction between *authorized* and *unauthorized* actions. Most events that take place on computers or networks are both routine and authorized and, therefore, are not of concern to security professionals. Sometimes, however, an event is part of an attack or is a security concern for some other reason. This definition of event is meant to capture both authorized and unauthorized actions. For example, if a user authenticates properly, by giving the correct user identification and password combination while logging in to an account, that user is given access to that account. It may be the case, however, that this user is masquerading as the actual user, after having obtained the user identification and password from snooping on the network. Either way, this is still considered authentication.

Finally, an important aspect of events is that not all of the possible events (the action–target combinations depicted in Exhibit 8.1) are considered likely or even possible. For example, an action to *authenticate* is generally associated with an *account* or a *process* and not a different target, such as *data* or a *component*. Other examples include *read* and *copy*, which are generally targeted toward *data*; *flooding*, which is generally targeted at an *account*, *process*, or *system*; or *stealing*, which is generally targeted against *data*, a *component*, or a *computer*.

We define *action* and *target* as follows:

Action—step taken by a user or process in order to achieve a result,¹¹ such as to probe, scan, flood, authenticate, bypass, spoof, read, copy, steal, modify, or delete.

Target—computer or network logical entity (account, process, or data) or a physical entity (component, computer, network or internetwork).

8.4.1.1 Actions. The actions depicted in Exhibit 8.1 represent a spectrum of activities that can take place on computers and networks. An action is a step taken by a *user* or a *process* in order to achieve a result. Actions are initiated by accessing a target, where *access* is defined as:

Access—establish logical or physical communication or contact.¹²

Two actions are used to gather information about targets: *probe* and *scan*. A probe is an action to determine one or more characteristics of a specific target. This is unlike a scan, which is an action where a user or process accesses a set of targets systematically, in order to determine which targets have one or more characteristics.

“Probe” and “scan” are terms commonly used by incident response teams. As a result, they have common, accepted definitions. Despite this, there is a logical ambiguity: A scan could be viewed as multiple probes. In other words, if an attacker is testing

	Test for One or More Characteristics
Test a Single Host	Probe
Nonsystematically Test Multiple Hosts	Multiple probes
Systematically Test a Set of Hosts	Scan

EXHIBIT 8.2 Probe Compared to Scan

for one or more characteristics on multiple hosts, this can be (a) multiple attacks (all *probes*), or (b) one attack (a *scan*). This point was discussed extensively in the Common Language Project workshops, and the conclusion was that the terms in the common language should match, as much as possible, their common usage. This common usage is illustrated in Exhibit 8.2.

With probes and scans, it is usually obvious what is taking place. The attacker is either “hammering away” at one host (a *probe*), randomly testing many hosts (multiple *probes*), or using some “automatic” software to look for the same characteristic(s) systematically across a group of hosts (a *scan*). As a practical matter, incident response teams do not usually have a problem deciding what type of action they are dealing with.

One additional point about *scan* is that the term “systematic” is not meant to specify some specific pattern. The most sophisticated attackers try to disguise the systematic nature of a scan. A scan may, at first, appear to be multiple probes. For example, an attacker may randomize a scan with respect to hosts and with respect to the characteristic(s) being tested. If the attack can be determined to involve testing of one or more characteristics on a group of hosts with some common property (e.g., an Internet Protocol [IP] address range) or if tests on multiple hosts appear to be otherwise related (e.g., having a common origin in location and time), then the multiple probes should be classified as a scan.

Unlike probe or scan, an action taken to *flood* a target is not used to gather information about the target. Instead, the desired result of a flood is to overwhelm or overload the target’s capacity by accessing the target repeatedly. An example is repeated requests to open connections to a port over a network or repeated requests to initiate processes on a computer. Another example is a high volume of email messages, which may exceed the resources available for the targeted account.

Authenticate is an action taken by a user to assume an identity. Authentication starts with a user accessing an authentication process, such as a login program. The user must claim to have a certain identity, such as by entering a user name. Usually verification is also required as a second authentication step. For verification, the user must prove knowledge of some secret (e.g., a password), prove the possession of some token (e.g., a secure identification card), and/or prove to have a certain characteristic (e.g., a retinal scan pattern). Authentication can be used not only to log in to an account but also to access other objects, such as to operate a process or to access a file. In other words, the target of an authentication action is the entity (e.g., account, process, or data) that the user is trying to access, not the authentication process itself.

Two general methods might be used to defeat an authentication process. First, a user could obtain a valid identification and verification pair that could be used to authenticate, even though it does not belong to that user. For example, during an

8 · 8 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

incident, an attacker might use a process operating on an Internet host computer that captures user name, password, and IP address combinations that are sent in clear text across the Internet. The attacker could then use this captured information to authenticate (log in) to accounts that belong to other users. It is important to note, as mentioned earlier, that this action is still considered *authenticate*, because the attacker presents valid identification and verification pairs, even though they have been stolen.

The second method that might be used to defeat an authentication process is to exploit a vulnerability in order to bypass the authentication process and access the target. *Bypass* is an action taken to avoid a process by using an alternative method to access a target. For example, some operating systems have vulnerabilities that an attacker could exploit to gain privileges without actually logging in to a privileged account.

As was discussed with respect to *authenticate*, an action to *bypass* does not necessarily indicate that the action is unauthorized. For example, some programmers find it useful to have a shortcut (“back-door”) method to enter an account or run a process, particularly during development. In such a situation, an action to *bypass* may be considered authorized.

Authenticate and *bypass* are actions associated with users identifying themselves. In network communications, processes also identify themselves to each other. For example, each packet of information traveling on a network contains addresses identifying both the source and the destination, as well as other information. “Correct” information in these communications is assumed, since it is automatically generated. Thus, no action is included on the list to describe this normal situation. Incorrect information could, however, be entered into these communications. Supplying such false information is commonly called an action to *spoof*. Examples include IP spoofing, mail spoofing, and Domain Name System (DNS) spoofing.

Spoofing is an active security attack in which one machine on the network masquerades as a different machine. . . . [It] disrupts the normal flow of data and may involve injecting data into the communications link between other machines. This masquerade aims to fool other machines on the network into accepting the imposter as an original, either to lure the other machines into sending it data or to allow it to alter data.¹³

Some actions are closely associated with data found on computers or networks, particularly with files: *read*, *copy*, *modify*, *steal*, and *delete*. There has been some confusion over these terms because their common usage in describing the physical world sometimes differs from their common usage describing the electronic world. For example, if I say that an attacker *stole* a computer, then you can assume I mean the attacker took possession of the target (computer) and did not leave an identical computer in that location. If I say, however, that the attacker stole a computer *file*, what does that actually mean? It is often taken to mean that the attacker *duplicated* the file and now has a copy, but also it means that the original file is still in its original location. In other words, “steal” sometimes means something different in the physical world than it does in the electronic world.

It is confusing for there to be differences in the meaning of actions in the physical world and the electronic world. Workshop participants attempted to reconcile these differences by carefully defining each term (*read*, *copy*, *modify*, *steal*, or *delete*) so it would have a very specific and mutually exclusive meaning that matches the physical-world meaning as much as possible.

Read is defined as an action to obtain the content of the data contained within a file or other data medium. This action is distinguished conceptually from the actual physical steps that may be required to read. For example, in the process of reading a computer

file, the file may be copied from a storage location into the computer's main memory and then displayed on a monitor to be read by a user. These physical steps (copy the file into memory and then onto the monitor) are not part of the abstract concept of *read*. In other words, to read a target (obtain the content in it), copying of the file is not necessarily required, and it is conceptually not included in our definition of *read*.

The same separation of concepts is included in the definition of the term “copy.” In this case, we are referring to acquiring a copy of a target without deleting the original. The term “copy” does not imply that the *content* in the target is obtained, just that a *copy* has been made and obtained. To get the content, the file must be *read*. An example is copying a file from a hard disk to a floppy disk. This copying is done by duplicating the original file while leaving the original file intact. A user would have to open the file and look at the content in order to *read* it.

Copy and *read* are both different concepts from *steal*, which is an action that results in the attacker taking possession of the target and the target also becoming unavailable to the original owner or user. This definition agrees with our concepts about physical property, specifically that there is only one object that cannot be copied. For example, if someone steals a car, then that person has deprived the owner of his or her possession. When dealing with property that is in electronic form, such as a computer file, often the term “steal” is used, when *copy* is what actually is meant. The term “steal” specifically means that the original owner or user has been denied access or use of the target. On the other hand, stealing also could mean *physically* taking a floppy disk that has the file located on it or stealing an entire computer.

Two other actions involve changing the target in some way. The first are actions to *modify* a target. Examples include changing the content of a file, changing the password of an account, sending commands to change the characteristics of an operating process, or adding components to an existing system. If the target is eliminated entirely, the term “delete” is used to describe the action.

As stated earlier, differences in usage of terms between the physical world and the electronic world are undesirable. As such, we tried to be specific and consistent in our usage. The resulting set of terms is exhaustive and mutually exclusive, but goes against the grain in some common usage for the electronic world, particularly with respect to the term “steal.” The situation seems unavoidable. Here are some examples that might clarify the terms:

- A user clicks on a link with the browser and sees the content of a Web page on the computer screen. We would classify this as a *read*. While what actually happens is that the content of the page is stored in volatile memory, copied to the cache on the hard drive, and displayed on the screen, from a *logical* (i.e., user) point of view, the Web page has *not* been copied (nor stolen). Now, if a user copies the content of the Web page to a file or prints it out, then the user *has* copied the Web page. Again, this would be a logical classification of the action, from the user's point of view.
- A user duplicates a file that is encrypted. We would classify this as *copy*, not *read*. In this case, the file was reproduced, but the content not obtained, so it was not read.
- A user deletes several entries in a password or group file. Should this action be described as several *delete* actions or as one action to *modify*? We would describe this action as *modify*, and the target is *data*. There is no ambiguity here because of the definition of “data.” Data are defined to be either a stationary file or a file in transit (see the next section). If a user deletes a line out of the password file, then the file has been modified. The action would be described as *delete* only if

8 · 10 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

the whole file was deleted. If we had defined data to include part of a file, then we would indeed have an ambiguity.

- A user copies a file and deletes the original. We would classify this as *steal*. Although the steps actually include a *copy* followed by a *delete*, that is the electronic way of stealing a file, and therefore it is more descriptive to describe the action as *steal*.

In reality, the term “steal” is rarely used (correctly) because attackers who copy files usually do not delete the originals. The term “steal” often is used *incorrectly*, as in “stealing the source code,” when in fact the correct term is *copy*.

The list of actions was hashed over in numerous group discussions, off and on, for several years before being put into the common language. Most people who participated in these discussions were not entirely happy with the list, but it is the best we have seen so far. Specifically, the list seems to capture all of the common terms with their common usage (*probe*, *scan*, *flood*, *spoof*, *copy*, *modify*, and *delete*) and the other terms are logical (to the people who participated in the discussion groups) and are necessary to make the action category exhaustive (*authenticate*, *bypass*, *read*, and *steal*).

Here is a summary of our definitions of the actions shown in Exhibit 8.1.

Probe—access a target in order to determine one or more of its characteristics.

Scan—access a set of targets systematically in order to identify which targets have one or more specific characteristics.¹⁴

Flood—access a target repeatedly in order to overload the target’s capacity.

Authenticate—present an identity to a process and, if required, verify that identity, in order to access a target.¹⁵

Bypass—avoid a process by using an alternative method to access a target.¹⁶

Spoof—masquerade by assuming the appearance of a different entity in network communications.¹⁷

Read—obtain the content of data in a storage device or other data medium.¹⁸

Copy—reproduce a target leaving the original target unchanged.¹⁹

Steal—take possession of a target without leaving a copy in the original location.

Modify—change the content or characteristics of a target.²⁰

Delete—remove a target or render it irretrievable.²¹

8.4.1.2 Targets. Actions are considered to be directed toward seven categories of targets. The first three of these are “logical” entities (*account*, *process*, and *data*), and the other four are “physical” entities (*component*, *computer*, *network*, and *internetwork*).

In a multiuser environment, an *account* is the domain of an individual user. This domain includes the files and processes the user is authorized to access and use. A special program that records the user’s account name, password, and use restrictions controls access to the user’s account. Some accounts have increased or special permissions that allow access to system accounts, other user accounts, or system files and processes, and often are called *privileged*, *superuser*, *administrator*, or *root* accounts.

Sometimes an action may be directed toward a *process*, which is a program executing on a computer or network. In addition to the program itself, the process includes the program’s data and stack; its program counter, stack pointer, and other registers; and all other information needed to execute the program.²² The action may then be to supply information to the process or command the process in some manner.

The target of an action may be *data* that are found on a computer or network. Data are representations of facts, concepts, or instructions in forms that are suitable for use by either users or processes. Data may be found in two forms: files or data in transit. *Files* are data that are designated by name and considered as a unit by the user or by a process. Commonly we think of files as being located on a storage medium, such as a storage disk, but files also may be located in the volatile or nonvolatile memory of a computer. *Data in transit* are data being transmitted across a network or otherwise emanating from some source. Examples of the latter include data transmitted between devices in a computer and data found in the electromagnetic fields that surround computer monitors, storage devices, processors, network transmission media, and the like.

Sometimes we conceptualize the target of an action as not being a *logical* entity (account, process, or data) but rather as a *physical* entity. The smallest of the physical entities is a *component*, which is one of the parts that make up a computer or network. A *network* is an interconnected or interrelated group of computers, along with the appropriate switching elements and interconnecting branches.²³ When a computer is attached to a network, it is sometimes referred to as a *host computer*. If networks are connected to each other, then they are sometimes referred to as an *internetwork*.

Here is a summary of our definitions of the targets shown in Exhibit 8.1.

Account—domain of user access on a computer or network that is controlled according to a record of information which contains the user's account name, password, and use restrictions.

Process—program in execution, consisting of the executable program, the program's data and stack, its program counter, stack pointer and other registers, and all other information needed to execute the program.²⁴

Data—representations of facts, concepts, or instructions in a manner suitable for communication, interpretation, or processing by humans or by automatic means.²⁵ Data can be in the form of *files* in a computer's volatile memory or nonvolatile memory, or in a data storage device, or in the form of *data in transit* across a transmission medium.

Component—one of the parts that make up a computer or network.²⁶

Computer—device that consists of one or more associated components, including processing units and peripheral units, that is controlled by internally stored programs and that can perform substantial computations, including numerous arithmetic operations or logic operations, without human intervention during execution. Note: may be stand-alone or may consist of several interconnected units.²⁷

Network—interconnected or interrelated group of host computers, switching elements, and interconnecting branches.²⁸

Internetwork—network of networks.

8.4.2 Attacks. Sometimes an event that occurs on a computer or network is part of a series of steps intended to result in something that is not authorized to happen. This event is then considered part of an *attack*. An attack has three elements.

1. It is made up a series of steps taken by an *attacker*. Among these steps is an action directed at a target (an *event*, as described in the previous section) as well as the use of some *tool* to exploit a *vulnerability*.

8 · 12 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

- 2. An attack is intended to achieve an *unauthorized result* as viewed from the perspective of the owner or administrator of the system involved.
- 3. An attack is a series of *intentional* steps initiated by the attacker. This differentiates an attack from something that is inadvertent.

We define an attack in this way:

Attack—a series of steps taken by an attacker to achieve an unauthorized result.

Exhibit 8.3 presents a matrix of possible attacks, based on our experience. Attacks have five parts that depict the logical steps an attacker must take. An attacker uses a (1) *tool* to exploit a (2) *vulnerability* to perform an (3) *action* on a (4) *target* in order to achieve an (5) *unauthorized result*. To be successful, an attacker must find one or more paths that can be connected (attacks), perhaps simultaneously or repeatedly. The first two steps in an attack, *tool* and *vulnerability*, are used to cause an *event* (action directed at a *target*) on a computer or network. The logical end of a successful attack is an *unauthorized result*. If the logical end of the previous steps is an *authorized* result, then an attack has not taken place.

The concept of *authorized* versus *unauthorized* is key to understanding what differentiates an attack from the normal events that occur. It is also a system-dependent concept in that what may be authorized on one system may be unauthorized on another.

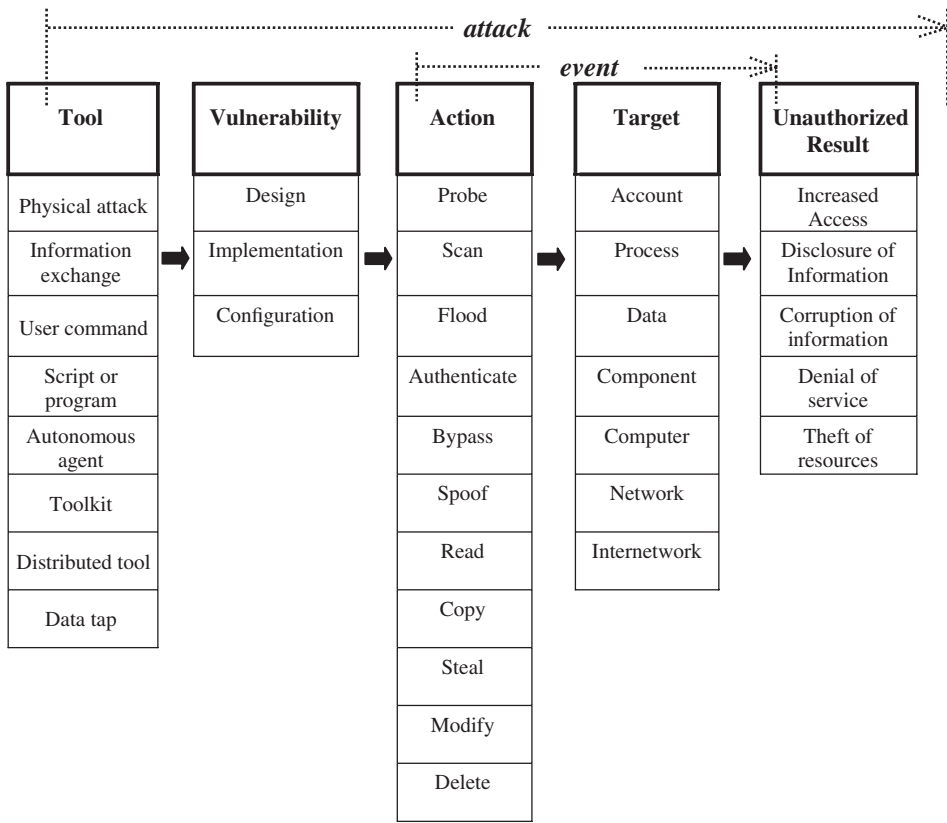

EXHIBIT 8.3 Computer and Network Attacks

For example, some services, such as anonymous File Transfer Protocol (FTP), may be enabled on some systems and not on others. Even actions that are normally viewed as hostile, such as attempts to bypass access controls to gain entry into a privileged account, may be authorized in special circumstances, such as during an approved test of system security or in the use of a “back door” during development. System owners or their administrators make the determination of what actions they consider authorized for their systems by establishing a security policy.²⁹ Here are the definitions for authorized and unauthorized.

Authorized—approved by the owner or administrator.

Unauthorized—not approved by the owner or administrator.

The steps *action* and *target* in Exhibit 8.1 are the two parts of an event as discussed in Section 8.4.1. The following sections discuss the other steps: *tool*, *vulnerability*, and *unauthorized result*.

8.4.2.1 Tool. The first step in the sequence that leads attackers to their unauthorized results is the *tool* used in the attack. A tool is some means that can be used to exploit a vulnerability in a computer or network. Sometimes a tool is simple, such as a user command or a physical attack. Other tools can be very sophisticated and elaborate, such as a Trojan horse program, computer virus, or distributed tool. We define *tool* in this way.

Tool—means of exploiting a computer or network vulnerability.

The term “tool” is difficult to define more specifically because of the wide variety of methods available to exploit vulnerabilities in computers and networks. When authors make lists of methods of attack, often they are actually making lists of tools. Based on our experience, these categories of tools are currently an exhaustive list. (See Exhibit 8.3)

Physical attack—means of physically stealing or damaging a computer, network, its components, or its supporting systems (e.g., air conditioning, electric power, etc.).

Information exchange—means of obtaining information either from other attackers (e.g., through an electronic bulletin board) or from the people being attacked (commonly called social engineering).

User command—means of exploiting a vulnerability by entering commands to a process through direct user input at the process interface. An example is entering UNIX commands through a telnet connection or commands at a protocol’s port.

Script or program—means of exploiting a vulnerability by entering commands to a process through the execution of a file of commands (script) or a program at the process interface. Examples are a shell script to exploit a software bug, a Trojan horse log-in program, or a password-cracking program.

Autonomous agent—means of exploiting a vulnerability by using a program or program fragment that operates independently from the user. Examples are computer viruses or worms.

8 · 14 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

Toolkit—software package that contains scripts, programs, or autonomous agents that exploit vulnerabilities. An example is the widely available toolkit called *rootkit*.

Distributed tool—tool that can be distributed to multiple hosts, which then can be coordinated to anonymously perform an attack on the target host simultaneously after some time delay.

Data tap—means of monitoring the electromagnetic radiation emanating from a computer or network using an external device.

With the exception of the physical attack, information exchange, and data tap categories, each of the tool categories may contain the other tool categories *within* itself. For example, toolkits contain scripts, programs, and sometimes autonomous agents. So when a *toolkit* is used, the *script or program* category is also included. *User commands* also must be used for the initiation of scripts, programs, autonomous agents, toolkits, and distributed tools. In other words, there is an order to some of the categories in the tools block, from the simple user command category to the more sophisticated distributed tools category. In describing or classifying an attack, generally a choice must be made among several alternatives within the tools block. We chose to classify according to the *highest* category of tool used, which makes the categories mutually exclusive in practice.

8.4.2.2 Vulnerability. To reach the desired result, an attacker must take advantage of a computer or network *vulnerability*.

Vulnerability—weakness in a system allowing unauthorized action.³⁰

A vulnerability in software is an error that arises in different stages of development or use.³¹ This definition can be used to give us three categories of vulnerabilities:

Design vulnerability—vulnerability inherent in the design or specification of hardware or software whereby even a perfect implementation will result in a vulnerability.

Implementation vulnerability—vulnerability resulting from an error made in the software or hardware implementation of a satisfactory design.

Configuration vulnerability—vulnerability resulting from an error in the configuration of a system, such as having system accounts with default passwords, having “world write” permission for new files, or having vulnerable services enabled.³²

8.4.2.3 Unauthorized Result. As shown in Exhibit 8.3, the logical end of a successful attack is an *unauthorized result*. At this point, an attacker has used a tool to exploit a vulnerability in order to cause an event to take place.

Unauthorized result—unauthorized consequence of an event.

If successful, an attack will result in one of the following³³:

Increased access—unauthorized increase in the domain of access on a computer or network.

Disclosure of information—dissemination of information to anyone who is not authorized to access that information.

Corruption of information—unauthorized alteration of data on a computer or network.

Denial of service—intentional degradation or blocking of computer or network resources.

Theft of resources—unauthorized use of computer or network resources.

8.4.3 Full Incident Information Taxonomy. Often attacks on computers and networks occur in a distinctive group that we would classify as being part of one *incident*. What makes these attacks a distinctive group is a combination of three factors, each of which we may only have partial information about.

1. There may be one attacker, or there may be several attackers who are related in some way.
2. The attacker(s) may use similar attacks, or they may be trying to achieve a distinct or similar objective.
3. The sites involved in the attacks and the timing of the attacks may be the same or may be related.

Here is the definition of *incident*:

Incident—group of attacks that can be distinguished from other attacks because of the distinctiveness of the attackers, attacks, objectives, sites, and timing.

The three parts of an incident are shown in simplified form in Exhibit 8.4, which shows that an attacker, or group of attackers, achieves objectives by performing attacks. An incident may comprise one single attack or multiple attacks, as illustrated by the return loop in the figure.

Exhibit 8.5 shows the full incident information taxonomy. It shows the relationship of events to attacks and attacks to incidents, and suggests that preventing attackers from achieving objectives could be accomplished by ensuring that an attacker cannot make any complete connections through the seven steps depicted. For example, investigations could be conducted of suspected terrorist *attackers*, systems could be searched periodically for attacker *tools*, system *vulnerabilities* could be patched, access controls could be strengthened to prevent *actions* by an attacker to access a *targeted* account, files could be encrypted so as not to *result* in disclosure, and a public education program could be initiated to prevent terrorists from achieving an *objective* of political gain.

8.4.3.1 Attackers and Their Objectives. *People* attack computers. They do so through a variety of methods and for a variety of objectives. What distinguishes the categories of attackers is a combination of who they are and their *objectives* (what they want to accomplish).

Attacker—individual who attempts one or more attacks in order to achieve an objective.

Objective—purpose or end goal of an incident.

EXHIBIT 8.4 Simplified Computer and Network Incident

8 · 16 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

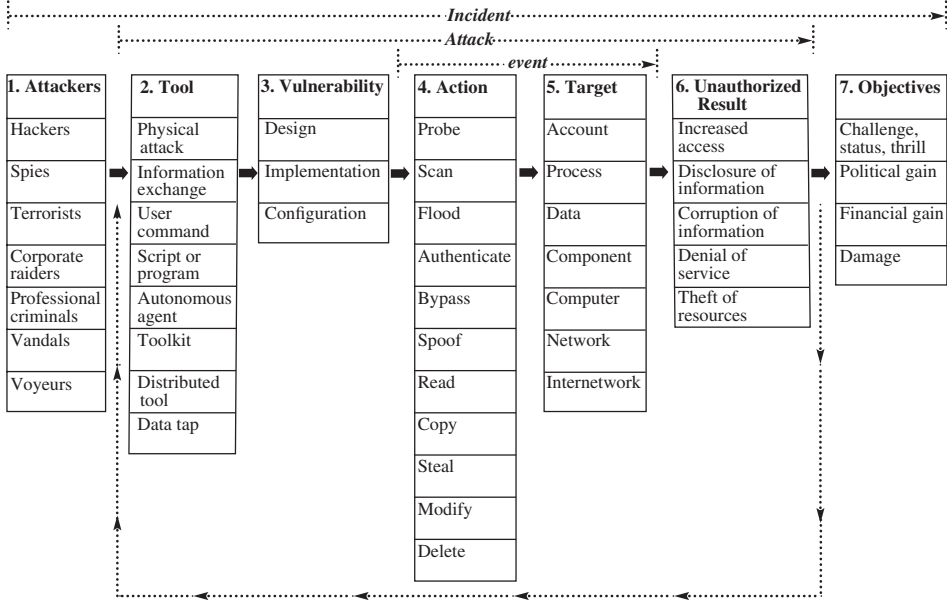

EXHIBIT 8.5 Computer and Network Incident Information Taxonomy

Based on their objectives, we have divided attackers into a number of categories:

Hackers—attackers who attack computers for challenge, status, or the thrill of obtaining access. (Note: We have elected to use the term “hacker” because it is common and widely understood. We realize that the term’s more positive connotation was once more widely accepted.)

Spies—attackers who attack computers for information to be used for political gain.

Terrorists—attackers who attack computers to cause fear, for political gain.

Corporate raiders—employees (attackers) who attack competitors’ computers for financial gain.

Professional criminals—attackers who attack computers for personal financial gain.

Vandals—attackers who attack computers to cause damage.

Voyeurs—attackers who attack computers for the thrill of obtaining sensitive information.

These seven categories of attackers and their four categories of objectives as shown in the leftmost and rightmost blocks of Exhibit 8.5 are fundamental to the difference between *incidents* and *attacks*. This difference is summed up in the phrase “attackers use attacks to achieve objectives.”

8.5 ADDITIONAL INCIDENT INFORMATION TERMS. The taxonomy of the last section presented all of the terms in the common language for computer security that describe how attackers achieve objectives during an incident. However, some other, more general terms are required to fully describe an incident. The next sections discuss these terms.

8.5.1 Success and Failure. Information on success or failure can be recorded at several levels in the overall taxonomy. In the broadest sense, overall success or failure is an indication of whether one or more attackers have achieved one or more objectives. A narrower focus would be to determine the success or failure of an individual attack by evaluating whether the attack leads to an unauthorized result. Information on success or failure, however, may simply not be known. For example, an attempt to log in to the root or superuser account on a system may be classified as a *success*, a *failure*, or as being *unknown*.

8.5.2 Site and Site Name. “Site” is the common term used to identify Internet organizations as well as physical locations. A “site” is also the organizational level of the site administrator or other authority with responsibility for the computers and networks at that location.

The term “site name” refers to a portion of the fully qualified domain name in the Internet’s Domain Name System (DNS). For sites in the United States, site names generally are at the second level of the DNS tree. Examples would be *cmu.edu* or *widgents.com*. In other countries, the site name is the third or lower level of the DNS tree, such as *widgents.co.uk*. Some site names occur even farther down the DNS tree. For example, a school in Colorado might have a site name of *myschool.k12.co.us*.

Here are the definitions of site and site name.

Site—organizational level with responsibility for security events; the organizational level of the site administrator or other authority with responsibility for the computers and networks at that location.

Site name—portion of the fully qualified domain name that corresponds to a site.

Some organizations, such as larger universities and companies, are large enough to be physically divided into more than one location, with separate administration. This separation cannot easily be determined. Therefore, often these different locations must be treated as one site.

8.5.3 Other Incident Terms. Several additional terms are necessary to fully describe actual Internet incidents. The first of these terms concern dates.

Reporting date—first date that the incident was reported to a response team or other agency or individuals collecting data.

Starting date—date of the first known incident activity.

Ending date—date of the last known incident activity.

Several terms concern the sites involved.

Number of sites—overall number of sites known to have reported or otherwise to have been involved in an incident.

Reporting sites—site names of sites known to have reported an incident.

Other sites—site names of sites known to have been involved in an incident but that did not report the incident.

For most incident response teams, actual site names are considered sensitive information. In our research, in order to protect the identities of the sites associated with an incident, we sanitize the site information by coding the site names prior to public

8 · 18 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

release. An example would be to replace a site name, such as the fictitious *widgets.com*, with numbers and the upper-level domain name, such as *123.com*.

Response teams often use incident numbers to track incidents and to identify incident information.

Incident number—reference number used to track an incident or identify incident information.

The last term we found to be of use is *corrective action*, which indicates those actions taken in the aftermath of an incident. These actions could include changing passwords, reloading systems files, talking to the intruders, or even criminal prosecution. Information on corrective actions taken during or after an incident is difficult to obtain for incident response teams, since response team involvement generally is limited to the early stages of an incident. CERT/CC records indicate that the variety of corrective actions is extensive, and a taxonomy of corrective actions may be a desirable future expansion of the common language.

Corrective action—action taken during or after an incident to prevent further attacks, repair damage, or punish offenders.

8.6 HOW TO USE THE COMMON LANGUAGE. Two things are important to emphasize about using the common language for computer security incident information. First, the common language really is a high-level set of terms. As such, it will not settle all the disputes about everything discussed concerning computer security incidents. For example, the common language includes “autonomous agent” as a term (a category of tool). Autonomous agents include *computer viruses*, *worms*, and the like, regardless of how those specific terms might be defined. In other words, the common language does not try to settle disputes on what should or should not be considered a *computer virus* but rather deals at a higher level of abstraction (“autonomous agent”) where, it is hoped, there can be more agreement and standardization. Stated another way, participants in the Common Language Project workshops anticipated that individuals and organizations would continue to use their own terms, which may be more specific in both meaning and use. The common language has been designed to enable these lower-level terms to be classified *within* the common language structure.

The second point to emphasize is that the common language, even though it presents a taxonomy, does not classify an incident (or individual attacks) as any *one* thing. Classifying computer security *attacks* or *incidents* is difficult because attacks and incidents are a *series of steps* that an attacker must take. In other words, attacks and incidents are not just *one* thing but rather a *series* of things. That is why I say the common language provides a taxonomy for computer security incident *information*.

An example of the problem is found in the popular and simple taxonomies often used to attempt to classify incidents. They appear as a list of single, defined terms. The following terms from Icove, Seger, and VonStorch provide an example.³⁴

Covert channels	Data diddling	Degradation of service
Denial of service	Dumpster diving	Eavesdropping on emanations
Excess privileges	Harassment	IP spoofing
Logic bombs	Masquerading	Password sniffing
Salamis	Scanning	Session hijacking
Software piracy	Timing attacks	Traffic analysis
Trap doors	Trojan horses	Tunneling
Unauthorized data copying	Viruses and worms	Wiretapping

Lists of terms are *not* satisfactory taxonomies for classifying actual attacks or incidents. They fail to have most of the six characteristics of a satisfactory taxonomy. First, the terms tend not to be mutually exclusive. For example, the terms “virus” and “logic bomb” are generally found on these lists, but a virus may *contain* a logic bomb, so the categories overlap. Actual attackers generally also use multiple methods so their attacks would have to be classified into multiple categories. This makes classification ambiguous and difficult to repeat.

A more fundamental problem is that, assuming that an exhaustive and mutually exclusive list could be developed, the taxonomy would be unmanageably long and difficult to apply. It also would not indicate any relationship between different types of attacks. Finally, none of these lists has become widely accepted, partly because it is difficult to agree on the definition of terms. In fact, many different definitions of terms are in common use.

The fundamental problems with these lists (and their variations) are that most incidents involve multiple attacks, and attacks involve multiple steps. As a result, information about the typical incident must be classified in multiple categories. For example, one of the attacks in an incident might be a flood of a host resulting in a denial of service. But this same incident might involve the exploitation of a vulnerability to compromise the host computer that was the specific origin of the flood. Should this be classified as a flood? As a root compromise? As a denial-of-service attack? In reality, the incident should be classified in all of these categories. In other words, this incident has multiple classifications.

In summary, in developing the common language, we have found that, with respect to *attacks* and *incidents*, we can really *only* hope to (1) present a common set of high-level terms that are in general use and have common definitions and (2) present a logical structure to the terms that can be used to classify information *about* an incident or attack *with respect to specific categories*.

Some examples may make this clear. As discussed earlier, most of the information about actual attacks and incidents is in the form of textual records. In a typical incident record at the CERT/CC, three observations might be reported:

1. We found *rootkit* on host xxx.xxx.
2. A flood of email was sent to account xxx@xxx.xxx, which crashed the mail server.
3. We traced the attack back to a teenager in Xyz city, who said he was not trying to cause any damage, just trying to see if he could break in.

For observation 1, we would classify *rootkit* in the “toolkit” category under “Tool” and the hostname in the “computer” category under “Target.” For observation 2, the “email flood” is a specific instantiation in the “flood” category under “Action” as well as in the “denial-of-service” category under “Unauthorized Result.” There is ambiguity as to the target for observation 2: Is it the account or the computer? As a practical matter, the observations would be classified as both, since information is available on both. For observation 3, it could be inferred that this is a “hacker” seeking “challenge, status, or thrill.”

What does this taxonomic process provide that is of practical value? First, the taxonomy helps us communicate to others what we have found. When we say that *rootkit* is a type of toolkit, then our common set of terms (“common language”) provides us the general understanding of what we mean. When it is said that 22 percent of incidents reported to CERT/CC from 1988 through 1995 involved various problems with

8 · 20 USING A COMMON LANGUAGE FOR COMPUTER SECURITY INCIDENT

passwords (a correct statistic³⁵), then the taxonomy has proven useful in communicating valuable information.

The application of the taxonomy, in fact, is a four-step process that can be used to determine the biggest security problems. Specifically, the process is to:

1. Take observations from fragmentary information in incident reports.
2. Classify those observations.
3. Perform statistical studies of these data.
4. Use this information to determine the best course(s) of action.

Over time, the same process can be used to determine the effects of these actions.

Two more points are important to emphasize about this taxonomy. First, an *attack* is a process that, with enough information, is *always* classified in multiple categories. For example: in a “Tool” category, in a “Vulnerability” category, in an “Action” category, in a “Target” category, and in an “Unauthorized Result” category. Second, an *incident* can involve multiple, perhaps thousands, of attacks. As such, the information gathered in an incident theoretically could be classified correctly into *all* of the taxonomy categories.

Within these guidelines, the common language for computer security incidents has proven to be a useful and increasingly accepted tool to gather, exchange, and compare computer security information. The taxonomy itself has proven to be simple and straightforward to use.

9.1 WHY MODELS ARE IMPORTANT. When you drive a new car, you look for specific items that will help you control the car: the accelerator, the brake, the shift, and the steering wheel. These exist on all cars and perform the function of speeding the car up, slowing it down, and turning it left and right. This forms a model of the car. With these items properly working, you can make a convincing argument that the model correctly describes what a car must have in order to move and be steered properly.

A model in computer security serves the same purpose. It presents a general description of a computer system (or collection of systems). The model provides a definition of “protect” (e.g., “keep confidential” or “prevent unauthorized change to”) and conditions under which the protection is provided. With mathematical models, the conditions can be shown to provide the stated protection. This provides a high degree of assurance that the data and programs are protected, assuming the model is implemented correctly.

This last point is critical. To return to our car analogy, notice the phrase “with these items properly working.” This also means that the average driver must be able to work

9 · 2 MATHEMATICAL MODELS OF COMPUTER SECURITY

them correctly. In most, if not all, cases the model is implemented in the obvious way: The accelerator pedal is to the right of the brake pedal, and speeds the car up; the brake pedal slows it down; and turning the steering wheel moves the car to the left or right, depending on the direction that the wheel is turned. The average driver is familiar with this implementation and so can use it properly. Thus, the model and the implementation together show that this particular car can be driven.

Now, suppose that the items are implemented differently. All the items are there, but the steering wheel is locked so it cannot be turned. Even though the car has all the parts that the model requires, they do not work the way the model requires them to work. The implementation is incorrect, and the argument that the model provides does not apply to this car, because the model makes assumptions—like the steering wheel turning—that are incorrect for this car. Similarly, in all the models we present in this chapter, the reader should keep in mind the assumptions that the models make. When one applies these models to existing systems, or uses them to design new systems, one must ensure that the assumptions are met in order to gain the assurance that the model provides.

This chapter presents several mathematical models, each of which serves a different purpose. We can divide these models into several types.

The first set of models is used to determine under what conditions one can prove types of systems secure. The access-control matrix model presents a general description of a computer system that this type of model uses, and it will give some results about the decidability of security in general and for particular classes of systems.

The second type of model describes how the computer system applies controls. The mandatory access-control model and the discretionary access-control model form the basis for components of the models that follow. The originator-controlled access-control model ties control of data to the originator rather than the owner, and has obvious applications for digital rights management systems. The role-based access-control model uses job function, rather than identity, to provide controls and so can implement the principle of least privilege more effectively than many models.

The next few models describe confidentiality and integrity. The Bell-LaPadula model describes a class of systems designed to protect confidentiality and was one of the earliest, and most influential, models in computer security. The Biba model's strict integrity policy is closely related to the Bell-LaPadula model and is in widespread use today; it is applied to programs to determine when their output can be trusted. The Clark-Wilson model is also an integrity model, but it differs fundamentally from Biba's model because the Clark-Wilson model describes integrity in terms of processes and process management rather than in terms of attributes of the data.

The fourth type of model is the hybrid model. The Chinese Wall model examines conflicts of interest, and is an interesting mix of both confidentiality and integrity requirements. This type of model arises when many real-world problems are abstracted into mathematical representations, for example, when analyzing protections required for medical records and for the process of recordation of real estate.¹

The main goal of this chapter is to provide the reader with an understanding of several of the main models in computer security, of what these models mean, and of when they are appropriate to use. An ancillary goal is to make the reader sensitive to how important assumptions in computer security are. Dorothy Denning said it clearly and succinctly in her speech when accepting the National Computer Systems Security Award in 1999:

The lesson I learned was that security models and formal methods do not establish security. They only establish security with respect to a model, which by its very nature is extremely

simplistic compared to the system that is to be deployed, and is based on assumptions that represent current thinking. Even if a system is secure according to a model, the most common (and successful) attacks are the ones that violate the model's assumptions. Over the years, I have seen system after system defeated by people who thought of something new.²

Given this, the obvious question is: Why are models important? Models provide a framework for analyzing systems and for understanding where to focus our security efforts: on either validating the assumptions or ensuring that the assumptions are met in the environment in which the system exists. The mechanisms that do this may be technical; they may be procedural. Their quality determines the security of the system. So the model provides a basis for asserting that, if the mechanisms work correctly, then the system is secure—and that is far better than simply implementing security mechanisms without understanding how they work together to meet security requirements.

9.2 MODELS AND SECURITY. Some terms recur throughout our discussion of models.

- A *subject* is an active entity, such as a process or a user.
- An *object* is a passive entity, such as a file.
- A *right* describes what a subject is allowed to do to an object; for example, the read right gives permission for a subject to read a file.
- The *protection state* of a system simply refers to the rights held by all subjects on the system.

The precise meaning of each right varies from actual system to system. For example, on Linux systems, if a process has *write* permission for a file, that process can alter the contents of the file. But if a process has *write* permission for a directory, that process can create, delete, or rename files in that directory. Similarly, having *read* rights over a process may mean the possessor can participate as a recipient of interprocess communications messages originating from that process. The point is that the meaning of the rights depends on the interpretation of the system involved. The assignment of meaning to the rights used in a mathematical model is called *instantiating the model*.

The first model we explore is the foundation for much work on the fundamental difficulty of analyzing systems to determine whether they are secure.

9.2.1 Access-Control Matrix Model. The *access-control matrix model*³ is perhaps the simplest model in computer security. It consists of a matrix, the rows of which correspond to subjects and the columns of which correspond to entities (subjects and objects). Each entry in the matrix contains the set of rights that the subject (row) has over the entity (column). For example, the access-control matrix in Exhibit 9.1 shows a system with two processes and two files. The first process has own rights over itself; read rights over the second process; read and execute rights over the first file; and read, write, and own rights over the second file. The second process can write to the first process; owns itself; can read, write, execute, and owns the first file; and can read the second file.

The access-control matrix captures a protection state of a system. But systems evolve; their protection state does not remain constant. So the contents of the

Process 2	write	own	read, write, execute, own	read

EXHIBIT 9.1 Example Access-Control Matrix with Two Processes and Two Files

access-control matrix must change to reflect this evolution. Perhaps the simplest set of rules for changing the access-control matrix are these *primitive operations*⁴:

- **Create subject** s creates a new row and column, both labeled s
- **Create object** o creates a new column labeled o
- **Enter** r **into** $A[s, o]$ adds the right r into the entry in row s and column o ; it corresponds to giving the subject s the right r over the entity o
- **Delete** r **from** $A[s, o]$ removes the right r from the entry in row s and column o ; it corresponds to deleting the subject s 's right r over the entity o
- **Destroy subject** s removes the row and column labeled s
- **Destroy object** o removes the column labeled o

These operations can be combined into *commands*. The next command creates a file f and gives the process p read and own rights over that file:

```
command createread( $p, f$ )
    create object  $f$ 
    enter read into  $A[p, f]$ 
    enter own into  $A[p, f]$ 
end.
```

A *mono-operational* command consists of a single primitive operation. For example, the command

```
command grantwrite( $p, f$ )
    enter write into  $A[p, f]$ 
end.
```

which gives p write rights over f , is mono-operational.

Commands may include conditions. For example, the next command gives the subject p execute rights over a file f if p has read rights over f :

```
command grantexec( $p, f$ )
    if read in  $A[p, f]$  then
        enter execute into  $A[p, f]$ 
end.
```

If p does not have read rights over f when this command is executed, it does nothing. This command has one condition and so is called *monoconditional*. *Biconditional* commands have two conditions joined by *and*:

```
command copyread( $p, q, f$ )
    if read in  $A[p, f]$  and own in  $A[p, f]$  then
        enter read into  $A[q, f]$ 
end.
```

This command gives a subject q read rights over the object f if the subject p owns f and has read rights over f .

Commands may have conditions only at the beginning, and if the condition is false, the command terminates. Commands may contain other commands as well as primitive operations.

If all commands in a system are mono-operational, the system is said to be *mono-operational*; if all the commands are monoconditional or biconditional, then the system is said to be *monoconditional* or *biconditional*, respectively. Finally, if the system has no commands that use the *delete* or *destroy* primitive operations, the system is said to be *monotonic*.

The access-control matrix provides a theoretical basis for two widely used security mechanisms: access-control lists and capability lists. In the realm of modeling, it provides a tool to analyze the difficulty of determining how secure a system is.

9.2.2 Harrison, Ruzzo, and Ullman and Other Results. The question of how to test whether systems are secure is critical to understanding computer security. Define *secure* in the simplest possible way: A system is secure with respect to a generic right r if that right cannot be added to an entity in the access-control matrix unless that square already contains it. In other words, a system is secure with respect to r if r cannot leak into a new entry in the access-control matrix. The question then becomes:

Safety Question. Is there an algorithm to determine whether a given system with initial state σ is secure with respect to a given right?

In the general case:

Theorem (Harrison, Ruzzo, and Ullman [HRU] Result).⁵ The safety question is undecidable.

The proof is to reduce the halting problem to the safety question.⁶ This means that, if the safety question were decidable, so would the halting problem be. But the undecidability of the halting problem is well known,⁷ so the safety problem must also be undecidable.⁸

These results mean that one cannot develop a general algorithm for determining whether systems are secure. One can do so in limited cases, however, and the models that follow are examples of such cases. The characteristics that classes of systems must meet in order for the safety question to be decidable are not yet known fully, but for specific classes of systems, the safety question can be shown to be decidable. For example:

Theorem.⁹ There is an algorithm that will determine whether mono-operational systems are secure with respect to a generic right r .

But these classes are sensitive to the commands allowed:

Theorem.¹⁰ The safety question for monotonic systems is undecidable.

Limiting the set of commands to biconditional commands does not help:

Theorem.¹¹ The safety question for biconditional monotonic systems is undecidable.

But limiting them to monoconditional operations:

Theorem.¹² There is an algorithm that will determine whether monoconditional monotonic systems are secure with respect to a generic right r .

In fact, adding the *delete* primitive operation does not affect this result (although the proof is different):

Theorem.¹³ There is an algorithm that will determine whether monotonic systems that do not use the *destroy* primitive operations are secure with respect to a generic right r .

9 · 6 MATHEMATICAL MODELS OF COMPUTER SECURITY

9.2.3 Typed Access-Control Model. A variant of the access-control matrix model adds type to the entities. The *typed access-control matrix model*, called TAM,¹⁴ associates a type with each entity and modifies the rules for matrix manipulation accordingly. This notion allows entities to be grouped into finer categories than merely *subject* and *object*, and enables a slightly different analysis than the HRU result suggests.

In TAM, a rule set is *acyclic* if neither an entity E nor any of its descendants can create a new entity with the same type as E . Given that definition:

Theorem.¹⁵ There is an algorithm that will determine whether acyclic, monotonic typed matrix models are secure with respect to a generic right r .

Thus, a system being acyclic and monotonic is sufficient to make the safety question decidable. But we still do not know exactly what properties are *necessary* to make the safety question decidable.

We now turn to models that have direct application to systems and environments and that focus on more complex definitions of “secure” and the mechanisms needed to achieve them.

9.3 MODELS AND CONTROLS. Models of computer security focus on control: who can access files and resources, and what types of access are allowed. The next characterizations of these controls organize them by flexibility of use and by the roles of the entities controlling the access. These are essential to understanding how more sophisticated models work.

9.3.1 Mandatory and Discretionary Access-Control Models. Some access-control methods are rule based; that is, users have no control over them. Only the system or a special user called (for example) the *system security officer* (SSO) can change them. The government classification system works this way. Someone without a clearance is forbidden to read TOP SECRET material, even if the person who has the document wishes to allow it. This rule is called *mandatory* because it must be followed, without exception. Examples of other mandatory rules are the laws in general, which are to be followed as written, and one cannot absolve another of liability for breaking the laws; or the Multics ring-based access-control mechanism, in which accessing a data segment from below the lower bound of the segment’s access bracket is forbidden regardless of the access permissions. This type of access control is called a *mandatory access control*, or MAC. These rules base the access decision on attributes of the subject and object (and possibly other information).

Other access-control methods allow the owner of the entity to control access. For example, a person who keeps a diary decides who can read it. She need not show it to anyone, and if a friend asks to read it, she can say no. Here the owner allows access to the diary at her discretion. This type of control is called *discretionary*. *Discretionary access control*, or DAC, is the most common type of access-control mechanism on computers.

Controls can be (and often are) combined. When mandatory and discretionary controls are combined to enforce a single access-control policy, the mandatory controls are applied first. If they deny access, the system denies access and the discretionary controls need never be invoked. If the mandatory rules permit access, then the discretionary controls are consulted. If both allow the accesses, access is granted.

9.3.2 Originator-Controlled Access-Control Model and DRM. Other types of access controls contain elements of both mandatory and discretionary access

controls. *Originator-controlled access control*,¹⁶ or ORCON,¹⁷ mechanisms allow the originator to determine who can access a resource or data.

Consider a large government research agency that produces a study of projected hoe-handle sales for the next year. The market for hoe handles is extremely volatile, and if the results of the study leak out prematurely, certain vendors will obtain a huge market advantage. But the study must be circulated to regulatory agencies so they can prepare appropriate regulations that will be in place when the study is released. Thus, the research agency must retain control of the study even as it circulates it among other groups.

More precisely, an originator-controlled access control satisfies two conditions. Suppose an object *o* is marked as ORCON for organization *X*. *X* decides to release *o* to subjects acting on behalf of another organization *Y*. Then

1. The subjects to whom the copies of *o* are given cannot release *o* to subjects acting on behalf of other organizations without *X*'s consent; and
2. Any copies of *o* must bear these restrictions.

Consider a control that implements these requirements. In theory, mandatory access controls could solve this problem. In practice, the required rules must anticipate *all* the organizations to which the data will be made available. This requirement, combined with the need to have a separate rule for each possible set of objects and organizations that are to have access to the object, makes a mandatory access control that satisfies the requirements infeasible. But if the control were discretionary, each entity that received a copy of the study could grant access to its copy without permission of the originator; so originator-controlled access control is neither discretionary nor mandatory.

However, a combination of discretionary and mandatory access controls can implement this control. The mandatory access-control mechanisms forbid the owner from changing access permissions on an object *o* and require that every copy of that object have the same access-control permissions as are on *o*. The discretionary access control says that the originator can change the access-control permissions on any copy of *o*.

As an example of the use of this model in a more popular context, record companies want to control the use of their music. Conceptually, they wish to retain control over the music *after* it is sold in order to prevent owners from distributing unauthorized copies to their friends. Here the originator is the record company and the protected resource is the music.

In practice, originator-controlled access controls are difficult to implement technically. The problem is that access-control mechanisms typically control access to *entities*, such as files, devices, and other objects. But originator-controlled access control requires that access controls be applied to *information* that is contained in the entities—a far more difficult problem for which there is not yet a generally accepted mechanism.

9.3.3 Role-Based Access-Control Models and Groups. In real life, job function often dictates access permissions. The bookkeeper of an office has free access to the company's bank accounts, whereas the sales people do not. If Anne is hired as a salesperson, she cannot access the company's funds. If she later becomes the bookkeeper, she can access those funds. So the access is conditioned not on the identity of the person but on the role that person plays.

9 · 8 MATHEMATICAL MODELS OF COMPUTER SECURITY

This example illustrates *role-based access control* (RBAC).¹⁸ It assigns a set of roles, called the *authorized roles of the subject s* , to each subject s . At any time, s may assume at most one role, called the *active role of s* . Then

Axiom. The *rule of role authorization* says that the active role of s must be in the set of authorized roles of s .

This axiom restricts s to assuming those roles that it is authorized to assume. Without it, s could assume any role, and hence do anything.

Extending this idea, let the predicate $canexec(s, c)$ be true when the subject s can execute the command c .

Axiom. The *rule of role assignment* says that if $canexec(s, c)$ is true for any s and any c , then s must have an active role.

This simply says that in order to execute a command c , s must have an active role. Without such a role, it cannot execute any commands. We also want to restrict the commands that s can execute; the next axiom does this.

Axiom. The *rule of transaction authorization* says that if $canexec(s, c)$ is true, then only those subjects with the same role as the active role of s may also execute transaction.

This means that every role has a set of commands that it can execute, and if c is not in the set of commands that the active role of s can execute, then s cannot execute it.

As an example of the power of this model, consider two common problems: containment of roles and separation of duty. Containment of roles means that a subordinate u is restricted to performing a limited set of commands that a superior s can also perform; the superior may also perform other commands. Assign role a to the superior and role b to the subordinate; as everything a subject with active role b can do, a subject with active role a can do, we say that role a *contains* role b . Then we can say that if a is an authorized role of s , and a contains b , then b is also an authorized role of s . Taking this further, if a subject is authorized to assume a role that contains other (subordinate) roles, it can also assume any of the subordinate roles.

Separation of duty is a requirement that multiple entities must combine their efforts to perform a task. For example, a company may require two officers to sign a check for more than \$50,000. The idea is that a single person may breach security, but two people are less likely to combine forces to breach security.¹⁹ One way to handle separation of duty is to require that two distinct roles complete the task and make the roles mutually exclusive. More precisely, let r be a role and $meauth(r)$, the mutually exclusive authorization set of r , be the set of roles that a subject with authorized role r can *never* assume. Then separation of duty is:

Axiom. The *rule of separation of duty* says that if a role a is in the set $meauth(b)$, then no subject for which a is an authorized role may have b as another authorized role.

This rule is applied to a task that requires two distinct people to complete. The task is broken down into steps that two people are to complete. Each person is assigned a separate role, and each role is in the mutually exclusive authorization set of the other. This prevents either person from completing the task; they must work together, each in their respective role, to complete it.

Roles bear a resemblance to groups, but the goals of groups and roles are different. Membership in a group is defined by essentially arbitrary rules, set by the managers of the system. Membership in a role is defined by job function and is tied to a specific set of commands that are necessary to perform that job function. Thus, a role is a type of group, but a group is broader than a role and need not be tied to any particular set of commands or functions.

9.3.4 Summary. The four types of access controls discussed in this section have different focuses. Mandatory, discretionary, and originator-controlled access controls are data-centric, determining access based on the nature or attributes of the data. Role-based access control focuses on the subject's needs. The difference is fundamental.

The principle of least privilege²⁰ says that subjects should have no more privileges than necessary to perform their tasks. Role-based access control, if implemented properly, does this by constraining the set of commands that a subject can execute. The other three controls do this by setting attributes on the data to control access to the data rather than by restricting commands. Mandatory access controls have the attributes set by a system security officer or other trusted process; discretionary access controls, by the owner of the object; and originator-controlled access controls, by the creator or originator of the data.

As noted, these mechanisms can be combined to make the controls easier to use and more precise in application. We now discuss several models that do so.

9.4 CLASSIC MODELS. Three models have played an important role in the development of computer security. The Bell-LaPadula model, one of the earliest formal models in computer security, influenced the development of much computer security technology, and it is still in widespread use. Biba, its analog for integrity, now plays an important role in program analysis. The Clark-Wilson model describes many commercial practices to preserve integrity of data. We examine each of these models in this section.

9.4.1 Bell-LaPadula Model. The Bell-LaPadula model²¹ is a formalization of the famous government classification system using UNCLASSIFIED, CONFIDENTIAL, SECRET, and TOP SECRET levels. We begin by using those four levels to explain the ideas underlying the model and then augment those levels to present the full model. Because the model involves multiple levels, it is an example of a *multilevel security model*.

The four-level version of the model assumes that the levels are ordered from lowest to highest as UNCLASSIFIED, CONFIDENTIAL, SECRET, and TOP SECRET. Objects are assigned levels based on their sensitivity. An object at a higher level is more sensitive than an object at a lower level. Subjects are assigned levels based on what objects they can access. A subject is *cleared* into a level, and that level is called the subject's *security clearance*. An object is *classified* at a level, and that level is called the object's *security classification*. The goal of the classification system is to prevent information from leaking, or flowing downward (e.g., a subject at CONFIDENTIAL should not be able to read information classified TOP SECRET).

For convenience, we write $level(s)$ for a subject's security clearance and $level(o)$ for an object's security classification. The name of the classification is called a *label*. So an object classified at TOP SECRET has the label TOP SECRET.

Suppose Tom is cleared into the SECRET level. Three documents, called Paper, Article, and Book, are classified as CONFIDENTIAL, SECRET, and TOP SECRET, respectively. As Tom's clearance is lower than Book's classification, he cannot read Book. As his clearance is equal to or greater than Article's and Paper's classification, he can read them.

Definition. The *simple security property* says that a subject s can read an object o if and only if $level(o) \leq level(s)$.

9 · 10 MATHEMATICAL MODELS OF COMPUTER SECURITY

This is sometimes called the *no-reads-up* rule, and it is a mandatory access control.

But that is insufficient to prevent information from flowing downward. Suppose Donna is cleared into the CONFIDENTIAL level. By the simple security property, she cannot read Article because

$$\text{level}(\text{Article}) = \text{SECRET} > \text{CONFIDENTIAL} = \text{level}(\text{Donna}).$$

But Tom can read the information in Article and write it on Paper. And Donna can read Paper. Thus, SECRET information has leaked to a subject with CONFIDENTIAL clearance.

To prevent this, Tom must be prevented from writing to Paper:

Definition. The **-property* says that a subject s can write an object o if and only if $\text{level}(s) \leq \text{level}(o)$.

This is sometimes called the *no-writes-down* rule, and it too is a mandatory access control. It is also known as the *star property* and the *confinement property*.

Under this rule, as $\text{level}(\text{Tom}) = \text{SECRET} > \text{level}(\text{Paper})$, Tom cannot write to Paper. This solves the problem.

Finally, the Bell-LaPadula model allows owners of objects to use discretionary access controls:

Definition. The *discretionary security property* says that a subject s can read an object o only if the access-control matrix entry for s and o contains the read right.

So, in order to determine whether Tom can read Paper, the system checks the simple security property and the discretionary security problem. As both hold for Tom and Paper, Tom can read Paper. Similarly, the system checks the **-property* to determine whether Tom can write to Paper. As the **-property* does not hold for Tom and Paper, Tom cannot write to Paper. Note that the discretionary security property need not be checked, because the relevant mandatory access-control property (the **-property*) denies access.

The basic security theorem states that, if a system starts in a secure state, and every operation obeys the three properties, then the system remains secure:

Basic Security Theorem. Let a system Σ have a secure initial state σ_0 . Further, let every command in this system obey the simple security property, the **-property*, and the discretionary security property. Then every state σ_i , $i \geq 0$, is also secure.

We can generalize this to an arbitrary number of levels. Let L_0, \dots, L_n be a set of security levels that are linearly ordered (i.e., $L_0 < \dots < L_n$). Then the simple security property, the **-property*, and the discretionary security property all apply, as does the Basic Security Theorem. This allows us to have many more than the four levels described.

Now suppose Erin works for the European Department of a government agency, and Don works for the Asia Department for the same agency. Erin and Don are both cleared for SECRET. But some information Erin will see is information that Don has no need to know, and vice versa. Introducing additional security levels will not help here, because then either Don would be able to read all of the documents that Erin could, or vice versa. We need an alternate mechanism.

The alternate mechanism is an expansion of the idea of “security level.” We define a *category* to be a kind of information. A *security compartment* is a pair (*level*, *category set*) and plays the role that the security level did previously.

As an example, suppose the category for the European Department is EUR, and the category for the Asia Department is ASIA. Erin will be cleared into the compartment (SECRET, {EUR}) and Don into the compartment (SECRET, {ASIA}). Documents have security compartments as well. The paper EurDoc may be classified as

(CONFIDENTIAL, {EUR}), and the paper AsiaDoc may be (SECRET, {ASIA}). The paper EurAsiaDoc contains information about both Europe and Asia, and so would be in compartment (SECRET, {EUR, ASIA}). As before, we write $level(Erin) = (SECRET, \{EUR\})$, $level(EurDoc) = (CONFIDENTIAL, \{EUR\})$, and $level(EurAsiaDoc) = (SECRET, \{EUR, ASIA\})$.

Next, we must define the analog to “greater than.” As noted earlier, security compartments are no longer linearly ordered, because not every pair of compartments can be compared. For example, Don’s compartment is not “greater” than Erin’s, and Erin’s is not “greater” than Don’s. But the classification of EurAsiaDoc is clearly “greater” than that of both Don and Erin.

We compare compartments using the relation *dom*, for “dominates.”

Definition. Let L and L' be security levels and let C and C' be category sets. Then

$(L, C) dom (L', C')$ if and only if $L' = L$ and $C' \subseteq C$

The *dom* relation plays the role that “greater than or equal to” did for security levels. Continuing our example, $level(Erin) = (SECRET, \{EUR\})$, $dom (CONFIDENTIAL, \{EUR\}) = level(EurDoc)$, and $level(EurAsiaDoc) = (SECRET, \{EUR, ASIA\}) dom (SECRET, \{EUR\}) = level(Erin)$.

We now reformulate the simple security property and *-property in terms of *dom*:

Definition. The *simple security property* says that a subject s can read an object o if and only if $level(s) dom level(o)$.

Definition. The **-property* says that a subject s can write to an object o if and only if $level(o) dom level(s)$.

In our example, assume the discretionary access controls are set to allow any subject all types of access. In that case, as $level(Erin) dom level(EurDoc)$, Erin can read EurDoc (by the simple security property) but not write EurDoc (by the *-property). Conversely, as $level(EurAsiaDoc) dom level(Erin)$, Erin cannot read EurAsiaDoc (by the simple security property) but can write to EurAsiaDoc (by the *-property).

A logical question is how to determine the highest security compartment that both Erin and Don can read and the lowest that both can write. In order to do this, we must review some properties of *dom*.

First, note that $level(s) dom level(s)$; that is, *dom* is reflexive. The relation is also antisymmetric, because if both $level(s) dom level(o)$ and $level(o) dom level(s)$ are true, then $level(s) = level(o)$. It is transitive, because if $level(s_1) dom level(o)$ and $level(o) dom level(s_2)$, then $level(s_1) dom level(s_2)$.

We also define the *greatest lower bound* (*glb*) of two compartments as:

Definition. Let $A = (L, C)$ and $B = (L', C')$. Then $glb(A, B) = (min(L, L'), C \cap C')$.

This answers the question of the highest security compartment that two subjects s and s' can read an object in. It is $glb(level(s), level(s'))$. For example, Don and Erin can both read objects in:

$glb(level(Don), level(Erin)) = (SECRET, \chi;).$

This makes sense because Don cannot read an object in any compartment except those with the category set {ASIA} or the empty set, and Erin can only read objects in a compartment with the category set {EUR} or the empty set. Both are at the SECRET level, so the compartment must also be at the SECRET level.

We can define the *least upper bound* (*lub*) of two compartments analogously:

Definition. Let $A = (L, C)$ and $B = (L', C')$. Then $lub(A, B) = (max(L, L'), C \cup C')$.

9 · 12 MATHEMATICAL MODELS OF COMPUTER SECURITY

We can now determine the lowest security compartment into which two subjects s and s' can write. It is $\text{lub}(\text{level}(s), \text{level}(s'))$. For example, Don and Erin can both write to objects in:

$$\text{glb}((\text{level}(\text{Don}), \text{level}(\text{Erin})) = (\text{SECRET}, \{\text{EUR}, \text{ASIA}\}).$$

This makes sense because Don cannot write to an object in any compartment except those with ASIA in the category set, and Erin can only write to objects in a compartment with EUR in the category set. The smallest category set meeting both these requirements is $\{\text{EUR}, \text{ASIA}\}$. Both are at the SECRET level, so the compartment must also be at the SECRET level.

The five properties of *dom* (reflexive, antisymmetric, transitive, existence of a least upper bound for every pair of elements, and existence of a greatest lower bound for every pair of elements) mean that the security compartments form a mathematical structure called a *lattice*. This has useful theoretical properties, and is important enough so models exhibiting this type of structure are called *lattice models*.

When the model is implemented on a system, the developers often make some modifications. By far the most common one is to restrict writing to the current compartment or to within a limited set of compartments. This prevents confidential information from being altered by those who cannot read it. The structure of the model can also be used to implement protections against malicious programs that alter files, such as system binaries. To prevent this, place the system binaries in a compartment that is dominated by those compartments assigned to users. By the simple security property, then users can read the system binaries, but by the *-property, users cannot write them. Hence, if a computer virus infects a user's programs or documents,²² it can spread within that user's compartment but not to system binaries.

The Bell-LaPadula model is the basis for several other models. We explore one of its variants that models integrity rather than confidentiality.

9.4.2 Biba's Strict Integrity Policy Model. Biba's strict integrity policy model,²³ usually called *Biba's model*, is the mathematical dual of the Bell-LaPadula model.

Consider the issue of trustworthiness. When a highly trustworthy process reads data from an untrusted file and acts based on that data, the process is no longer trustworthy—as the saying goes, “garbage in, garbage out.” But if a process reads data more trustworthy than the process, the trustworthiness of that process does not change. In essence, the trustworthiness of the result is as trustworthy as the least trustworthy of the process and the data.

Define a set of *integrity classes* in the same way that we defined security compartments for the Bell-LaPadula model, and let $i\text{-level}(s)$ be the integrity compartment of s . Then the preceding text says that “reads down” (a trustworthy process reading untrustworthy data) should be banned, because it reduces the trustworthiness of the process. But “reads up” is allowed, because it does not affect the trustworthiness of the process. This is exactly the opposite of the simple security property.

Definition. The *simple integrity property* says that a subject s can read an object o if and only if $i\text{-level}(o) \text{ dom } i\text{-level}(s)$.

This definition captures the notion of allowing “reads up” and disallowing “reads down.”

Similarly, if a trustworthy process writes data to an untrustworthy file, the trustworthiness of the file may (or may not) increase. But if an untrustworthy process writes

data to a trustworthy file, the trustworthiness of that file drops. s “writes down” should be allowed and “writes up” forbidden.

Definition. The **-integrity property* says that a subject s can write to an object o if and only if $i\text{-level}(s) \text{ dom } i\text{-level}(o)$.

This property blocks attempts to “write up” while allowing “writes down.”

A third property relates to execution of subprocesses. Suppose process $date$ wants to execute the command $time$ as a subprocess. If the integrity compartment of $date$ dominates that of $time$, then any information $date$ passes to $time$ is passed to a less trustworthy process, and hence is allowed under the **-integrity property*. But if the integrity compartment of $time$ dominates that of $date$, then the **-integrity property* is violated. Hence:

Definition. The *execution integrity property* says that a subject s can execute a subject s' if and only if $i\text{-level}(s') \text{ dom } i\text{-level}(s)$.

Given these three properties, one can show:

Theorem. If information can be transferred from object o_1 to object o_n , then by the simple integrity property, the **-integrity property*, and the execution integrity property, $i\text{-level}(o_1) \text{ dom } i\text{-level}(o_n)$.

In other words, if all the rules of Biba’s model are followed, the integrity of information cannot be corrupted because information can never flow from a less trustworthy object to a more trustworthy object.

This model suggests a method for analyzing programs to prevent security breaches. When the program runs, it reads data from a variety of sources: itself, the system, the network, and the user. Some of these sources are trustworthy, such as the process itself and the system. The user and the network are under the control of ordinary users (or remote users) and so are less trustworthy. So, apply Biba’s model with two integrity compartments, (UNTAINTED, \emptyset) (this means the set of categories in the compartment is empty) and (TAINTED, \emptyset), where $(\text{UNTAINTED}, \emptyset) \text{ dom } (\text{TAINTED}, \emptyset)$. For notational convenience, we shall write (UNTAINTED, \emptyset) as UNTAINTED and (TAINTED, \emptyset) as TAINTED; and dom as \geq . Thus, $\text{UNTAINTED} \geq \text{TAINTED}$.

The technique works with either static or dynamic analysis but is usually used for dynamic analysis. In this mode, all constants are assigned the integrity label UNTAINTED. Variables are assigned labels based on the data flows within the program. For example, in an assignment, the integrity label of the variable being assigned to is set to the integrity label of the expression assigned to it. When UNTAINTED and TAINTED variables are mixed in the expression, the integrity label of the expression is TAINTED. If a variable is assigned a value from an untrusted source, the integrity label of the variable is set to TAINTED.

When data are used as (for example) parameters of system calls or library functions, the system checks that the integrity label of the variable dominates that of the parameter. If it does not, the program takes some action, such as aborting, or logging a warning, or throwing an exception. This action either prevents an exploit or alerts the administrator of the attack.

For example, suppose a programmer wishes to prevent a format string attack. This is an attack that exploits a vulnerability in the C printing function *printf*. The first argument to *printf* is a format string, and the contents of that string determine how many other arguments *printf* expects. By manipulating the contents of a format string, an attacker can overwrite values of variables and corrupt the stack, causing the program to malfunction—usually to the attacker’s benefit. The key step of the attack is to input an unexpected value for the format string. Here is a code fragment with the flaw:

```
if (fgets(buf, sizeof(buf), stdin) != NULL) printf(buf);
```

9 · 14 MATHEMATICAL MODELS OF COMPUTER SECURITY

This reads a line of characters from the input into an array *buf* and immediately prints the contents of the array. If the input is “xyzyy%n”, then some element of the stack will be overwritten by the value 5.²⁴ Hence, the first parameter to *printf* must always have integrity class UNTAINTED.

Under this analysis technique, when the input function *fgets* is executed, the variable *buf* would be assigned an integrity label of TAINTED, because the input (which is untrusted) is stored in it. Then, at the call to *printf*, the integrity class of *buf* is compared to that required for the first parameter of *printf*. The former is TAINTED; the latter is UNTAINTED. But we require that the variable’s integrity class (TAINTED) dominate that of the parameter (UNTAINTED), and here $\text{TAINTED} \leq \text{UNTAINTED}$. Hence, the analysis has found a disallowed flow and acts accordingly.

9.4.3 Clark-Wilson Model. Lipner²⁵ identified five requirements for commercial integrity models:

1. Users may not write their own programs to manipulate trusted data. Instead, they must use programs authorized to access that data.
2. Programmers develop and test programs on nonproduction systems, using non-production copies of production data if necessary.
3. Moving a program from nonproduction systems to production systems requires a special process.
4. That special process must be controlled and audited.
5. Managers and system auditors must have access to system logs and the system’s current state.

Biba’s model can be instantiated to meet the first and last conditions by appropriate assignment of integrity levels, but the other three focus on integrity of processes. Hence, while Biba’s model works well for some problems of integrity, it does not satisfy these requirements for a commercial integrity model.

The Clark-Wilson model²⁶ was developed to describe processes within many commercial firms. There are several specialized terms and concepts needed to understand the Clark-Wilson mode; these are best introduced using an example:

- Consider a bank. If *D* are the day’s deposits, *W* the day’s withdrawals, *I* the amount of money in bank accounts at the beginning of the day, and *F* the amount of money in bank accounts at the end of the day, those values must satisfy the constraint $I + D - W = F$.
- This is called an *integrity constraint* because, if the system (the set of bank accounts) does not satisfy it, the bank’s integrity has been violated.
- If the system does satisfy its integrity constraints, it is said to be in a *consistent* state.
- When in operation, the system moves from one consistent state to another. The operations that do this are called *well-formed transactions*. For example, if a customer transfers money from one account to another, the transfer is the well-formed transaction. Its component actions (withdrawal from the first account and deposit in the second) individually are not well-formed transactions, because if only one completes, the system will be in an inconsistent state.

- Procedures that verify that all integrity constraints are satisfied are called *integrity verification procedures* (IVPs).
- Data that must satisfy integrity constraints are called *constrained data items* (CDIs), and when they satisfy the constraints are said to be in a *valid* state.
- All other data are called *unconstrained data items* (UDIs).
- In addition to integrity constraints on the data, the functions implementing the well-formed transactions themselves are constrained. They must be *certified* to be well formed and to be implemented correctly. Such a function is called a *transformation procedure* (TP).

The model provides nine rules, five of which relate to the certification of data and TPs and four of which describe how the implementation of the model must enforce the certifications.

The first rule captures the requirement that the system be in a consistent state:

Certification Rule 1. An IVP must ensure that the system is in a consistent state.

The relation *certified* associates some set of CDIs with a TP that transforms those CDIs from one valid state to a (possibly different) valid state. The second rule captures this.

Certification Rule 2. For some set of associated CDIs, a TP transforms those CDIs from a valid state to a (possibly different) valid state.

The first enforcement rule ensures that the system keeps track of the *certified* relation and prevents any TP from executing with a CDI not in its associated *certified* set:

Enforcement Rule 1. The system must maintain the *certified* relation, and ensure that only TPs certified to run on a CDI manipulates that CDI.

In a typical firm, the set of users who can use a TP is restricted. For example, in a bank, a teller cannot move millions of dollars from one bank to another; doing that requires a bank officer. The second enforcement rule ensures that only authorized users can run TPs on CDIs by defining a relation *allowed* that associates a user, a TP, and the set of CDIs that the TP can access on that user's behalf:

Enforcement Rule 2. The system must associate a user with each TP and set of CDIs. The TP may access those CDIs on behalf of the associated user. If a user is not associated with a particular TP and set of CDIs, then the TP cannot access those CDIs on behalf of that user.

This implies that the system can correctly identify users. The next rule enforces this:

Enforcement Rule 3. The system must authenticate each user attempting to execute a TP.

This ensures that the identity of a person trying to execute a TP is correctly bound to the corresponding user identity within the computer. The form of authentication is left up to the instantiation of the model, because differing environments suggest different authentication requirements. For example, a bank officer may use a biometric device and a password to authenticate herself to the computer that moves millions of dollars; a teller whose actions are restricted to smaller amounts of money may need only to supply a password.

Separation of duty, already discussed, is a key consideration in many commercial operations. The Clark-Wilson model captures it in the next rule:

Certification Rule 3. The *allowed* relation must meet the requirements imposed by separation of duty.

A cardinal principle of commercial integrity is that the operations must be auditable. This requires logging of enough information to determine what the transaction did. The next rule captures this requirement:

Certification Rule 4. All TPs must append enough information to reconstruct the operation to an append-only CDI.

The append-only CDI is, of course, a log.

So far we have considered all inputs to TPs to be CDIs. Unfortunately, that is infeasible. In our bank example, the teller will enter account information and deposit and withdrawal figures; but those are not CDIs; the teller may mistype something. Before a TP can use that information, it must be vetted to ensure it will enable the TP to work correctly. The last certification rule captures this:

Certification Rule 5. A TP that takes a UDI as input must perform either a well-formed transaction or no transaction for any value of the UDI. Thus, it either rejects the UDI or transforms it into a CDI.

This also covers poorly crafted TPs; if the input can exploit vulnerabilities in the TP to cause it to act in unexpected ways, it cannot be certified under this rule.

Within the model lies a possible conflict. In the preceding rules, one user could certify a TP to operate on a CDI and then execute the TP on that CDI. The problem is that a malicious user may certify a TP that does not perform a well-formed transaction, causing the system to violate the integrity constraints. Clearly, an application of the principle of separation of duty would solve this problem, and indeed the last rule in the model does just that:

Enforcement Rule 4. Only the certifier of a TP may change the *certified* relation for that TP. Further, no certifier of a TP, or of any CDI associated with that TP, may execute the TP on the associated CDI.

This separates the ability to certify a TP from the ability to execute that TP and the ability to certify a CDI for a given TP from the ability to execute that TP on that CDI. This enforces the separation of duty requirement.

Now, revisit Lipner's requirements for commercial integrity models. The TPs correspond to Lipner's programs and the CDIs to the production data. To meet requirement 1, the Clark-Wilson certifiers need to be trusted, and ordinary users cannot certify either TPs or CDIs. Then Enforcement Rule 4 and Certification Rule 5 enforce this requirement. Requirement 2 is met by not certifying the development programs; as they are not TPs, they cannot be run on production data. The "special process" in requirement 3 is a TP. Certification Rule 4 describes a log; the special process in requirement 3 being a TP, it will append information to the log that can be audited. Further, the TP is by definition a controlled process, and Enforcement Rule 4 and Certification Rule 5 control its execution. Before the installation, the program being installed is a UDI; after it is installed, it is a CDI (and a TP). Thus, requirement 4 is satisfied. Finally, the Clark-Wilson model has a log that captures all aspects of what a TP does, and that is the log the managers and auditors will have access to. They also have access to the system state because they can run an IVP to check its integrity. Thus, Lipner's requirement 5 is met. So the Clark-Wilson model is indeed a satisfactory commercial integrity model.

This model is important for two reasons. First, it captures the way most commercial firms work, including applying separation of duty (something that Biba's model does not capture well). Second, it separates the notions of certification and enforcement. Enforcement typically can be done within the instantiation of the model. But the model cannot enforce how certification is done; it can only require that a certifier claim to have done it. This is true of all models, of course, but the Clark-Wilson model specifically states the assumptions it makes about certification.

9.4.4 Chinese Wall Model. Sometimes called the *Brewer-Nash model*, the goal of the Chinese Wall model²⁷ is to prevent conflicts of interest. It does so by grouping objects that belong to the same company into *company data sets* and company data sets into *conflict-of-interest classes*. If two companies (represented by their associated company data sets) are in the same conflict-of-interest class, then a lawyer or stockbroker representing both would have a conflict of interest. The rules of the model ensure that a subject can read only one company data set in each conflict-of-interest class.

In general, objects are documents or resources that contain information that the company wishes to (or is required to) keep secret. There is, however, an exception. Companies release data publicly, in the form of annual reports; that information is carefully *sanitized* to remove all confidential content. To reflect business practice, the model must allow *all* subjects to see that data. The model therefore defines a conflict-of-interest class called the *sanitized class* that has one company data set holding *only* objects containing sanitized data.

Now consider a subject reading an object. If the subject has never read any object in the object's conflict-of-interest class, reading the object presents no conflict of interest. If the subject has read an object in the same company data set, then the only information that the subject has seen in that conflict-of-interest class is from the same company as the object it is trying to read, which is allowed. But if the subject has read an object in the same conflict-of-interest class but a *different* company data set, then were the new read request granted, the subject would have read information from two different companies for which there is a conflict of interest—exactly what the model is trying to prevent. So that is disallowed.

The next rule summarizes this:

Definition. The *CW-simple security property* says that a subject s can read an object o if and only if either:

1. s has not read any other object in o 's conflict-of-interest class; or
2. The only objects in o 's conflict-of-interest class that s has read are all in o 's company data set.

To see why this works, suppose all banks are in the same conflict-of-interest class. A stockbroker represents The Big Bank. She is approached to represent The Bigger Bank. If she agreed, she would need access to The Bigger Bank's information, specifically the objects in The Bigger Bank's company data set. But that would mean she could read objects from two company data sets in the same conflict-of-interest class, something the CW-simple security property forbids. The temporal element of the model is important; even if she resigned her representation of The Big Bank, she cannot represent The Bigger Bank because condition 2 of the CW-simple security property considers all objects she previously read. This makes sense, because she has had access to The Big Bank, and could unintentionally compromise the interests of her previous employer while representing The Bigger Bank.

The CW-simple security property implicitly says that s can read any sanitized object. To see this, note that if s has never read a sanitized object, condition 1 holds. If s has read a sanitized object, then condition 2 holds because all sanitized objects are in the same company data set.

Writing poses another problem. Suppose Barbara represents The Big Bank, and Percival works for The Bigger Bank. Both also represent The Biggest Toy Company, which—not being a financial institution—is in a different conflict-of-interest class from

either bank. Thus, there is no conflict of interest in either Barbara's or Percival's representation of a bank and the toy company. But there is a path along which information can flow from Barbara to Percival, and vice versa, that enables a conflict of interest to occur. Barbara can read information from an object in The Big Bank's company data set and write it to an object in The Biggest Toy Company's company data set. Percival can read the information from the object in The Biggest Toy Company's company data set, thereby effectively giving him access to The Big Bank's information—which is a conflict of interest. That he needs Barbara's help does not detract from the problem. The goal of the model requires that this conspiracy be prevented. The next rule does so:

Definition. The CW^* -property says that a subject s can write to an object o if and only if both of the following conditions are met:

1. The CW -simple security property allows s to read o ; and
2. All unsanitized objects that s can read are in the same company data set as o .

Now Barbara can read objects in both The Big Bank's company data set and The Biggest Toy Company's data set. But when she tries to write to The Biggest Toy Company's data set, the CW^* -property prevents her from doing so as condition 2 is not met (because she can read an object in The Big Bank's company data set).

This also accounts for sanitized objects. Suppose that Skyler represents The Biggest Toy Company and no other company. He can also read information from the sanitized class. When he tries to write to an object in The Biggest Toy Company's company data set, he meets both conditions of the CW -simple security property (because he has only read objects in that company data set), and all unsanitized objects that he can read are in the same company data set as the object he can read. Thus, both conditions of the CW^* -property are met, so Skyler can write the object.

The conditions of the CW^* -property are very restrictive; effectively, a subject can write to an object only if it has access to the company data set containing that object, *and no other company data set except the company data set in the sanitized class*. But without this restriction, conflicts of interest are possible.

9.4.5 Summary. The four models discussed in this section have played critical roles in the development of our understanding of computer security. Although it is not the first model of confidentiality, the Bell-LaPadula model describes a widely used security scheme. The Biba model captured notions of “trust” and “trustworthiness” in an intuitive way, and recent advances in the analysis of programs for vulnerabilities have applied that model to great effect. The Clark-Wilson model moved the notion of commercial integrity models away from multilevel models to models that examine process integrity as well as data integrity. The Chinese Wall model explored conflict of interest, an area that often arises when one is performing confidential services for multiple companies or has access to confidential information from a number of companies. These models are considered classic because their structure and ideas underlie the rules and structures of many other models.

9.5 OTHER MODELS. Some models examine specific environments. The Clinical Information Systems Security model²⁸ considers the protection of health records, emphasizing accountability as well as confidentiality and integrity. *Traducement*²⁹

describes the process of real estate recordation, which requires a strict definition of integrity and accountability with little to no confidentiality.

Other models generalize the classic models. The best known are the models of *noninterference security* and *deducibility security*. Both are multilevel security models with two levels, HIGH and LOW. The noninterference model³⁰ defines security as the ability of a HIGH subject to interfere with what the LOW subject sees. For example, if a HIGH subject can prevent a LOW subject from acquiring a resource at a particular time, the HIGH subject can transmit information to the LOW subject. In essence, the interference is a form of writing, and must be prevented, just as the Bell-LaPadula model prevents a HIGH subject from writing to a LOW object. The deducibility model³¹ examines whether a LOW subject can infer anything about a HIGH subject's actions by examining only the LOW outputs. Both these models are useful in analyzing the security of systems³² and intrusion detection mechanisms,³³ and led to work that showed connecting two secure compute systems may produce a nonsecure system.³⁴ Further work is focusing on establishing conditions under which connecting two secure systems produces a secure system.³⁵

9.6 CONCLUSION. The efficacy of mathematical modeling depends on the application of those models. Typically, the models capture system-specific details and describe constraints ensuring the security of the system or the information on the system. If the model does not correctly capture the details of the *entire* system, the results may not be comprehensive, and the analysis may miss ways in which security could be compromised.

This is an important point. For example, the Bell-LaPadula model captures a notion of what the *system* must do to prevent a subject cleared for TOP SECRET leaking information to a subject cleared for CONFIDENTIAL. But if the system enforces that model, the TOP SECRET subject could still meet the CONFIDENTIAL subject and hand her a printed version of the TOP SECRET information. That is outside the system and so was not captured by the model. But if the model also embraces procedures, then a procedure is necessary to prevent this “writing down.” In that case, the flaw would be in the implementation of the procedure that failed to prevent the transfer of information—in other words, an incorrect instantiation of the model, exactly what Dorothy Denning’s comment in the introduction to this section referred to.

The models described in this section span the foundational (access-control matrix model) to the applied (Bell-LaPadula, Biba, Clark-Wilson, and Chinese Wall). All play a role in deepening our understanding of what security is and how to enforce it.

The area of mathematical modeling is a rich and important area. It provides a basis for demonstrating that the design of systems is secure, for specific definitions of *secure*. Without these models, our understanding of how to secure systems would be diminished.

10.1 INTRODUCTION. This chapter provides guidance for critical reading of research results about computer crime. It will also alert designers of research instruments who may lack formal training in survey design and analysis to the need for professional support in developing questionnaires and analyzing results.

10.1.1 Value of Statistical Knowledge Base. Security specialists are often asked about computer crime; for example, customers want to know who is attacking which systems, how often, using what methods. These questions are perceived as important because they bear on the strategies of risk management; in theory, in order to estimate the appropriate level of investment in security, it would be helpful to have a sound grasp of the probability of different levels of damage. Ideally, one would want to evaluate an organization's level of risk by evaluating the experiences of other organizations with similar system and business characteristics. Such comparisons would be useful in competitive analysis and in litigation over standards of due care and diligence in protecting corporate assets.

10 · 2 UNDERSTANDING STUDIES AND SURVEYS OF COMPUTER CRIME

10.1.2 Limitations on Our Knowledge of Computer Crime. Unfortunately, in the current state of information security, no one can give reliable answers to such questions. There are two fundamental difficulties preventing us from developing accurate statistics of this kind. These difficulties are known as the problems of ascertainment.

10.1.2.1 Detection. The first problem is that an unknown number of crimes of all kinds are undetected. For example, even outside the computer crime field, we do not know how many financial frauds are being perpetrated. We do not know because some of them are not detected. How do we know they are not detected? Because some frauds are discovered long after they have occurred. Similarly, computer crimes may not be detected by their victims but may be reported by the perpetrators.

In a landmark series of tests at the Department of Defense (DoD), the Defense Information Systems Agency found that very few of the penetrations it engineered against unclassified systems within the DoD seem to have been detected by system managers. These studies were carried out from 1994 through 1996 and attacked 38,000 systems. About two-thirds of the attacks succeeded; however, only 4 percent of these attacks were detected.¹

A commonly held view within the information security community is that only one-tenth or so of all the crimes committed against and using computer systems are detected.

10.1.2.2 Reporting. The second problem of ascertainment is that even if attacks are detected, few seem to be reported in a way that allows systematic data collection. This commonly held belief is based in part on the unquantified experience of information security professionals who have conducted interviews of their clients; it turns out that only about 10 percent of the attacks against computer systems revealed in such interviews were ever reported to any kind of authority or to the public. The DoD studies mentioned earlier were consistent with this belief; of the few penetrations detected, only a fraction of 1 percent were reported to appropriate authorities.

Given these problems of ascertainment, computer crime statistics generally should be treated with skepticism.

10.1.3 Limitations on the Applicability of Computer Crime Statistics. Generalizations in this field are difficult to justify. Even if we knew more about types of criminals and the methods they use, it still would be difficult to have the kind of actuarial statistic that is commonplace in the insurance field. For example, the establishment of uniform building codes in the 1930s in the United States led to the growth in fire insurance as a viable business. With official records of fires in buildings that could be described using a standard typology, statistical information began to provide an actuarial basis for using probabilities of fires and associated costs to calculate reasonable insurance rates.

In contrast, even if we had access to accurate reports, it would be difficult to make meaningful generalizations about vulnerabilities and incidence of successful attacks for the information technology field. We use a bewildering variety and versions of processors, operating systems, firewalls, encryption, application software, backup methods and media, communications channels, identification, authentication, authorization, compartmentalization, and operations.

How would we generalize from data about the risks at (say) a mainframe-based network running Multiple Virtual Systems (MVS) in a military installation to the kinds of risks faced by a UNIX-based intranet in an industrial corporation, or to a Windows New Technology (NT)-based Web server in a university setting? There are so many differences among systems that if we were to establish a multidimensional analytical table where every variable was an axis, many cells would likely contain no or only a few examples. Such sparse matrices are notoriously difficult to use in building statistical models for predictive purposes.

10.2 BASIC RESEARCH METHODOLOGY. This is not a chapter about social sciences research. However, many discussions of computer crime seem to take published reports as gospel, even though these studies may have no validity whatsoever. In this short section, we look at some fundamentals of research design so that readers will be able to judge how much faith to put in computer crime research results.

10.2.1 Some Fundamentals of Statistical Design and Analysis. The way in which a scientist or reporter represents data can make an enormous difference in the readers' impressions.

10.2.1.1 Descriptive Statistics. Suppose three companies reported these losses from penetration of their computer systems: \$1 million, \$2 million, and \$6 million. We can describe these results in many ways. For example, we can simply list the raw data; however, such lists could become unacceptably long as the number of reports increased, and it is hard to make sense of the raw data.

We could define classes such as "2 million or less" and "more than 2 million" and count how many occurrences there were in each class:

Class	Freq
≤ \$2M	2
> \$2M	1

Alternatively, we might define the classes with finer granularity as < \$1M, ≥ \$1M but < \$2M, and so on; such a table might look like this:

Class	Freq
< \$1M	0
≥ \$1M & < \$2M	1
≥ \$2M & < \$3M	1
≥ \$3M & < \$4M	0
≥ \$4M & < \$5M	0
≥ \$5M & < \$6M	0
≥ \$6	1

10 · 4 UNDERSTANDING STUDIES AND SURVEYS OF COMPUTER CRIME

Notice how the definition of the classes affects perception of the results: The first table gives the impression that the results are clustered around \$2 million and gives no information about the upper or lower bounds.

10.2.1.1.1 Location. One of the most obvious ways we describe data is to say where they lie in a particular dimension. The *central tendency* of our three original data (\$1 million, \$2 million, and \$6 million) can be represented in various ways; for example, two popular measures are:

- Arithmetic mean or average = $$(1+2+6)M/3 = \$3M$
- Median (the middle of the sorted list of losses) = \$2M

Note that if we tried to compute the mean and the median from the first table (with its approximate classes), we would get the wrong value. Such statistics should be computed from the original data, not from summary tables.

10.2.1.1.2 Dispersion. Another aspect of our data that we frequently need is *dispersion*—that is, variability. The simplest measure of dispersion is the range: the difference between the smallest and the largest value we found; in our example, we could say that the range was from \$1 million to \$6 million or that it was \$5 million. Sometimes the range is expressed as a percentage of the mean; then we would say that the range was $5/3 = 1.6 \dots$ or ~ 167 percent.

The *variance* (σ^2) of these particular data is the average of the squared deviations from the arithmetic mean; the variance of the three numbers would be $\sigma^2 = (1-3)^2 + (2-3)^2 + (6-3)^2/3 = (4+1+9)/3 \approx 4.67$.

The square root of the variance (σ) is called the *standard deviation* and is often used to describe dispersion. In our example, $\sigma = \sqrt{4.67} \approx 2.16$.

Dispersion is particularly important when we compare estimates about information from different groups. The greater the variance of a measure, the more difficult it is to form reliable generalizations about an underlying phenomenon, as described in the next section.

10.2.1.2 Inference: Sample Statistics versus Population Statistics.

We can accurately describe any data using descriptive statistics; the question is what we then do with those measures.

Usually we expect to extend the findings in a *sample* or subset of a *population* to make generalizations about the population. For example, we might be trying to estimate the losses from computer crime in commercial organizations with offices in the United States and with more than 30,000 employees. Or perhaps our sample would represent commercial organizations with offices in the United States and with more than 30,000 employees and whose network security staff was willing to respond to a survey questionnaire.

In such cases, we try to infer the characteristics of the population from the characteristics of the sample. Statisticians say that we try to estimate the *parametric* statistics by using the *sample* statistics.

For example, we estimate the parametric (population) variance (usually designated σ^2) by multiplying the variance of the sample by $n/(n-1)$. Thus, we would say that the estimate of the parametric variance (s^2) in our sample would be $s^2 = 4.67 * 3/2 = 7$. The estimate of the parametric standard deviation (s) would be $s = \sqrt{7} \approx 2.65$.

10.2.1.3 Hypothesis Testing. Another kind of inference that we try to make from data is *hypothesis testing*. For example, suppose we were interested in whether there was any association between the presence or absence of firewalls and the occurrence of system penetration. We can imagine collecting these data about penetrations into systems with or without firewalls:

Firewalls	Penetration		Totals
	No	Yes	
No	25	75	100
Yes	70	130	200
Totals	95	205	300

We would frame the hypothesis (the *null hypothesis*, sometimes represented as H_0) that there was *no* relationship between the two independent variables, penetration and firewalls, and *test* that hypothesis by performing a test of independence of these variables. In our example, a simple chi-square test of independence would give a *test statistic* of $\chi^2_{[1]} = 2.636$. If there really were no association between penetration and firewalls in the population of systems under examination, the parametric value of this statistic would be zero. In our imaginary example, we can show that such a large value (or larger) of $\chi^2_{[1]}$ would occur in only 10.4 percent of the samples taken from a population where firewalls had no effect on penetration. Put another way, if we took many samples from a population where the presence of firewalls was not associated with any change in the rate of penetration, we would see about 10.4 percent of those samples producing $\chi^2_{[1]}$ statistics as large as or larger than 2.636.

Statisticians have agreed on some conventions for deciding whether a test statistic deviates enough from the value expected under the null hypothesis to warrant inferring that the null hypothesis is wrong. Generally, we describe the likelihood that the null hypothesis is true—often shown as $p(H_0)$ —in this way:

- When $p(H_0) > 0.05$, we say the results are *not statistically significant* (often designated with the symbols *ns*);
- When $0.05 \geq p(H_0) > 0.01$, the results are described as statistically significant (often designated with the symbol *);
- When $0.01 \geq p(H_0) > 0.001$, the results are described as highly statistically significant (often designated with the symbols **);
- When $p(H_0) \leq 0.001$, the results are described as extremely statistically significant (often designated with the symbols ***).

10.2.1.4 Random Sampling, Bias, and Confounded Variables. The most important element of sampling is randomness. We say that a sample is *random* or *randomized* when every member of the population we are studying has an equal probability of being selected. When a population is defined one way but the sample is drawn nonrandomly, the sample is described as *biased*. For example, if the population we are studying was designed to be, say, all companies worldwide with more than 30,000 full-time employees, but we sampled mostly from such companies in the United States, the sample would be biased toward U.S. companies and their characteristics.

10 · 6 UNDERSTANDING STUDIES AND SURVEYS OF COMPUTER CRIME

Similarly, if we were supposed to be studying security in all companies in the United States with more than 30,000 full-time employees, but we sampled only from those companies that were willing to respond to a security survey, we would be at risk of having a biased sample.

In this last example, involving studying only those who respond to a survey, we say that we are potentially *confounding* variables: We are looking at people-who-respond-to-surveys and hoping they are representative of the larger population of people from all companies in the desired population. But what if the people who are *willing* to respond are those who have better security and those who do not respond have terrible security? Then *responding to the survey* is confounded with *quality of security*, and our biased sample could easily mislead us into overestimating the level of security in the desired population.

Another example of how variables can be confounded is comparisons of results from surveys carried out in different years. Unless exactly the same people are interviewed in both years, we may be confounding individual variations in responses with changes over time; unless exactly the same companies are represented, we may be confounding differences among companies with changes over time; if external events have led people to be more or less willing to respond truthfully to questions, we may be confounding willingness to respond with changes over time. If the surveys are carried out with different questions or used by different research groups, we may be confounding changes in methodology with changes over time.

10.2.1.5 Confidence Limits. Because random samples naturally vary around the parametric (population) statistics, it is not very helpful to report a *point estimate* of the parametric value. For example, if we read that the mean damage from computer crimes in a survey was \$180,000 per incident, what does that imply about the population mean?

To express our confidence in the sample statistic, we calculate the likelihood of being right if we give an *interval estimate* of the population value. For example, we might find that we would have a 95 percent likelihood of being right in asserting that the mean damage was between \$160,000 and \$200,000. In another sample, we might be able to narrow these 95 *percent confidence limits* to \$175,000 and \$185,000.

In general, the larger the sample size, the narrower the confidence limits will be for particular statistics.

The calculation of confidence limits for statistics depends on some necessary *assumptions*:

- Random sampling
- A *known error distribution* (usually the *Normal* distribution—sometimes called a *Gaussian* distribution)
- *Equal variance* at all values of the measurements

If any of these assumptions is wrong, the calculated confidence limits for our estimates will be wrong; that is, they will be misleading. There are tests of these assumptions that analysts should carry out before reporting results; if the data do not follow Normal error distributions, sometimes one can apply *normalizing transformations*.

In particular, percentages do not follow a Normal distribution. Here is a reference table of confidence limits for various percentages in a few representative sample sizes.

95 Percent Confidence Limits for Percentages			
Percentage	Sample size		
	100	500	1000
0	0–3.0%	0–0.6%	0–0.3%
10	4.9–17.6%	7.5–13.0%	8.2–12.0%
20	12.7–29.1%	16.6–23.8%	17.6–22.6%
50	40.0–60.1%	45.5–54.5%	46.9–53.1%
80	70.9–87.3%	76.2–83.4%	77.4–82.4%
90	82.4–95.1%	87.0–92.5%	88.0–91.8%
100	97.0–100%	99.4–100%	99.7–100%

10.2.1.6 Contingency Tables. One of the most frequent errors in reporting results of studies is to provide only part of the story. For example, one can read statements such as “Over 70 percent of the systems without firewalls were penetrated last year.” Such a statement may be true, but it cannot be interpreted correctly as meaning that systems with firewalls were necessarily more or less vulnerable to penetration than systems without firewalls. The statement is incomplete; to make sense of it, we need the other part of the implied *contingency table*—the percentage of systems *with* firewalls that were penetrated last year—before making any assertions about the relationship between firewalls and penetrations. Compare, for example, these two hypothetical tables:

	With Firewalls in Default Configuration			With Firewalls Properly Configured	
	Without Firewalls			Without Firewalls	
Penetrated	70%	70%	Penetrated	70%	10%
Not Penetrated	30%	30%	Not Penetrated	30%	90%

In both cases, someone could say that “70 percent of the systems without firewalls were penetrated,” but the implications would be radically different in the two data sets. Without knowing the right-hand column, the original assertion would be meaningless.

10.2.1.7 Association versus Causality. Continuing our example with rates of penetration, another error that untrained people often make when studying statistical information is to mistake *association* for *causality*. Imagine that a study showed that a lower percentage of systems with fire extinguishers was penetrated than systems without fire extinguishers and that this difference was statistically highly significant. Would such a result necessarily mean that fire extinguishers *caused* the reduction in penetration? No. We know that it is far more reasonable to suppose that the fire extinguishers were installed in organizations whose security awareness and security policies were more highly developed than in the organizations where no fire extinguishers were installed. In this imaginary example, the fire extinguishers might actually have *no causal effect* whatever on resistance to penetration. This result would illustrate the effect of

10 · 8 UNDERSTANDING STUDIES AND SURVEYS OF COMPUTER CRIME

confounding variables: *presence of a fire extinguisher* with *state of security awareness and policies*.

10.2.1.8 Control Groups. Finally, to finish our penetration example, one way to distinguish between association and causality is to *control* for variables. For example, one could measure the state of security awareness and policy as well as the presence or absence of fire extinguishers and make comparisons only among groups with the same level of awareness and policy. There are also statistical techniques for mathematically controlling for differences in such *independent variables*.

10.2.1.9 A Priori versus a Posteriori Testing. Amateurs or beginners sometimes forget the principle of *random sampling* that underlies all statistical inference (see Section 10.2.1.4). None of the hypothesis tests or confidence limit calculations work if a sample is not random. For example, if someone is wandering through a supermarket and notices that Granny Smith apples seem to be bigger than Macintosh apples, selecting a sample—even a random sample—of the apples that specifically gave rise to the hypothesis will not allow reliable computations of probability that the applies have the same average weight. The problem is that those *particular* apples would not have been sampled at all had the observer not been moved to formulate the hypothesis. So even if a particular statistical comparison produces a sample statistic that appears to have a probability of, say, 0.001, it is not possible to know how much the sampling deviated from randomness.

Applying statistical tests to data *after* one notices an interesting descriptive value, comparison, or trend is known as *a posteriori testing*. Formulating a hypothesis, obtaining a random sample, and computing the statistics and probabilities in accordance with the assumptions of those statistics and probabilities is known as *a priori testing*.

A well-used example of the perils of a posteriori testing is the unfortunate habit of searching through sequences of results such as long strings of guesses collected in student tests of paranormal abilities and calculating statistical values on carefully selected subsets of the strings. These a posteriori tests are then presented as if they were a priori and cause great confusion and arguments, such as: “Look, even though the overall proportion of correct guesses was (say) 50.003 percent in this run of <some very large number> guesses, there was a run of <much smaller number> guesses that were correct <any value greater than 50 percent> of the time! The probability of such a result by chance is <very small number>. That proves that there was a real effect of <whatever the treatment was>.” Unfortunately, a long series of numbers can produce any desired nonrandom-looking string; there are even tests known as *runs tests* that can help a researcher evaluate the nonrandomness of such occurrences.

In practical terms, statisticians have established a convention for limiting the damaging effects of a posteriori testing: Use the 0.001 level of probability as the equivalent of the minimum probability of the null hypothesis. This custom makes it far less likely that an a posteriori comparison will trick the user into accepting what is in fact a random variation that caught someone’s eye.

The best solution to the bias implicit in a posteriori testing is to use a completely *new* sample for the comparison. In the apple example, one could ask the store manager for new, unobserved, and randomly selected batches of both types of applies. The comparison statistics would then be credible and could be expected to follow the parametric distribution underlying calculations of probability of the null hypothesis. The populations from which these apples were selected still would have to be carefully

determined. Would the populations be apples at this particular store? For this particular chain? For this particular region of the country or of the world?

10.2.2 Research Methods Applicable to Computer Crime

10.2.2.1 Interviews. Interviewing individuals can be illuminating. In general, interviews provide a wealth of data that are unavailable through any other method. For example, one can learn details of computer crime cases or motivations and techniques used by computer criminals. Interviews can be structured (using precise lists of questions) or unstructured (allowing the interviewer to respond to new information by asking additional questions at will).

Interviewers can take notes or record the interviews for later word-for-word transcription. In unstructured interviews, skilled interviewers can probe responses to elucidate nuances of meaning that might be lost using cruder techniques such as surveys. Techniques such as thematic analysis can reveal patterns of responses that can then be examined using exploratory data analysis.² Thematic analysis is a technique for organizing nonquantitative information without imposing a preexisting framework on the data; exploratory data analysis uses statistical techniques to identify possibly interesting relationships that can be tested with independently acquired data. Such exploratory techniques can correctly include a posteriori testing as described in Section 10.2.1.9, but the results are used to propose further studies that can use a priori tests for the best use of resources.

10.2.2.2 Focus Groups. Focus groups are like group interviews. Generally, the facilitator uses a list of predetermined questions and encourages the participants to respond freely and to interact with each other. Often, the proceedings are filmed from behind a one-way mirror for later detailed analysis. Such analysis can include nonverbal communications, such as facial expressions and other body language as the participants speak or listen to others speak about specific topics.

10.2.2.3 Surveys. Surveys consist of asking people to answer a fixed series of questions with lists of allowable answers. They can be carried out face to face or by distributing and retrieving questionnaires by telephone, mail, fax, and email. Some questionnaires have been posted on the Web.

The critical issue when considering the reliability of surveys is *self-selection bias*—the obvious problem that survey results include only the responses of people who agreed to participate. Before basing critical decisions on survey data, it is useful to find out what the response rate was; although there are no absolutes, in general, we tend to trust survey results more when the response rate is high. Unfortunately, response rates for telephone surveys are often less than 10 percent; response rates for mail and email surveys can be less than 1 percent. It is very difficult to make any case for random sampling under such circumstances, and all results from such low-response-rate surveys should be viewed as indicating the range of problems or experiences of the respondents rather than as indicators of population statistics.

Regarding Web-based surveys, there are two types from a statistical point of view: those that use strong identification and authentication and those that do not. Those that do not are vulnerable to fraud, such as repeated voting by the same individuals. Those that provide individual universal resource locators (URLs) to limit voting to one per

10 · 10 UNDERSTANDING STUDIES AND SURVEYS OF COMPUTER CRIME

person nonetheless suffer from the same problems of self-selection bias as any other survey.

10.2.2.4 Instrument Validation. Interviews and other social sciences research methodologies can suffer from a systematic tendency for respondents to shape their answers to please the interviewer or to express opinions that may be closer to the norm in whatever group they see themselves. Thus, if it is well known that every organization ought to have a business continuity plan, some respondents may misrepresent the state of their business continuity planning to look better than they really are.

In addition, survey instruments may distort responses by phrasing questions in a biased way; for example, the question “Does your business have a completed business continuity plan?” may have a more accurate response rate than the question “Does your business comply with industry standards for having a completed business continuity plan?” The latter question is not neutral and is likely to increase the proportion of “yes” answers.

The sequence of answers may bias responses; exposure to the first possible answers can inadvertently establish a baseline for the respondent. For example, a question about the magnitude of virus infections might ask:

In the last 12 months, has your organization experienced total losses from virus infections of

- (a) \$1 million or greater;
- (b) less than \$1 million but greater than or equal to \$100,000;
- (c) less than \$100,000;
- (d) none at all?

To test for bias, the designer can create versions of the instrument in which the same information is obtained using the opposite sequence of answers:

In the last 12 months, has your organization experienced total losses from virus infections of

- (a) none at all;
- (b) less than \$100,000;
- (c) less than \$1 million but greater than or equal to \$100,000;
- (d) \$1 million or greater?

The sequence of questions can bias responses; having provided a particular response to a question, the respondent will tend to make answers to subsequent questions about the same topic conform to the first answer in the series. To test for this kind of bias, the designer can create versions of the instrument with questions in different sequences.

Another instrument validation technique inserts questions with no valid answers or with meaningless jargon to see if respondents are thinking critically about each question or merely providing any answer that pops into their heads. For example, one might insert the nonsensical question, “Does your company use steady-state quantum interference methodologies for intrusion detection?” into a questionnaire about security and invalidate the results of respondents who answer yes to this and other diagnostic questions.

Finally, independent verification of answers provides strong evidence of whether respondents are answering truthfully. However, such intrusive investigations are rare.

10.2.2.5 Meta-analysis. Sometimes it is useful to evaluate a hypothesis based on several studies. We can combine probabilities P of the *same* null hypothesis from k trials using the formula

$$X^2 = -2 \sum \ln P$$

where X^2 is distributed as $\chi^2_{[2k]}$ if the null hypothesis is true in all the trials.

For example, suppose a forensic specialist is evaluating the possibility that log files have been tampered with in a specific period.

- She runs a test of the frequency distribution of individual digits in the data for the suspect period to evaluate the likelihood that the distribution is consistent with the null hypothesis of randomness. The P for the two-tailed chi-square test is 0.072ns.
- She looks at the average number of disk I/Os per second in the records for the suspect period and compares the data with the same statistic in the control period using ANOVA; the P for the two-tailed test is 0.096ns.

In this case, $X^2 = -2 \sum \ln P = -2(\ln 0.072 + \ln 0.096) = -2(-2.63109 - 2.34341) = 9.948992$ with 4 degrees of freedom. The P for the null hypothesis is 0.0413*. In other words, the chances of observing the results of both tests by chance alone if the suspect data were consistent with the raw data from comparison data is statistically significant. There is reason to reject the null hypothesis: Someone may very well have tampered with the log files for the suspect period.

This technique is subject to constraints. Most meta-analyses require the probabilities of the null hypothesis to be computed for a single tail in the same direction; it doesn't make sense to combine probabilities from conflicting hypotheses using two-tailed probabilities. However, as in the example above, if the null hypotheses are consistent, even two-tailed probabilities may be usefully combined.

Another problem is more systemic. There is considerable reason to be concerned that investigators and publishers sometimes suppress experimental results that do not conform to their expectations or desires. Such suppression biases the published results to *appear* to support the desired result.

Identifying such suppression is difficult. One approach is to examine the distributions of the published data and look for indications of data exclusion. For example, if the frequency distribution for raw data in a published report shows an abrupt disappearance of data in one direction (e.g., if the frequency distribution looks like a normal curve except that the left side suddenly drops to zero at a certain point) then the publication may be using a truncated data set. Meta-analysis based on data of dubious validity will itself be dubious. Garbage in, garbage out.

10.3 SUMMARY. In summary, all studies about computer crime should be studied carefully before we place reliance on their results. Some basic take-home questions about such research:

- What is the population we are sampling?
- Keeping in mind the self-selection bias, how representative of the wider population are the respondents who agreed to participate in the study or survey?
- How large is the sample?
- Are the authors testing for the assumptions of randomness, normality, and equality of variance before reporting statistical measures?

10 · 12 UNDERSTANDING STUDIES AND SURVEYS OF COMPUTER CRIME

- What are the confidence intervals for the statistics being reported?
- Are comparisons confounding variables?
- Are correlations being misinterpreted as causal relations?
- Were the test instruments validated?

11.1 INTRODUCTION. This chapter is not for lawyers or law students. Rather, it is written for computer professionals who might find it useful to understand how their concerns at work fit into a legal framework, and how that framework shapes strategies that they might employ in their work. It is not intended to be definitive but to help readers spot issues when they arise and to impart an understanding that is the first part of a fully integrated computer security program.

Cyberlaw is a compendium of traditional law that has been updated and applied to new technologies. When gaps have developed or traditional law is inadequate, particular statutes have been enacted. It is a little like the old story of the three blind men and the elephant: One of the blind men touching the elephant's leg believes he is touching a tree; the other touching its ear believes it is a wing, and the third, touching the tail, thinks it is a snake. Issues of cyberspace, electronic data, networks, global transmissions, and positioning have neither simple unitary solutions nor a simple body of law to consult.

In thinking about the application of law to computer security, it is helpful to think about the problems as issues in which the computer is

- The target of the activity
- The tool used for the activity
- Incidental to the activity itself

For example, “hacking” into a computer can be analogized to the tort¹ of trespass (i.e., entering the property of another without permission), and “cracking” can be viewed as conversion of someone else’s property. Similarly, using the computer to make illegal copies is a violation of copyright law in its most basic sense. Although trademark law has very little to do with computers, using trade names as part of keywords for search engines, or domain names to misdirect Internet traffic to a competitive Web site can be a violation of a trademark. While touching on some of the more traditional tort remedies, this chapter focuses on the property rights being invaded by such activities and the remedies that exist in the context of a business operation.

Recognizing that the body of law which touches on these problems is as global as the Internet itself, this chapter is intended to help readers actually see the elephant in the room. In selecting what legal issues to highlight, we have tried to consider the routine needs of the computer professional. We have focused largely on the law of the United States, recognizing that these problems and subject matters often transcend national boundaries. There is a very simple reason for this. Most often, the impact of the computer security attack, denial of service, decryption, or theft of computer materials will have occurred here, or have a direct impact here, no matter where it originates. Imagine for a second a gunman—standing in Canada—who takes aim at someone in the United States, pulls the trigger, and hits his target. Since there is purposeful conduct aimed at this country, in the ordinary instance the U.S. judiciary will not only assert jurisdiction over the gunman but also apply its laws. There may be other problems, such as actually catching the gunman, but the example underlines the importance of the law of the United States for entities located here. For orientation purposes, we have also included a section at the end of this chapter that discusses some international issues.

One other introductory note: We use the phrase “security program” in this chapter with some frequency. Understanding that this phrase can mean one thing to a lawyer or risk manager and another thing to a computer security professional, we intend it as a shorthand reference to the generic and systemic effort to secure information stored on computers and not solely to the applications that may be employed as part of that effort.

11.2 THE MOST FUNDAMENTAL BUSINESS TOOL FOR PROTECTION OF TECHNOLOGY IS THE CONTRACT.

The computer security professional’s job is to understand, anticipate, and then worry about risk: risks that are beyond control and risks that can be controlled. The most fundamental tool for controlling risk, whether predictable or unforeseeable, is the contract. Unlike other forms of risk control, a contract need not be static; it can be adaptable. We can limit use; we can limit distribution; we can impose conditions and confidentiality; we can specify rights as well as provide for certain remedies through contract. Contracts actually can take many forms: the traditional signed agreement; an email exchange; Web site or product terms of use; employment agreements; workplace manuals and policies; and so-called shrink-wrap or click-wrap agreements. We sell or license products. Where we can contract, we can also define and limit risk.

11 · 4 FUNDAMENTALS OF INTELLECTUAL PROPERTY LAW

11.2.1 Prevention Begins at Home—Employee and Fiduciary Duties.

There is an old hoary concept in the law that employees owe to their employers the fiduciary duty of utmost loyalty. The scope and extent of that fiduciary duty is a matter of common law that varies in each state. Generally, employees' fiduciary duty prohibits them from using any property that belongs to the employer in competition with the employer or for personal gain. Employees, however, are entitled to retain and use for whatever purpose their own skill and knowledge, which arguably could include contacts that they develop over the course of their employment unless those contacts are trade secrets. What comes or does not come within the ambit of fiduciary duty has spawned endless arguments and lawsuits. There is a simple remedy to this problem: the contract that covers technology issues and ownership as well as it covers pay and other benefits.

11.2.2 Employment Contract, Manual, and Handbook. Whatever policy the security professional develops should be implemented through the organization's employment contract, manual, and handbook. Many contractual provisions can be applied, such as: nondisclosure agreements; definition of proprietary policy; restrictive covenants; concessions of ownership regarding discoveries, know-how, improvements, inventions, and the like during the term of employment; email policies; terms of use regarding computer systems; and statements of authorized and unauthorized activity. The point is that employment contracts and handbooks should be the starting point for computer security.

11.2.3 Technology Rights and Access in Contracts with Vendors and Users. Security protection necessarily includes vigilance about all contracts and licenses with vendors and users. This may not be sexy, but it is blocking and tackling. Vendors can be subject to many of the same limitations and nondisclosure agreements as employees. Rights of access to intranets and data should be controlled and privileges specified. Careful consideration should be given to what rights a user will have, the rules surrounding user access, and enforcement of those rules. Is this a sale or a license? There are many virtues to controlling technology through licenses (as opposed to sales), including imposing limits on rights of use, and specifying remedies for breaches of the license, or for unauthorized activity that involves the licensed product.

"Shrink-wrap" or "click-wrap" licenses have become common parlance. They are now accepted tools for licensing and controlling software distribution so long as: (a) they are business to business and thus between parties of roughly equal bargaining position; (b) their terms for other users or consumers are not unconscionable; and (c) they do not violate public policy. Concerns over whether contractual terms are unconscionable or the contracts are ones of adhesion arise because the licenses are not products of negotiation but of fiat, which users accept when they open the shrink-wrapped package or through an online click. These concerns have been addressed through requirements that users have been provided with adequate notice of the terms, an opportunity to reject, and conduct that sufficiently manifests consent. For shrink-wrap agreements, the opening of the product, its installation, and retention have been deemed sufficient acts to show consent to the terms of the license, noting that if the consumer does not wish to consent, the product could be returned.² Thus, it is not necessary for the prospective user to be aware of all of the terms of a license before purchase if the remedy includes return after purchase. The license can impose restrictions on use, limit the number of machines on which the product can be installed, copying, and even available remedies.³

The issues of notice, actual or constructive, an opportunity to accept or reject, and manifestation of consent have led to general acceptance of online agreements such as the presentation of licensing terms followed by an active need to check, accept, or reject by clicking on the appropriate box.⁴ The same analysis applies to terms of use especially for intranet or network use.⁵ In *Register.com v. Verio, Inc.*,⁶ downloading data from a WHOIS database, having knowledge of the terms of use, was acceptance of those terms even if there was no click-through. These examples show that terms of use, properly positioned, can be binding on the user.

An active security program begins with a review of the contracts, licenses, and terms of use in all relationships with your organization. Just because a contractual arrangement has not existed does not mean that you cannot create one through proper notice of the terms of the contract and conduct that shows assent to those terms. Such contracts are the security professional's first line of defense. They give you the ability to limit risk with an organization's employees, contractors, vendors, and affiliates. With that in mind, this chapter addresses issues that arise largely outside of the terms of contractual protections and also suggests additional potential self-help remedies.

11.3 PROPRIETARY RIGHTS AND TRADE SECRETS. For many years, unless an idea was patentable, the primary protection for internal business data, confidential or proprietary information, and computer code was through the common law doctrine of trade secrets.⁷ Generally, a trade secret might be considered any internal, nonpublished manufacturing know-how, drawings, formulas, or sales information used in a trade or business that has commercial applicability and that provides a business with some strategic advantage.⁸ Such information, so long as it was (a) not published or disseminated to others who were not obligated to maintain its confidentiality,⁹ and (b) maintained in confidence with the protecting organization, could be protected as a trade secret.

The law of trade secret thus recognized a business's ownership or proprietary interest in such information, data, or processes. There are, however, important practical limitations on the application of trade secret protection. First and foremost, for any product sold in the market, the law does not protect against a competitor seeing the product and then using it to figure out how to manufacture like or similar items. Competitors are therefore free to reverse engineer a product so long as the reverse engineering is done wholly independently.

The second caveat is that an organization has to prove not only that the information qualifies for trade secret protection, but also that it protected the secrecy of the information as required by the law of the applicable jurisdiction. This means that ownership will be a matter not of record but of case-by-case proof, making enforcement of trade secret protection time consuming and expensive. Generally, the required proof consists of a showing that there was an active security program in place that was sufficient to protect the information as confidential. Various programs may be deemed adequate, depending on the circumstances, but usually such programs have five principles in common:

1. An inventory of trade secret information that is periodically updated
2. A security program to protect the technology at issue, often on a need-to-know basis with clear marking of information as "confidential, access restricted"
3. A written description of the security program that is provided to all employees

11 · 6 FUNDAMENTALS OF INTELLECTUAL PROPERTY LAW

4. An enforcement officer or oversight procedure
5. An enforcement program, including litigation, if necessary, to enjoin unauthorized access or distribution

In the field of computing, these principles often mean that source code or other readable formats should be secured in a locked file and marked CONFIDENTIAL. All representations of the code as stored on magnetic or other media should be marked CONFIDENTIAL and secured. Computerized information should be password protected with restrictions on circulation of the password and periodic password changes. A notice of confidentiality should be displayed as soon as access to the program is obtained, with appropriate warnings on limitation of use. Levels of access should be controlled so that privileges to copy, read, and write are appropriately restricted. Surveillance of entries and logon should be routinely conducted to verify that there has been no unauthorized entry. Finally, periodic audits should be conducted to test and substantiate the security procedures.

For many years, each state developed its own brand of trade secret protection through evolving judicial decisions that establish something in this country called the common law, as distinguished from legislative enactments of a statute addressing the same issue. In 1985, the Uniform Trade Secrets Act (UTSA) was promulgated by the National Conference of Commissioners on Uniform State Laws, with one of its purposes to make uniform the rights and remedies available to a holder of a trade secret. This model law, however, needed to be adopted by each state before it became the law of the state. As of this writing, it has been adopted to some degree in 46 states with the exception of Massachusetts, New Jersey, New York, and Texas.

The UTSA defines a trade secret as information, including a formula, pattern, compilation, program device, method, technique, or process, that: (a) derives independent economic value, actual or potential, from *not being generally known to, and not being readily ascertainable by proper means by*, other persons who can obtain economic value from its disclosure or use; and (b) is the subject of efforts that are reasonable under the circumstances to maintain its secrecy. It also defines the unlawful taking of a trade secret, or misappropriation, as the wrongful use of a trade secret, including (a) knowingly acquiring the secret through improper means or (b) disclosing the secret without consent.

11.3.1 Remedies for Trade Secret Misappropriation. Misappropriation of a trade secret is the unauthorized use or disclosure of the trade secret. In simple parlance, it is a taking or theft. The taking can be by one who owes a fiduciary duty of confidentiality, such as an employee; it can be in breach of an agreement of confidentiality; or the taking can occur through improper access or means. The misappropriation can be treated under common law as the tort of conversion, trespass, unfair competition, or interference with contractual relations. As discussed, there are now specific statutory provisions under the UTSA for trade secret misappropriation. The UTSA grants the wronged party certain remedies that include enjoining the use of the misappropriated property, damages, and attorney's fees. When the misappropriation is of a physical item, such as a disk drive, the owner may ask the court to order seizure and return of its property.¹⁰ In addition, where the misappropriation also violates other laws protecting intellectual property, such as where the taking infringes a copyright, the property owner may be entitled to additional relief.

Exactly what remedies are available will vary among the states. Interestingly, the very uniformity that the UTSA was intended to create has led to different treatment of

available claims and remedies. For example, before the UTSA, an employee's theft of the employer's confidential customer lists triggered a common law claim for breach of the implied fiduciary obligation owed by an employee to the employer as well as a claim for misappropriation of trade secrets. The UTSA provides that its remedies preempt other common law remedies; in other words, a claim under the UTSA trumps the claim for breach of fiduciary duty as well as the claim for misappropriation of trade secrets. There is a split in the courts as to whether the UTSA replaces only common law causes of action for misappropriation of trade secrets or extends to any tortious claims for relief that arise out of the misappropriation no matter how stated. The broader reach of the UTSA appears to be favored by the growing majority of courts that have considered this issue to date. The takeaway from this uncertainty is that computer security professionals should protect trade secrets, confidential information, and other valuable data through contractual terms with, among others, employees, vendors, and users to minimize the reliance on the UTSA.

In the event of a misappropriation, in addition to civil remedies, often separate state statutes treat the taking as a theft and a criminal act. Such statutes are generally state specific. Prior to 1996, the Trade Secrets Act (TSA) was the only federal statute prohibiting trade secret misappropriation. The TSA, however, was of limited utility because it did not apply to private sector employees and provided only limited criminal sanctions.¹¹ To combat an increase in computer crimes, Congress enacted the Economic Espionage Act of 1996 (EEA), which provided greater protection for the proprietary and economic information of both corporate and governmental entities against foreign and domestic theft.¹²

The EEA criminalizes two principal categories of corporate espionage: economic espionage and theft of trade secrets.¹³ Section 1831 punishes those who steal trade secrets "to benefit a foreign government, foreign instrumentality, or foreign agent." Section 1832 is the general criminal trade secret provision.¹⁴ The EEA criminalizes stealing, concealing, destruction, sketching, copying, transmitting, or receiving trade secrets without authorization, or with knowledge that the trade secrets have been misappropriated. It also criminalizes attempting to and conspiring to do any of these acts.¹⁵ The EEA penalizes parties responsible for a taking that is intended to benefit a foreign government with fines up to \$250,000 and imprisonment up to 10 years.¹⁶

The EEA explicitly defines a trade secret to include information stored in electronic media and includes "programs or codes, whether tangible or intangible" so long as:

- (a) the owner thereof has taken reasonable measures to keep such information secret; and
- (b) the information derives independent economic value, actual or potential, from not being generally known to, and not being readily ascertainable through proper means by, the public.¹⁷

Although one might assume that this definition is relatively straightforward, not everything is as it appears. In a case of domestic trade secret theft, the Court of Appeals for the Seventh Circuit examined what the EEA means when it says that the data or material "derives independent economic value, actual or potential, from not being generally known to, and not being readily ascertainable through proper means by, the public."¹⁸ Noting that others had assumed that the word "public" meant the general public, the court in *Lange* astutely observed that this was not, in fact, the case. Moreover, the standard for measuring the persons who might readily ascertain the economic value of (in this case) the design and composition of airplane brake assemblies is not the average person in the street, for this assumes (as the court mentions) that any person can understand and apply something as arcane as Avogadro's number. Instead, the definition

11 · 8 FUNDAMENTALS OF INTELLECTUAL PROPERTY LAW

of the term “the public” should take into account the segment of the population that would be interested in and understand the nature of that which has allegedly been misappropriated.

The international reach of the act is limited, extending outside of the United States only if: “(1) the offender is a natural person who is a citizen or permanent resident alien of the United States, or an organization organized under the laws of the United States or a State or political subdivision ... or (2) an act in furtherance of the offense was committed in the United States.”¹⁹ Few defendants have been charged under the act since its passage in 1996, so the precise reach has yet to be tested. However, the language of the EEA applies its provisions to corporations with headquarters or operations subject to U.S. jurisdiction that could be prosecuted under the act. Finally, the remedies under the EEA can be invoked only by the United States. There is no private right of action under the act.

11.3.2 Vigilance Is a Best Practice. The key points of practice to remember are: Security and trade secret law are forever linked together. A trade secret cannot exist without such security. The maxim “Eternal vigilance is the price of liberty,” often attributed to Thomas Jefferson, should in the context of business information protection be restated as “Eternal vigilance is the price of trade secret protection.” It is not as catchy a phrase, but it is the price each business must pay if it relies in whole or in part on trade secret law for protection. In such situations, the greatest assurance of protection can be obtained through rigorous contractual terms and strenuous enforcement.

11.4 COPYRIGHT LAW AND SOFTWARE. Because of anxiety over the true extent of protection afforded software under patent and copyright law, software programs initially were protected as trade secrets. Such protection became increasingly problematic in today’s society, where information technology and pressure for the free flow of information makes confidentiality controls more difficult to police. Copyright law now has evolved to include computer programs.

Since 1964, the United States Copyright Office has permitted registration of computer programs, although judicial decisions were divided on the applicability of the Copyright Act. In 1976, Congress passed the Copyright Act of 1976, which did little to resolve the ambiguity. Clarification finally was obtained in the Computer Software Copyright Act of 1980, which explicitly extended the protection of the copyright laws to software.²⁰ Any type of work that can be fixed in any tangible medium can be protected by copyright as literary works based on the authorship of the source and object code²¹ even if the work can only be machine reproduced.

Copyright protection, however, does not protect “ideas.”²² Rather, it protects the particular expression of the idea. As can be seen by the parallel proliferation of spreadsheet programs, the idea for the spreadsheet program cannot be protected, but the particular code that produces the spreadsheet can be. In order to qualify for copyright protection, the work must be (a) original, (b) fixed in a tangible medium, and (c) not just the embodiment of an idea. Once obtained, copyright protection grants to the copyright owner the exclusive right to reproduce, to publish, to prepare derivative works, to distribute, to display, and to perform the copyrighted work. In 1990, Congress passed the Computer Software Rental Amendments Act,²³ which added to the list of copyright infringements the distribution of a computer program for commercial advantage. Materials copyrighted after 1978 are protected for the lesser of 75 years from the date of first publication or 100 years from the date of creation.

11.4.1 Works for Hire and Copyright Ownership. The copyright for a work does not always belong to the person who creates it. The most frequent exceptions are works that fall under the concept of a “work for hire.” A work for hire is not owned by the creator but by the persons who hired the creator to create the work. Most often the concept applies to employees who have created a work *within the scope* of their employment. The key concept is the scope of employment. Even though a work is created outside of the office and normal working hours, it still will be a work for hire if it is within the scope of employment. However, a work that falls outside the scope of employment and that is created outside the office is likely not to be deemed a work for hire. Because of such issues, it is better practice when dealing with employees or independent contractors to provide specificity in an agreement as to what is a work and when the creation of a work will be governed by the doctrine of work for hire.

11.4.2 Copyright Rights Adhere from the Creation of the Work. Everyone who has looked at a copyrighted work is probably familiar with the symbol © affixed to any published copyrighted work, together with the name of the copyright holder and the year of creation or publication of the work. For many years, such notice was a fortiori necessary for copyright protection. Today, however, the copyright arises from the creation of a copyrighted work itself. It is still good practice to advise the world of potential infringement by inserting the formalities of a copyright on the work itself. In addition, one should register the work in the United States Copyright Office, which is currently developing a process for online registration. Registration of the copyright also permits one to claim statutory damages ranging from \$500 to \$20,000 for each violation, which often is useful to prevent additional infringements when no actual damages can be demonstrated. Moreover, in some jurisdictions, it may be necessary to register the copyright with the copyright office before one can actually sue to protect the copyright.

The change in copyright protection has interesting applications when applied to electronic works. The creation of the work in some permanent form is sufficient to trigger copyright protection. Thus, the creation of an electronic copy is sufficient permanency. What that means is that any electronic data are already conceivably subject to copyright protection at the time that they are viewed or received. Thus, in using any such information or “work,” care must be taken that one does not infringe on a potential copyright without a license.

11.4.3 First Sale Limitation. The holder of the copyright has the right to sell or license the work. If the work is sold, the holder essentially loses all rights to control the resale of the work. This is known as the first sale doctrine. Once the item is placed in commerce, subsequent transfers cannot be restricted. The doctrine applies only to the copy that has actually been sold. It does not create a license to copy the item itself.

To avoid what sometimes can be a problem if the program winds up in the hands of a competitor, companies often prefer to license the item instead of selling it outright. If the work is licensed, only those rights that are contained in the license are transferred. All other rights of ownership remain with the licensor. Thus, a breach of the license gives the licensor of the copyrighted work the right to reclaim the work or prevent its further use or publication. However, if the license has all the basic indicia of a sale, it will be treated as one, notwithstanding the label.

One interesting intersection of these two principles is the requirement when upgrading software that the old version be present. As a condition of making the upgrade

available at a reduced rate, the seller normally requires that the older version be authenticated before the newer version can be installed. Such requirements are legal, as the owner of the earlier version could choose to sell it, but then would have to pay a higher price for the newer version and work to restrain subsequent sales of software from a user who expects to upgrade in the future.

11.4.4 Fair Use Exception. All copyright protection is subject to the doctrine of fair use.²⁴ Fair use permits the use of a work without authorization for a limited purpose. But what use constitutes fair use? The Copyright Act of 1976 suggested four, nonexclusive factors, for a court to consider:

1. What is the purpose and character of the use?
2. What is the nature of the copyrighted work?
3. How much of the copyrighted work is used?
4. What is the effect on the potential market for the work?

Despite its codification in the Copyright Act of 1976, fair use remains a nebulous doctrine—an equitable rule of reason, with each case to be decided on its own facts.²⁵ It is often misquoted and misapplied. The essential concept behind the doctrine of fair use is to permit public discussion, review, and debate of a copyrighted work without violating the copyright. Thus, the Copyright Act of 1976 gives as examples of fair use, situations of “criticism, comment, news reporting, teaching (including multiple copies for classroom use), scholarship, or research.”

Fair use is not an antidote for failing to license a work. It should be invoked with care—understanding that the more material that is used and the more commercial the purpose, the less likely a court will find it applicable. Indeed, sometimes the only way to harmonize cases on whether a use is a fair use is to decide whether the court ultimately viewed the user as a “good” or “bad” guy.

11.4.5 Formulas Cannot Be Copyrighted. There are limitations on what expressions can be protected by copyright law. A frequent source of argument is whether, since one cannot protect the idea, the expression is directly driven by its content (i.e., the expression is simply a function of the idea). For that reason, formulas cannot be copyrighted.²⁶ This means that when formulas are part of a computer program, other modes of defense need to be considered, such as trade secret or possibly patent protection. If one were to disclose the formula through copyright publication, one would lose the ability to protect that information.

11.4.6 Copyright Does Not Protect the “Look and Feel” for Software Products. Copyright protection ordinarily extends to the physical manifestation of the computer program in the source code and object code. The operation of that code, as it translates to what the human mind perceives, has been described as the “look and feel” of the program. In attempting to quantify the concept of “look and feel,” courts have considered whether the organization, structure, and sequence of the program can be protected. In the United States, *Whelan Associates, Inc. v. Jaslow Dental Lab., Inc.*,²⁷ gave the greatest extension to protecting look and feel. In that case, none of the code had been copied and the program operated on a different platform. Nonetheless, copyright infringement was found because the organization, structure, and sequence of the program had been copied. The court recognized that the structure and logic of

the program are the most difficult to create and that the idea could be protected as it was embodied in the program structure since, given the variety that was possible, the structure was not necessarily just an extension of the idea. Since *Whelan*, courts in the United States have retreated from such broad protection. In 1992, *Computer Associates, Inc. v. Altai, Inc.*²⁸ developed the so-called abstraction-filtration test. The results of that test define as unprotectable: (a) program structures that are dictated by operating efficiency or functional demands of the program and therefore deemed part of the idea and (b) all tools and subroutines that may be deemed included in the public domain. Only what remains is to be compared for possible copyright infringement.

While protection of look and feel may vary among the different federal circuits, in general, the courts are swinging away from broader protection. However, this may not necessarily be true internationally; English law appears to grant the broader protections afforded by the *Whelan* decision.

11.4.7 Reverse Engineering as a Copyright Exception. Within the field of computer software, cases have considered whether “dissection” in order to reverse engineer the program is a violation of the copyright. To those involved in protecting software programs, as well as those involved with competing products, the answer appears to be that reverse engineering does not constitute an infringement, even though the disassembly of the program falls squarely within the category of acts prohibited by the Copyright Act because of the doctrine of fair use. The Ninth Circuit in *Sega Enterprises Ltd. v. Accolade, Inc.*²⁹ found as a matter of law that:

... where disassembly is the only way to gain access to the ideas and functional elements embodied in a copyrighted computer program and where there is a legitimate reason for seeking such access, disassembly is a fair use of the copyrighted work.³⁰

The Ninth Circuit is not the only circuit that has upheld reverse engineering against a copyright claim. The Federal Circuit reached a similar conclusion regarding reverse engineering of object code to discern the “ideas” behind the program in *Atari Games Corp. v. Nintendo of America, Inc.*³¹ The fair use rationale of *Sega* was also adopted by the Eleventh Circuit in *Bateman v. Mnemonics, Inc.*³² on the grounds that it advanced the sciences. In addition, in *Assessment Techs. of WI, LLC, v. WIREDData, Inc.*, the Seventh Circuit relied on *Sega* and determined that WIREDData, Inc. could extract uncopyrighted data from a copyrighted computer program, noting that the purpose of the extraction was to get the raw data, not compete with Assessment Technologies by selling copies of the program itself.³³ In *Evolution, Inc. v. SunTrust Bank*, the Tenth Circuit relied on both *Sega* and *WIREDData* when it allowed the defendant to copy part of plaintiff’s source code to extract uncopyrighted data from plaintiff’s copyrighted computer program.³⁴ Thus, unless careful thought is given to the application of copyright protection, merely copyrighting the software will not necessarily protect against imitation.

11.4.8 Interfaces. There is an open issue as to whether copyright protects the format for interfacing between application and data. Competitors, particularly in the area of gaming, look to reverse engineer the interface format to make new modules compatible with existing hardware. Such reverse engineering has been held not to violate the copyright laws, so long as the new product does not display copyrighted images or other copyrightable expressions.³⁵ Thus, the nonprotectable interface may be protected if such copyrighted images or expressions are embedded in the display.

11 · 12 FUNDAMENTALS OF INTELLECTUAL PROPERTY LAW

11.4.9 Transformative Uses. One of the factors that the doctrine of fair use considers is the “amount and substantiality of the portion used in relation to the copyrighted work as a whole.”³⁶ In practical terms, this means that courts look at how much was taken and for what purpose. One could take a little but still take the essence of the program. One could also take a little that did not attempt to duplicate but rather used the copyrighted material as a springboard for a new creation. Out of this qualitative and quantitative investigation comes the notion of transformative use, which became the coin of analysis in the Supreme Court’s 1994 decision in *Campbell v. Acuff-Rose Music, Inc.*³⁷ *Campbell* addressed the concept in terms of a claim of copyright infringement involving a rap parody of a popular song. There, taking its clues from the opening language of Section 107 codifying fair use, the Supreme Court asked whether the “new” work “adds something new, with a further purpose or different character, altering the first with new expression, meaning or message; it asks, in other words, whether and to what extent the new work is transformative.”³⁸ The Court then laid down the test to be applied.

Although such transformative use is not absolutely necessary for a finding of fair use, ... the goal of copyright, to promote science and the arts, is generally furthered by the creation of transformative works. Such works thus lie at the heart of the fair use doctrine’s guarantee of breathing space within the confines of copyright, ... and the more transformative the new work, the less will be the significance of other factors, like commercialism, that may weigh against a finding of fair use.³⁹

Thus, a transformative use may play off of a prior copyright and still not be deemed an infringement so long as the resulting new work is just that—new.

11.4.10 Derivative Works. Under Section 106(2) of the Copyright Act of 1976, the copyright owner has the exclusive right “to prepare derivative works based upon the copyrighted work.” The act defines a “derivative work” as:

... a work based upon one or more pre-existing works, such as a translation, musical arrangement, dramatization, fictionalization, motion picture version, sound recording, art reproduction, abridgement, condensation, or any other form in which a work may be recast, transformed, or adapted. A work consisting of editorial revisions, annotations, elaborations, or other modifications which, as a whole, represent an original work of authorship, is a “derivative work.”

A “derivative work” is thus defined as an original work that is independently copyrightable. To infringe the exclusive right to prepare a derivative work granted by the Copyright Act to the copyright owner, the infringer need not actually have copied the original work or even have fixed in a tangible medium of expression the allegedly infringing work.⁴⁰ The right, therefore, to create the derivative work can be a useful tool in counterbalancing attempts to pirate computer programs and the issue of fair use.

The Copyright Act creates an exemption for a lawful owner of a purchased license for a computer program to adapt the copyrighted program if the actual adaptation “is created as an essential step in the utilization of the computer program in conjunction with a machine and it is used in no other manner.”⁴¹ The adaptation cannot be transferred to a third party. The right to adapt is, in essence, the right to modify or, in the language of the act, to create a derivative work. Such changes can be made even without the consent of the software owner so long as such modifications are used only internally and are necessary to the continuing use of the software.⁴²

11.4.11 Semiconductor Chip Protection Act of 1984. The Semiconductor Chip Protection Act of 1984 (SCPA) protects as part of the Copyright Act “mask works fixed in a semiconductor product.”⁴³ The SCPA protects not the product itself but the copying of the circuit design or blueprint. Because of reverse engineering, the protections afforded by SCPA are limited in practice.

11.4.12 Direct, Contributory, or Vicarious Infringement. Copyright infringement generally requires a showing of substantial similarity between allegedly offending use and the protected expression contained in a work. Infringement can occur through the simple act of printing (without permission), by posting on the Web or other form of unauthorized distribution, by creating a derivative work, or by another act that interferes with the copyright holder’s rights.

A copyright can be infringed directly, contributorily, or vicariously. Direct infringement is the term ascribed to the actor who violates the copyright. Contributory infringement involves knowingly providing the means for the violation to occur. Liability for contributory infringement may be predicated on actively encouraging (or inducing) infringement through specific acts, or on distributing a product that distributees use to infringe copyrights, if the product is not capable of “substantial” or “commercially significant” noninfringing uses.⁴⁴ But secondary liability for copyright infringement does not exist in the absence of direct infringement by a third party. Vicarious infringement occurs when one is responsible for or controls the actions of another who violates the infringement. The usual situation is that of an employer’s responsibility for the acts of an employee.

Not all situations admit themselves of simple answers, as when a person commits direct infringement by actually photocopying a work. New technologies constantly pose issues as to whether infringement has occurred and whether the infringement violates the public interest. In general, when faced with an issue of potential copyright infringement, the questions to ask are:

- Can the product or service be used to infringe a copyright, or is the product capable of substantial noninfringing uses?
- If so, did the owner of the product or service encourage the user to use it for infringement?
- Alternatively, did the owner of the product or service have knowledge of the specific infringing use and have the ability to prevent it?

Today, we take Internet service providers (ISPs) for granted. But application of these questions initially led courts to conclude that ISPs were liable for contributory infringement. For example, a Web site that encouraged and facilitated the uploading of copyrighted materials was found to be a direct infringer of the copyright of the owner even though the provider did not actually do the uploading.⁴⁵ Similarly, an ISP that was notified of a copyright violation that was posted on its server and failed to correct it could be found to have contributory liability for the infringement.⁴⁶ In its wisdom, however, Congress, in the Digital Millennium Copyright Act (DMCA), created a safe harbor for ISPs so that, as a matter of public policy, an ISP does not have to monitor each and every transmission for potential copyright infringement.

11.4.13 Civil and Criminal Remedies. The Copyright Act contains several sections that specifically address the penalties and remedies for infringement. They

include injunctive relief (i.e., a court order terminating the infringing conduct),⁴⁷ impounding and disposing of infringing articles,⁴⁸ damages,⁴⁹ litigation costs and attorneys' fees,⁵⁰ and criminal penalties.⁵¹ Although this chapter cannot address all of the permutations of remedies and penalties available, a few are worth mentioning.

Generically, a copyright owner must choose between its actual losses (i.e., what it actually lost and any profits realized by the infringer) and statutory damages.⁵² Actual damages imply economic losses actually suffered as a result of the infringement. The kinds of actual damages that have been awarded include development costs of the software,⁵³ the economic consequences of lost customers,⁵⁴ lost future sales,⁵⁵ the value of the infringer's licensing fees where the licensor is precluded from market sales,⁵⁶ lost market value of the material infringed,⁵⁷ and lost royalty payments.⁵⁸ An award of actual damages is not automatic; the license holder has the burden of proving that the infringing activity and the economic loss are causally connected, at which point the infringing party must show that the license holder would have incurred the loss anyway.⁵⁹

A copyright owner may elect to receive statutory damages rather than actual damages and the infringer's profits.⁶⁰ Making the election is mandatory, and it must be done before final judgment is entered. Once the election is made, it is final. The statutory damages generally range from \$500 to \$20,000 "for all infringements involved in the action, with respect to any one work, for which any two or more infringers are liable jointly and severally. ... For purposes of this section, all the parts of a compilation or derivative work constitute one work."⁶¹ This amount may be increased to \$100,000 if the court finds that the infringement was willful and reduced to \$200 if the court finds that the infringer "was not aware and had no reason to believe" that the act was an infringement.⁶²

Statutory damages theoretically⁶³ are intended to approximate the actual damages suffered, and were crafted as an alternative compensation scheme for copyright owners, when actual damages are difficult to calculate. In determining whether to elect actual or statutory damages, a copyright owner ought to perform a careful analysis to determine how many separate infringements occurred that justify, under the statute, separate awards. Although posting different copyrighted computer software programs on a bulletin board for downloading constitutes multiple infringements,⁶⁴ making multiple copies of the same cartoon character in different poses constitutes a single infringement because only one work was copied.⁶⁵

As mentioned, this is one of the statutory schemes that discourage frivolous litigation by imposing the cost of litigating on the losing party. The statute permits the substantially prevailing party to recover its reasonable attorneys' fees and costs from the losing party. Who is the substantially prevailing party and what constitutes reasonable attorneys' fees are separate and distinct issues that will be decided by the courts.

Copyright violations also can be criminally prosecuted, and generally require demonstration of *mens rea*, or intent. One or more infringements having a total retail value of more than \$1,000 within a 180-day period or "for purposes of commercial advantage or private financial gain" can be punished by one to five years of imprisonment and fines. Even without demonstration of a motive of financial gain, 10 or more infringements having a value in excess of \$2,500 can result in up to three years in jail and fines. Repeated violations carry stiffer penalties. Finally, one who knowingly aids or abets a copyright infringement is also subject to criminal prosecution.

11.5 DIGITAL MILLENNIUM COPYRIGHT ACT. In 1998, Congress passed the Digital Millennium Copyright Act (DMCA) to address concerns raised by the

Internet and copyright issues in the context of our increasingly technological society. The DMCA creates a civil remedy for its violation as well as criminal penalties starting after October 2000. One of the purposes of the DMCA is to protect the integrity of copyright information. Removal of a copyright notice, or distribution knowing that such copyright has been removed, is now actionable.⁶⁶

11.6 CIRCUMVENTING TECHNOLOGY MEASURES. Article 11 of the World Intellectual Property Organization Copyright Treaty required all signatory countries to provide adequate legal protection and remedies against the circumvention of technical measures intended to secure copyrights. In response, Congress adopted Section 1201 of the DMCA, which generally prohibits the act of circumventing, and trafficking in the technology that enables circumvention of, protection measures designed to control access to copyrighted work.⁶⁷ Both civil and criminal remedies also now exist under the DMCA if one circumvents “a technological measure that effectively controls access to a work protected” by the Copyright Act.⁶⁸ It is a civil violation and a crime to “manufacture, import, offer to the public, provide or otherwise traffic in any technology, product, service, device, component, or part thereof” that “is primarily designed or produced for the purpose of circumventing a technological measure that effectively controls access to a work protected” under the Copyright Act.⁶⁹ A technological measure effectively controls access to a work if the measure, “in the ordinary course of its operation, requires the application of information or a process or a treatment, with the authority of the copyright owner, to gain access to the work.”⁷⁰ One circumvents such technology measure if one uses a means “to descramble a scrambled work, to decrypt an encrypted work, or otherwise to avoid, bypass, remove, deactivate, or impair a technological measure,” without the authority of the copyright owner.⁷¹

In *RealNetworks, Inc. v. Streambox, Inc.*,⁷² Streambox distributed software that enabled users to bypass the authentication process employed by RealNetworks, which distributes audio and video content over the Internet. Thus, Streambox users could get the benefit of the RealNetworks streaming audio and video content without compensating the copyright owners. The United States District Court in Washington State found that the Streambox software was a technological measure that was designed to circumvent the access and copy control measures intended to protect the copyright owners.⁷³

In a case involving digital video disc (DVD) encryption, a U.S. District Court in New York enjoined posting links to sites where visitors may download the decryption program as trafficking in circumvention technology and a violation of the DMCA.⁷⁴ In *Universal City Studios, Inc. v. Reimerdes*, the court rejected an argument that the use of the decryption software constituted free expression protected by the First Amendment of the U.S. Constitution. On appeal, the appellant argued that the injunction violated the First Amendment because computer code was speech, was entitled to full protection, and was unable to survive the strict scrutiny given to protected speech.⁷⁵ The appellate court found that the computer code used in the program was protected speech:

Communication does not lose constitutional protection as “speech” simply because it is expressed in the language of computer code. Mathematical formulae and musical scores are written in “code,” i.e., symbolic notations not comprehensible to the uninitiated, and yet both are covered by the First Amendment. If someone chose to write a novel entirely in computer object code by using strings of 1’s and 0’s for each letter of each word, the resulting work would be no different for constitutional purposes than if it had been written in English. The “object code” version would be incomprehensible to readers outside the programming community (and tedious to read even for most within the community), but it would be no more incomprehensible

than a work written in Sanskrit for those unversed in that language. The undisputed evidence reveals that even pure object code can be, and often is, read and understood by experienced programmers. And source code (in any of its various levels of complexity) can be read by many more. See *Universal I*, 111 F. Supp. 2d at 326. Ultimately, however, the ease with which a work is comprehended is irrelevant to the constitutional inquiry. If computer code is distinguishable from conventional speech for First Amendment purposes, it is not because it is written in an obscure language.⁷⁶

The court then analyzed the type of scrutiny that should be applied where the restriction is content neutral:

Having concluded that computer code conveying information is “speech” within the meaning of the First Amendment, we next consider, to a limited extent, the scope of the protection that code enjoys. As the District Court recognized, *Universal I*, 111 F. Supp. 2d at 327, the scope of protection for speech generally depends on whether the restriction is imposed because of the content of the speech. Content-based restrictions are permissible only if they serve compelling state interests and do so by the least restrictive means available. See *Sable Communications of California, Inc. v. FCC*, 492 U.S. 115, 126, 106 L. Ed. 2d 93, 109 S. Ct. 2829 (1989). A content-neutral restriction is permissible if it serves a substantial governmental interest, the interest is unrelated to the suppression of free expression, and the regulation is narrowly tailored, which “in this context requires ... that the means chosen do not ‘burden substantially more speech than is necessary to further the government’s legitimate interests.’” *Turner Broadcasting System, Inc. v. FCC*, 512 U.S. 622, 662, 129 L. Ed. 2d 497, 114 S. Ct. 2445 (1994) (quoting *Ward v. Rock Against Racism*, 491 U.S. 781, 799, 105 L. Ed. 2d 661, 109 S. Ct. 2746 (1989)).⁷⁷

Finding that the government’s interest in preventing unauthorized access to encrypted copyrighted material is unquestionably substantial, and that the regulation of decryption programs served that interest, the appellate court upheld the prohibitions against both posting of, and linking to, the decryption program.

Not all efforts to “circumvent” restrictions, however, come within the prohibitions of the DCMA. In *I.M.S. Inquiry Mgmt. Sys. v. Berkshire Info. Sys.*,⁷⁸ the defendant had used a valid password provided to plaintiff’s own customers and user identification to view plaintiff’s e-Basket system exactly as the customer itself might have done. The court concluded that although this might be viewed as a technology measure, it was not circumvention of a digital wall within the meaning of the DCMA.

11.6.1 Exceptions to the Prohibitions on Technology Circumvention.

The DMCA, however, explicitly carves out all defenses to copyright infringement, including the doctrine of fair use, as being unaffected by the passage of the DMCA. In some circumstances fair use can include reverse engineering.

11.6.1.1 Fair Use and Reverse Engineering. Thus, one can spy through reverse engineering still without running afoul of copyright protection or the DMCA.

However, in *Bowers v. Baystate Technologies, Inc.*,⁷⁹ a split Federal Circuit Court of Appeals found that a shrink-wrap license prohibiting reverse engineering was enforceable against the licensee who had reverse engineered Bowers’s CAD Designer’s Toolkit to develop a competing product. The *Bowers* court found that the contractual language trumped the “fair use” permitted under the Copyright Act. The Fifth Circuit has reached the opposite result in the earlier decision of *Vault Corp. v. Quaid Software, Ltd.*,⁸⁰ specifically finding that the Copyright Act preempts state law that attempts to prohibit disassembly, and holding a mass distribution license agreement unenforceable.

Thus, the extent to which *Bowers* may be followed is still unclear, but it appears to be questioned in subsequent decisions.⁸¹ *Bowers* suggests a course that businesses can attempt to follow to curtail reverse engineering, which is to limit that right by contract. If *Bowers* becomes widely accepted, the United States will be in conflict with the European Union on this issue. In its 1991 Software Directive, the European Union set forth a right to reverse engineer that is consonant with “fair use” under the Copyright Act. The Software Directive also provided that the right cannot be waived by contract. So, until *Bowers* is settled, if a shrink-wrap license prohibits reverse engineering, it would be best to consider engaging in such activity abroad.

11.6.1.2 Other Exceptions. The DMCA also creates an important exception that recognizes the right to reverse engineer if (a) the person has lawfully obtained the right to use a copy of a computer program, and (b) the sole purpose of circumventing the technology measure is to identify and analyze “those elements of the program that are necessary to achieve interoperability of an independently created computer program with other programs.”⁸² The DMCA creates a similar exemption for circumvention for the purpose of “enabling the interoperability of an independently created computer program with other programs, if such means are necessary to achieve such interoperability.”⁸³ The term “interoperability” is defined to encompass the “ability of computer programs to exchange information and of such programs mutually to use the information which has been exchanged.”⁸⁴ The information acquired through these permitted acts of circumvention may also be provided to third parties so long as it is solely used for the same purposes.⁸⁵

Circumvention is permissible under these exemptions, however, “only to the extent [that it] does not constitute copyright infringement.” Two cases, *Chamberlain Group, Inc. v. Skylink Techs., Inc.*,⁸⁶ and *Lexmark Int’l, Inc. v. Static Control Components, Inc.*,⁸⁷ are particularly instructive. In both cases, the courts permitted a competitor’s access and reverse engineering under this exemption. In contrast, in *Storage Tech Corp. v. Custom Hardware Engineering Consulting, Inc.* (D. Mass. 2004), the defendant bypassed a protective access key to activate the diagnostics program by copying the code into the random access memory (RAM) of the defendant’s access device. The District Court found that this copying constituted infringement. The result was reversed in a 2 to 1 decision in the United States Federal Circuit⁸⁸ based on a reading of sections 117(a) and (c) of the DMCA, which permits copying for maintenance purposes. This string of decisions has led to recommendations that access be controlled by a method that would cause copyright infringement and that access protect not just the copyrighted program but copyrighted data so as to exclude the rationale of the Federal Circuit. Suggestions have been made that certain parts of copyrighted executable code be encrypted and that a decryption key be required that will create a copy of the code and protected data as part of the process so as to create an argument of copyright infringement. These types of recommendations remain untested, and the simpler course may be control through terms inserted into the licensing agreement.

Exempt from the DMCA, as well, are “good faith” acts of circumvention where the purpose is encryption research. A permissible act of encryption research requires that (a) the person lawfully have obtained a copy, (b) the act is necessary to the research, (c) there was a good faith effort to obtain authorization before the circumvention, and (d) such act does not constitute an infringement under a different section of the Copyright Act or under the Computer Fraud and Abuse Act of 1986. With the caveat that it must be an act of good faith encryption research, the technological means for circumvention can be provided to others who are working collaboratively on such

research. The issue of good faith encryption research looks to what happened to the information derived from the research. If it was disseminated in a manner that was likely to assist infringement, as opposed to reasonably calculated to advance the development of encryption technology, then the act still falls outside of the exemption. Other factors that go into the determination of good faith are whether the person conducting the research is trained, experienced, or engaged in the field of encryption research and whether the researcher provides the copyright owner with a copy of the findings.

The DMCA also has a bias against the collection or dissemination of personally identifying information. Thus, it is not a violation of the DMCA to circumvent a technology measure that essentially protects, collects, or disseminates personally identifying information, provided that the circumvention has no other effect, and provided that the program itself does not contain a conspicuous notice warning against the collection of such information and a means to prevent or restrict such collection.⁸⁹ In short, one can disable cookies if the program does not itself permit a user to do so.

Finally, insofar as relevant to this chapter, the DMCA also excludes from its scope “security testing.” The DMCA grants permission to engage in security testing that, but for that permission, would violate the terms of the DMCA. If the security testing, for some reason, violated some other provision of the Copyright Act or the Computer Fraud and Abuse Act of 1986, then it is still an act of infringement. The DMCA, in part, considers whether a violation occurred, and by whom the information was used. The factors to be considered include if the information was used to promote the security of the owner or operator of the computer network or system, if it was shared with the developer, and if it was used in a manner that would not facilitate infringement.⁹⁰ For purposes of the DMCA, security testing means accessing either an individual computer or network for the purpose of “good faith testing, investigating, or correcting, a security flaw or vulnerability, with the authorization of the owner or operator.”⁹¹

11.6.1.3 Remedies. The criminal penalties for violation of the DMCA can be quite severe. If the violation is willful for commercial gain, the first offense bears a fine of up to \$500,000 or 5 years’ imprisonment. Subsequent violations bear fines of up to \$1 million dollars or 10 years imprisonment. Civil remedies include an order to restrain the violation, damages for lost profits, damages for recovery of the infringer’s profits, or statutory damages for each violation. Depending on the section of the DMCA at issue, each violation can generate fines of up to \$2,500 or \$25,000. Since each act of infringement can constitute a violation, the statutory fines can become quite substantial.

11.7 PATENT PROTECTION. Ideas, which are not protected by copyright, can be protected through a patent. In general, the patent laws protect the functionality of a product or process.

11.7.1 Patent Protection Requires Disclosure. A patent can be properly obtained if the invention is new, useful, nonobvious, and disclosed. The patent exchanges a grant of an exclusive monopoly over the invention in return for disclosure. Disclosure is the trigger point for patentability. The disclosure supports the claims of patentability (i.e., it sets up the claim that the invention is both new and nonobvious) and also the scope of what can be protected. Thus, 35 U.S.C. section 112 provides:

The specification shall contain a *written description* of the invention, and of the manner and process of making and using it, in such full, clear, concise and exact terms as to *enable any person skilled in the art* to which it pertains, or with which it is most nearly connected, to make

and use the same, and shall set forth the *best mode* contemplated by the inventor of carrying out his invention.

The specification shall conclude with one or more claims particularly pointing out and *distinctly claiming* the subject matter which the applicant regards as his invention. [Emphasis added.]

A patent therefore must disclose the best mode for implementing the invention, a clear written description of the invention, sufficient detail so that a practitioner can understand and make use of the description, and distinct claims, in order for a patent to issue.⁹² Through adequate disclosure of the invention, the application gives notice of the technology involved in the patent so as to put the public on fair notice of what would constitute an infringement. From a public policy perspective, the disclosure enlarges the public knowledge. From the inventor's perspective, the trade-off is disclosure for exclusivity. Depending on how the invention is to be used and the areas in which protection will be necessary, disclosure may not be the best means of protecting the invention. This is particularly true if the inventor is not convinced it will be deemed nonobvious from prior art, in which case it will be subject to challenge, or if, after disclosure, other companies may legally use the disclosed information for competitive advantage. The effects of disclosure should be carefully considered before applying for patent protection.

11.7.2 Patent Protection in Other Jurisdictions. Patent protection is jurisdictional. What that means, in general, is that a patent has legal meaning in the country that granted it. The United States is a signatory to the Paris Convention for the Protection of Industrial Properties, which has roughly 160 signatories. The Paris Convention essentially grants a one-year grace period for filing national patent applications in each selected signatory, to obtain the benefit of the original filing date in the United States. An alternative, open to members of the Paris Convention, is the Patent Cooperation Act. This permits the filing of an international patent that basically gives the patentee an 8- to 18-month window to test feasibility, and which simplifies the national application process.

11.7.3 Patent Infringement. Like the remedies for copyright infringement, the remedies for patent infringement include injunctive relief and damages that, by statute, are not less than a reasonable royalty for the infringing use.⁹³ If the infringement is willful, the damages can be trebled. Attorneys' fees can be awarded, but only in exceptional cases.

In the area of exported computer software, an issue of note has arisen under 35 U.S.C. section 271(f). Section 271(f) was added in 1984 to the patent law to prevent infringers from avoiding liability by finishing goods outside of the United States. An infringer will be liable if its intent is to manufacture or supply a component from the United States to be combined elsewhere, if it would be an infringement had it occurred within the United States. Exported software may be considered a "component" under section 271(f). In *Microsoft Corp. v. AT&T Corp.*,⁹⁴ the issue was whether a master disk supplied by Microsoft abroad for duplication and installation abroad of its Windows program ran afoul of AT&T's patent. In overruling the Federal Circuit, the Supreme Court concluded that it did not.

Section 271(f) prohibits the supply of components "from the United States . . . in such manner as to actively induce the combination of such components." § 271(f) (1). Under this formulation, the very components supplied from the United States, and not copies thereof, trigger § 271(f)

liability when combined abroad to form the patented invention at issue. Here, as we have noted, the copies of Windows actually installed on the foreign computers were not themselves supplied from the United States. Indeed, those copies did not exist until they were generated by third parties outside the United States. Copying software abroad, all might agree, is indeed easy and inexpensive. But the same could be said of other items: “Keys or machine parts might be copied from a master; chemical or biological substances might be created by reproduction; and paper products might be made by electronic copying and printing.”... The absence of anything addressing copying in the statutory text weighs against a judicial determination that replication abroad of a master dispatched from the United States “supplies” the foreign-made copies from the United States within the intendment of § 271(f).

Unless section 271(f) is amended, it may have profound implications for subverting the ability of a U.S. company to control patent infringement where software is a component of a patented invention.

11.8 PIRACY AND OTHER INTRUSIONS. For as long as ideas and innovation have been a source of commercial or social value, the terms on which these ideas and innovations have been available for use and exchange by others has been the subject of significant tension. Although inventors and creators of commercially viable products and processes want to maximize the return on their investment, marketplace pressure for cost efficiency (often motivated by human and corporate greed) fuels a constant drive to remove the inventors’ and creators’ royalties from the cost of production. Thus, the ancient notion of piracy, the unauthorized boarding of a ship to commit theft, and the unauthorized use of another’s invention or production⁹⁵ remains alive and well. The piracy we speak of is not simply the unauthorized copying of millions of compact discs (CDs); increasingly it includes the unauthorized scraping of data from Web sites, abuse of authorized Internet use, theft of employee data, and similar activities.

11.8.1 Marketplace. The demand for unlicensed access to and use of software and entertainment media increases annually. In its 2007 survey regarding computer security among corporate and governmental institutions, the Computer Security Institute and the U.S. Federal Bureau of Investigation found that 59 percent of all respondents discovered employees who abused Internet privileges for a variety of unauthorized purposes.⁹⁶ A 2007 study by the Software & Industry Information Association reported worldwide revenue loss from the piracy (unlawful copying and distribution) of software exceeding \$28.8 billion in 2007.⁹⁷ In countries such as China, despite recent overtures to the contrary, piracy is not merely sanctioned, it constitutes an investment by government agencies.⁹⁸

In recent years, in large part due to the saturation of Internet access, there has been a tremendous proliferation of technologies designed to access and distribute (without authorization) protected software applications and entertainment media. This has posed a tremendous challenge for license holders, legislators, and law enforcement authorities. The results have included attempts to punish both unauthorized access and use of protected material. In the process, there has been a transformation in the definition of what is protected and some confusion about the extent of that protection when the Internet is involved.

11.8.2 Database Protection. Databases, the organized compilation of information in an electronic format, are prominent elements of any discussion concerning copyright protection. Compilations of information, data, and works are protectable under the Copyright Act.⁹⁹ To secure copyright protection for a compilation, a party

must demonstrate that (1) it owned a valid copyright in the compilation; (2) the alleged infringer copied at least a portion of the compilation; and (3) the portion so copied was protected under the Copyright Act.¹⁰⁰ In this context, the Copyright Act protects the “original” selection, coordination, or arrangement of the data contained in the compilation.¹⁰¹

To the extent that compilations contain purely factual information (e.g., existing prices of products and services), there is no protection because the facts themselves lack originality.¹⁰² It does not matter that the author “created” the facts of the prices being charged for the product or service.¹⁰³ To sustain a claim of copyright protection for compilations of fact, the author must demonstrate creativity in the arrangement of the data. Standard or routine arrangements are likewise beyond the act’s umbrella.¹⁰⁴ This is in contrast to the European Union’s Database Directive, which does not require creativity as an element for the protection of a database. Rather it protects investment in databases under copyright protection subject, however, to fair use qualifications.

The United States Supreme Court has held that the compilation into a database of original works by contributing authors to newspapers and magazines violates the copyrights of the individual authors when the database does not reproduce the authors’ articles as part of the original collective work to which the articles were contributed. In *New York Times Co., Inc. v. Tasini*,¹⁰⁵ authors who contributed articles and other works to the *New York Times*, *Time* magazine, and *Newsday* sued when they learned that the articles that they sold to the publishers for use in the respective publications were being reproduced and made available online, through LEXIS/NEXIS, an online database, and on CD-ROM. In most instances, the reproductions were of the individual articles outside of the newspaper or magazine context, in a collection of works separately protected by the Copyright Act. The Supreme Court held that, because the publishers of the new collective works made no original or creative contribution to the individual authors’ original works, they could not reproduce and distribute those works outside of the format that each publisher created for the original collections of works, without permission from, or payments to, each author.¹⁰⁶

11.8.3 Applications of Transformative and Fair Use. The concepts of transformative use and fair use (to the extent that they are separable) discussed earlier in this chapter have played a substantial role in recent decisions involving the authorized use of electronic media and the Internet. The starting point for this application of the doctrine is the U.S. Supreme Court’s decision in *Sony Corporation v. Universal City Studios, Inc.*,¹⁰⁷ the famous battle over Betamax initiated by the movie industry. At issue was whether electronic recording machines could record television programs to permit individuals to “time-shift” television programs (i.e., to record programs for viewing at a time other than the time of airing). In its decision, the *Sony* Court found that time shifting was a productive use of the television programs for a purpose other than the original commercial broadcast, and was not an attempt either to duplicate the original purpose or to impact the commercial market for these programs. The Court emphasized the noncommercial element inherent in time shifting.¹⁰⁸

11.8.4 Internet Hosting and File Distribution. The growth of the breadth and scope of the Internet has been accompanied by increasing questions about the extent to which the distribution of otherwise protected expressions change their form when converted into an electronic format. These questions arise for ISPs, which provide the pathway for distributing protected material, and for end users who post such materials

on their Web sites and bulletin boards. For ISPs, the DMCA provides some initial comfort.

Title II of the DMCA, designated the “Online Copyright Infringement Limitation Act,” establishes several infringement liability safe harbors for service providers. The “Information residing on systems or networks at direction of users”¹⁰⁹ safe harbor is available to any provider of “online services or network access, or the operator of facilities thereof, . . .” including “digital online communications, between or among points specified by user, of material of the user’s choosing, without modification to the content of the material as sent or received”¹¹⁰ that “has adopted and reasonably implemented, and informs subscribers and account holders of the service provider’s system or network of, a policy that provides for the termination in appropriate circumstances of subscribers and account holders of the service provider’s system or network who are repeat infringers” and “accommodates and does not interfere with standard technical measures.”¹¹¹ To qualify for the safe harbor, the service provider must demonstrate that:

1. It has no actual or constructive knowledge that information on its system is infringing, it is not aware of circumstances from which infringement is apparent or, upon obtaining such knowledge or awareness, it acts expeditiously to remove those materials;
2. It receives no financial benefit directly attributable to the infringing activity, *and*
3. Upon receipt of a notice of infringing material on its system, responds expeditiously to remove, or disable access to, the material.¹¹²

Assuming that the safe harbor does not apply (as, for instance, because the ISP failed to act on a notice of infringing activity), many service providers may nonetheless escape liability. In the first, and seminal, case on this topic, *Religious Technology Center v. Netcom On-Line Communication Services, Inc.*,¹¹³ an ISP hosted a bulletin board service on which Church of Scientology publications were posted by a former minister. The District Court held that the ISP must demonstrate that its use was of public benefit (facilitating dissemination of creative works including, but not limited to, the infringing work); that its financial gain was unrelated to the infringing activity (e.g., subscription fees from providing email systems rather than fees from the display or sale of the infringing work); that its use was unrelated to the use of the owner of the work; that the ISP copied only what was necessary to provide its service; and that its use of the material had no demonstrable effect on the potential market for the work.¹¹⁴ In *CoStar Group, Inc. v. LoopNet, Inc.*, the Fourth Circuit relied on *Netcom*, its codification in the DMCA, and the fact that the DMCA does not limit the application of other infringement defenses, and held that “the automatic copying, storage, and transmission of copyrighted materials, when instigated by others, does not render an ISP strictly liable for copyright infringement under §§501 and 106 of the Copyright Act.”¹¹⁵

For Web site owners and users who post allegedly infringing material, the courts have had much less difficulty discarding the transformative fair use arguments. This has been particularly true in the purely commercial setting, as where the infringing party gains direct financial benefit from the infringing material,¹¹⁶ and where the posted material is an exact copy of the protected work without any transformation to something creative or original.¹¹⁷ In a case that goes to the heart of the open-access nature of the Internet, one court recently held that a copyright owner who posts its work on the Internet for

free distribution as shareware may defeat a transformative fair use defense by also posting an express reservation of distribution rights.¹¹⁸

11.8.5 Web Crawlers and Fair Use. The Internet, premised on open exchange of data and economic efficiency, has spawned a spate of data search and aggregation software tools that scan the Web looking for information requested by the user. The process used by these search engines¹¹⁹ includes identifying data on the Web that conforms to the search parameters and then downloading that data. Since the copying usually occurs without the express permission of the copyright owner, some have argued that such copying constitutes an infringement. Although there is very little precedent concerning the application of transformative fair use to automated data retrieval systems, at least one court has upheld the use of the defense to an infringement claim.¹²⁰

11.8.6 HyperLinking. In *Perfect 10 v. Google, Inc.*,¹²¹ affirmed in part and remanded in part, *Perfect 10, Inc. v. Amazon.com, Inc.*,¹²² Perfect 10 (P10) claimed that Google was infringing its ownership of copyrights in certain images and thumbnails hosted by third-party and P10's Web sites when Google's image search picked them up for display as framed full-size images and as thumbnails on computers and cell phones. The court concluded that hyperlinking did not constitute display for purposes of direct copyright infringement. On appeal, the case was remanded for further consideration as to whether the conduct fell within the general rule for contributory liability. To appreciate the context in which the courts are wrestling with these issues in the light of new technology, a review of the District Court's analysis should be studied.

11.8.7 File Sharing. Transformative fair use will not protect the verbatim retransmission of protected work in a different medium when there is a substantial and detrimental impact on the market for the protected work. In *A&M Records, Inc. v. Napster, Inc.*,¹²³ Napster enabled users to share music files over the Internet by downloading the file-sharing software to their hard drive, using the software to search for MP3 music files stored on other computers, and transferring copies of MP3 files from other computers. The court of appeals held that Napster users were merely retransmitting original works in a different medium and that this did not constitute a transformation of the original work. The court also found that sharing of music files over the Internet had, and would have, a significant and detrimental impact on the existing and potential market for CDs and digital downloads of the copyright owners' works. Picking up on the *Sony* decision's emphasis on the distinction between commercial and personal use, the Court of Appeals found that Napster's Web site effectively made the works available for use by the general public and not simply for the personal use of individual users.¹²⁴

Napster's demise, however, did not end the controversy over file sharing. Trying to avoid Napster's method of directly enabling file sharing, entities such as Grokster and StreamCast developed software creating peer-to-peer networks through which individual computers communicate to exchange files without the necessity of a central server.¹²⁵ The Supreme Court recently revisited copyright infringement and file sharing specifically with respect to these peer-to-peer networks and applied the "inducement rule" to file-sharing services. Evidence demonstrated that 90 percent of the files available to download from Grokster and StreamCast were copyrighted works, and Grokster and StreamCast conceded that most users were downloading copyrighted material. There was also an abundance of evidence that through their respective software

applications and advertisements, both entities marketed themselves as the alternative to Napster, and their business models demonstrated “that their principal object[ive] was [the] use of their software to download copyrighted works.”¹²⁶ The Court vacated the court of appeals’ affirmation of summary judgment for Grokster and StreamCast, and rejected the court of appeals’ broad interpretation of *Sony Corp. v. Universal City Studios*, but declined to further discuss the balance between protecting copyrighted works and promoting commerce in the context of how much noninfringing use each service was capable of providing, and did not at all discuss the issue of fair use. Instead, the Court noted that *Sony* did not preclude other forms of infringement liability and, focusing on the intent of the defendants in their inducement of file sharing, held that “one who distributes a device with the object of promoting its use to infringe copyright, as shown by clear expression or other affirmative steps taken to foster infringement, is liable for the resulting acts of infringement by third parties.”¹²⁷ Citing *Sony*, the Court further opined that mere knowledge of potential or actual infringement are not sufficient bases for liability, but that “the inducement rule ... premises liability on purposeful, culpable expression and conduct, and thus does nothing to compromise legitimate commerce or discourage innovation having a lawful purpose.”¹²⁸

Since the service and software in *Grokster* had other lawful purposes, the Supreme Court’s decision underscores the importance of proving an intent to infringe or cause infringement. Thus, when asking a court to look behind stratagems and disclaimers that hide unlawful purposes, the copyright holder should consider what other evidence exists or is likely to exist of product design, advertising, marketing, external and internal communications, revenue plans, and other factors that would prove unlawful intent. In addition, for copyright holders, the problem remains that many providers of file-sharing software may not be subject to the jurisdiction of U.S. courts and that file-sharing software, such as “Darknet,” provides anonymity to users illegally downloading copyrighted materials. As will be discussed, many countries are signatories to TRIPS (see Section 11.11.1 of this chapter) and subscribe to international copyright protection. Following *Grokster*, the maker of KaZaa file-sharing software was enjoined in Australia from using its software to commit copyright infringement. The remedy required alteration of the software so that it would not duplicate copyrighted works.

11.9 OTHER TOOLS TO PREVENT UNAUTHORIZED INTRUSIONS. Several legal principles and laws support the right to prevent and prosecute unauthorized intrusions. These include the definition of trespass, terms of use, and several critically important and widely used laws explicitly addressing the issues.

11.9.1 Trespass. Trespass is a common law concept that we are all familiar with when applied to land. We have all seen and probably at some point in our youth violated the no-trespassing signs that are posted on an unfriendly neighbor’s property. Trespass is also a concept that can apply to computers and informational databases. Courts have been taking older concepts and reapplying them to new situations.

In *eBay, Inc. v. Bidder’s Edge, Inc.*,¹²⁹ the Federal District Court granted eBay an injunction forbidding Bidder’s Edge from using a software robot to scrape information from eBay’s Web site. The court based the injunction on its finding that accessing the Web site in a manner that was beyond eBay’s posted notice (there were actual letters of objection) constituted a trespass. The court reasoned that the “electronic signals

sent by Bidder's Edge to retrieve information from eBay's computer system [were] sufficiently tangible to support a trespass cause of action." The court further viewed the ongoing violation of eBay's fundamental right to exclude others from its computer system as creating sufficient irreparable harm to warrant an injunction. Thus, it was not necessary that eBay prove that the access actually interfered with the operation of the Web site. Rather, proof of the "intermeddling with or use of another's personal property" was sufficient to establish the cause of action for trespass. What is significant here is that eBay did permit others to access its Web site under license, and the court viewed conduct that exceeded the licensed use, upon notice to the violator, to be a trespass.

However, the applicability of trespass to unauthorized computer activity is not settled. Where trespass involves an object, rather than land, there must not only be improper use but also some harm to the physical condition or value of the object, or the misuse must deprive the rightful owner of the use of the object for a substantial period of time. The two must be causally related. In *Intel v. Hamidi*,¹³⁰ the California Supreme Court reversed a lower court's banning a former employee from sending unsolicited emails on the grounds of trespass. The court thought that the reach of the doctrine had been extended too far, concluding that bad analogies (i.e., viewing servers as houses and electronic waves as intrusions) create bad law. The court declined to view computers as real property. Rather, finding that they were like other personal property, the court found that this communication was no different from a letter delivered by mail or a telephone call. In short, the court declined to find a trespass because there was an "unwelcome communication, electronic or otherwise" that had fictitiously caused an "injury to a communication system." Here there was no injury to the computer system although Intel claimed injury to its business.

Intel v. Hamidi simply warns against overbreadth of application of the concept of trespass. If injury to the computer system can be demonstrated, then the concept of trespass does lie as a tool in the arsenal of remedies assuming that the trespasser can be identified.

11.9.2 Terms of Use. Terms of use can constitute a contract with respect to Web site usage. Thus, in any situation where electronic access is requested or permitted, the terms and conditions of use, together with an acknowledgment that such terms have been seen and consented to, can be enforced as restricting usage. In *Register.com, Inc. v. Verio, Inc.*,¹³¹ the Second Circuit upheld an order enjoining Web site access primarily on the issue of contract. There, as described by the Second Circuit, the defendant Verio, against whom the preliminary injunction was issued, was engaged in the business of selling a variety of Web site design, development, and operation services. In the sale of such services, Verio competed with Register's Web site development business. To facilitate its pursuit of customers, Verio undertook to obtain daily updates of the WHOIS information relating to newly registered domain names. To achieve this, Verio devised an automated software program, or robot, which each day would submit multiple successive WHOIS queries through the port 43 accesses of various registrars. Upon acquiring the WHOIS information of new registrants, Verio would send them marketing solicitations by email, telemarketing, and direct mail. To the extent that Verio's solicitations were sent by email, the practice was inconsistent with the terms of the restrictive legend Register attached to its responses to Verio's queries.

Register at first complained to Verio about this use and then adopted a new restrictive legend on its Web site that undertook to bar mass solicitation "via direct mail, electronic

mail, or by telephone.” The court concluded that Verio’s conduct formed a contract, like buying an apple at a roadside fruit stand, which Verio breached:

We recognize that contract offers on the Internet often require the offeree to click on an “I agree” icon. And no doubt, in many circumstances, such a statement of agreement by the offeree is essential to the formation of a contract. But not in all circumstances. While new commerce on the Internet has exposed courts to many new situations, it has not fundamentally changed the principles of contract. It is standard contract doctrine that when a benefit is offered subject to stated conditions, and the offeree makes a decision to take the benefit with knowledge of the terms of the offer, the taking constitutes an acceptance of the terms, which accordingly become binding on the offeree. See, e.g., *Restatement (Second) of Contracts* § 69 (1)(a) (1981) (“Silence and inaction operate as an acceptance . . . where an offeree takes the benefit of offered services with reasonable opportunity to reject them and reason to know that they were offered with the expectation of compensation.”)

* * *

Returning to the apple stand, the visitor, who sees apples offered for 50 cents apiece and takes an apple, owes 50 cents, regardless whether he did or did not say, “I agree.” The choice offered in such circumstances is to take the apple on the known terms of the offer or not to take the apple. As we see it, the defendant in Ticketmaster and Verio in this case had a similar choice. Each was offered access to information subject to terms of which they were well aware. Their choice was either to accept the offer of contract, taking the information subject to the terms of the offer, or, if the terms were not acceptable, to decline to take the benefits.

Id., at 403; and was also a trespass because:

The district court found that Verio’s use [**31] of search robots, consisting of software programs performing multiple automated successive queries, consumed a significant portion of the capacity of Register’s computer systems. While Verio’s robots alone would not incapacitate Register’s systems, the court found that if Verio were permitted to continue to access Register’s computers through such robots, it was “highly probable” that other Internet service providers would devise similar programs to access Register’s data, and that the system would be overtaxed and would crash. We cannot say these findings were unreasonable.

Id., at 405.

Similarly, although in a different setting, in *ProCD v. Zeidenberg*,¹³² where ProCD sold a CD with noncopyrightable data. Access to the data, however, was controlled by a license agreement; if there was no acceptance, there was also no access. The license agreement prohibited the use of the data for any commercial use. Zeidenberg took the data and posted it on a Web site, which he used commercially to sell advertising. Thus, the data were being used to attract visitors. The court found the license limitation on use enforceable.

The importance of this decision is that so long as the owner prominently specifies the limitations, the restrictions can become a contract that is accepted by accepting the benefits of access and can be one safeguard against misuse of the access.

11.9.3 Computer Fraud and Abuse Act¹³³

11.9.3.1 Prohibited Behavior and Damages. In 1984, Congress passed the original version of the Computer Fraud and Abuse Act (CFAA).¹³⁴ The general purpose was to protect “Federal interest computers” by criminalizing intentional and unauthorized access to those computers that resulted in damage to the computers or the data stored on them. The statute was substantially amended in 1986¹³⁵ and again in 1996¹³⁶ and now contains both criminal and private civil enforcement provisions.

The statute proscribes these activities:

- ... knowingly accessing a computer without authority or in excess of authority, thereafter obtaining U.S. government data to which access is restricted and delivering, or attempting to deliver, the data to someone not entitled to receive it¹³⁷;
- intentionally accessing a computer without authority or in excess of authority and thereby obtaining protected consumer financial data¹³⁸;
- intentional and unauthorized access of a U.S. government computer that affects the use of the computer by or for the U.S. government¹³⁹;
- accessing a computer used in interstate commerce knowingly and with the intent to defraud and, as a result of the access, fraudulently obtaining something valued in excess of \$5,000¹⁴⁰;
- causing damage to computers used in interstate commerce by (i) knowingly transmitting a program, code, etc. that intentionally causes such damage, or (ii) intentionally accessing the computer without authority and causing such damage¹⁴¹;
- knowingly, and with the intent to defraud, trafficking in computer passwords for computers used in interstate commerce or by the U.S. government¹⁴²; and
- transmitting threats to cause damage to a protected computer with the intent to extort money or anything of value.¹⁴³

The linchpin among the relevant decisions concerning access to data under the CFAA is whether the access is “without authority” or “in excess of authority.” The factors considered by the courts include the steps taken by the owner of the information to protect against disclosure or use, the extent of the defendants’ knowledge regarding their authority to access or use the data, and the use(s) made of the data after gaining access. The legislative history indicates that the statute was intended to “punish those who illegally use computers for commercial advantage.”¹⁴⁴

Broadly speaking, there are two sets of circumstances to consider. In the first instance, is the actual access authorized, either expressly or impliedly? In the Internet context, where there is a presumption of open access, the site or data owners must show that they took steps to protect the contents of their site and to limit access to the data at issue.¹⁴⁵ Once those steps are taken, the protection constitutes a wall through which even automated search retrieval systems may not go without express permission.¹⁴⁶ Without the wall, there must be some evidence of an intent to access for an impermissible purpose, as when Intuit inserted cookies into the hard drives of home computers.¹⁴⁷

Second, has the authorized access been improperly exceeded? Generally speaking, those who use their permitted access for an unauthorized purpose to the detriment of the site or data owner have violated the CFAA. Examples include employees who obtain trade secret information and transmit it via the employer’s email system to a competitor for which the employee is about to begin work¹⁴⁸; using an ISP subscription membership to gain access to and harvest email addresses of other subscribers in order to transmit unsolicited bulk emails¹⁴⁹; and using access to an employer’s email system to alter and delete company files.¹⁵⁰

The criminal penalties range from fines to imprisonment for up to 20 years for multiple offenses. As discussed in Section 11.9, the CFAA has become a prominent element of claims by the U.S. government and private parties seeking to protect data that are not always protected by other statutory schemes.

11.9.3.2 Its Application to Web Crawling and Bots. Web robots, or “bots,” have become widespread to scrape data from Web sites. All of that data generally are available to the public. That is, any individual can access the same information,

but not with the speed or accuracy of a Webspider. But when does such “scraping” run afoul of the CFAA? To what extent does the law protect site operators or company data from penetration by an outside third party?

The key to the analysis under the CFAA is to ask whether the data are in fact publicly available. Are there technical barriers, such as passwords or codes, that have to be circumvented? Do the terms of use prohibit access or use other than by an individual consumer? These questions are critical to determining whether the access either exceeds authority or is without authority under the CFAA.

If the answer to either one of these questions (or similar questions) is yes, one needs to consider access carefully since such access and downloading of data is likely to violate the CFAA. In *EF Cultural Travel v. Zefer Corporation*, Zefer designed a Web bot to scrape travel trip and pricing information from the Web site of EF Cultural Travel (EF) for use by a competitive travel Web site. The bot, designed by Zefer, downloaded the information by calling URLs on which each separate trip and pricing information was stored, reading the source code for the key features, and storing the information on a spreadsheet. The bot did so in a fashion not to burden or interfere with EF’s Web site. Once gathered, the information was turned over to a competitor, who used the information to adjust price and trip information that it offered. Zefer’s scraping did not occur continuously, but only on two dedicated occasions. EF sued, claiming that a violation of the CFAA had occurred. The First Circuit Court of Appeals disagreed, refusing to read into what is or is not authorized some “reasonable expectations” standard, instead requiring that the Web site operator expressly state any limitations on access in its terms and conditions. On remand to the Federal District Court, the court, following the First Circuit, granted summary judgment for Zefer.

11.9.3.3 Simple Preventive Measures. Not surprisingly, there are several methods for preventing unauthorized access in the first instance and, if unsuccessful, in prevailing in any subsequent claim arising under the CFAA. Perhaps the most obvious measure, and one that the First Circuit Court of Appeals underscored, is to make sure that each visitor to a Web site is adequately notified that the owner of the site intends only limited use or access to the data on the site. The notice can take many forms.

For example, a detectable message easily identifiable on a home page warning visitors that the posted information is available only for viewing and not for use in any manner adverse to the host’s interests would be sufficient. Understandably, most Web hosts are reluctant to post such a blatant limitation—it is not necessarily “good for business.” For those interested in an equally effective but less direct message, an increasingly common practice is to compel site visitors to register before gaining access to links and other pages available through the home page. The more difficult the registration process, the greater the host’s apparent intent to restrict access to, and use of, the information that will be accessible after registration is completed.

Those hosts that require the payment of money, some kind of membership, or an access agreement before providing access establish what, for purposes of statutes like the CFAA that criminalize unauthorized access, will most often be seen as providing sufficient notice of the limits of authorized access. In the case of membership sites, the presumption is that each registrant is prequalified and therefore authorized to view and use the more restricted data, at least for purposes consistent with the terms of access. Enforceable click-wrap access agreements establish not only notice of access limitations; they also secure each visitor’s agreement to use the Web site and the data therein within the stated limitations.

Securing Web-based data against unauthorized use or users is, in some ways, antithetical to the information-sharing intent and purpose of the Web. In this regard, however, the question arising when we post information on the Web differs little from the question posed over the centuries regarding the extent to which each of us wants our competitors or adversaries to use our proprietary work against our interests. The greater the concern, the more likely that each host will have to limit the data posted on the Web, or else increase each visitor's awareness of the rules of access.

11.9.4 Electronic Communications and Privacy. Electronic privacy is becoming the issue in our society of databases and networking. Most of the U.S. "privacy" statutes are subject matter specific: the Telephone Consumer Protection Act of 1991 (do not call, for telemarketers); Health Insurance Portability Accountability Act of 1996 (privacy with respect to uses and disclosure of medical information); Children's Online Privacy Protection Act of 1998 (regulating collection of information from children under the age of 13 by Web sites directed to children); Gramm-Leach-Bliley Act of 1999 (regulating sharing of customer data by financial institutions); Controlling the Assault of Non-Solicited Pornography and Marketing Act of 2003 (restricting spammers and requiring an ability to opt out); the Fair and Accurate Credit Transaction Act of 2003 (providing very limited assistance with respect to identity theft such as the obligation to provide a yearly credit report). These laws do not provide assurances of privacy in the same way that the European Union did in its 1996 Data Protection Directive.¹⁵¹ The EU Data Directive establishes protections against release of personal data, including emails, within the European Union, and restrictions on the transmission of such data outside the EU to countries or companies that do not have equivalent protections in place.¹⁵²

In 2005, ChoicePoint, a large data broker, admitted that it had sold personal data on over 160,000 people to phony companies established by identity thieves. Since then, other companies have announced data break-ins and data leaks. As a result of such data security breaches, approximately half of the states have passed laws that require disclosure of unauthorized access to personal data.¹⁵³

In the United States, the primary protection for privacy remains a lawsuit for tortious invasion of one's privacy. Because those rights are defined state by state, a review is beyond the scope of this chapter. However, most states recognize some form of the tort of invasion of privacy, and the tort has been recognized in the *Restatement (Second) of Torts* § 652, which courts reference as an authoritative source of the law. In general, the Restatement makes actionable (a) intentional intrusion, that is highly offensive to a reasonable man, into the seclusion of another's private affairs, (b) the public disclosure of private facts if such disclosure is highly offensive to a reasonable person, and is not a legitimate public concern, and (c) the appropriation for his own use or benefit of the name or likeness of another.

This chapter has already discussed the fiduciary obligation owed by employees to their employers with respect to confidential information. The development of the tort of privacy suggests that companies owe a similar obligation to their employees. Although slightly different in scope, but foreshadowing the growing body of law in this area, in *Remsburg v. Docusearch, Inc.*,¹⁵⁴ the New Hampshire Supreme Court was faced with a database company that had supplied information to a client that included a woman's personal information. The client used it to confront her and kill her. The New Hampshire Supreme Court held that the company had to act with "reasonable care in

disclosing a third person's personal information to a client." This decision is as yet an unanswered invitation to other courts.

On the federal level, the CFAA, of course, does address "unauthorized" access to computerized information. In addition, Congress has enacted some statutory regulations that specifically address electronic communications and privacy.

11.9.4.1 Wiretap Act and Electronic Communications Privacy Act.

The Omnibus Crime Control and Safe Streets Act of 1968, generally referred to as the Federal Wiretap Act,¹⁵⁵ established the general parameters for permitted interception of communications by law enforcement. As originally crafted, the Wiretap Act covered only "wire and oral communications." In 1986, Congress enacted the Electronic Communications Privacy Act (ECPA),¹⁵⁶ which amended the Wiretap Act and created the Stored Wire and Electronic Communications and Transactional Records Act (Stored Communications Act or SCA) to "update and clarify federal privacy protections and standards in light of changes in computers and telecommunication technologies."¹⁵⁷ The SCA makes it unlawful to knowingly access a prohibited electronic communications service facility without authority, or in excess of authority, and for such public service provider to disclose information contained in such facilities. The ECPA allows a private plaintiff to bring a claim for knowing or intentional violation of the statute to recover actual damages or the statutory minimum of \$1,000.

The 1986 amendment extended the Wiretap Act's coverage to include "electronic communications," which is defined as "any transfer of signs, signals, writing, images, sounds, data, or intelligence of any nature transmitted in whole or in part by a wire, radio, electromagnetic, photo-electronic or photo-optical system."¹⁵⁸ "Intercept" is defined as "the aural or other acquisition of the contents of any wire, electronic, or oral communication through the use of any electronic, mechanical, or other device."¹⁵⁹ Consequently, the Wiretap Act now makes it an offense to "intentionally *intercept* ... any wire, oral, or *electronic communication*."¹⁶⁰ Thus, the definitions in the act now cover Internet transmissions such as emails or file transfers.

There is an important exception to this prohibition. Under the "consent of a party" exception, it is permissible to intercept communications where "one of the parties to the communication has given prior consent to such interception."¹⁶¹ The requisite consent may be express or implied from the surrounding circumstances.¹⁶² Furthermore, an employer may obtain consent by informing the employee of the monitoring practices in an employment contract or in an employee handbook.¹⁶³

Under the "provider exception," a provider of electronic communication services "whose facilities are used in the transmission of a wire or electronic communication, [may] intercept, disclose or use that communication in the normal course of his employment while engaged in any activity which is a necessary incident ... to the protection of the rights or property of the provider of that service."¹⁶⁴ This exception may allow an employer to lawfully intercept communications to detect an employee's unauthorized disclosure of trade secrets to third parties.¹⁶⁵

11.9.4.2 Contemporaneous Transmission Requirement. The Wiretap Act only prohibits *interceptions* of electronic communications,¹⁶⁶ a term that has been more narrowly defined by the courts than the definition in the act might suggest. The definition of interception provides that an individual "intercepts" a wire, oral, or electronic communication "merely by *acquiring* its contents, regardless of when or under what circumstances the acquisition occurs."¹⁶⁷ In the context of this section, a serious question arises about the legality of intercepting electronic communications as they

were being transmitted and once they were stored, either temporarily or permanently. Although Congress intended to liberalize one's ability to monitor "wire communications" while it sought to make the monitoring of "electronic communications" more difficult,¹⁶⁸ courts have held that Congress intended to make acquisitions of electronic communications unlawful under the Wiretap Act "*only if they occur contemporaneously with their transmissions*"¹⁶⁹ and before they actually cross the finish line and become stored.¹⁷⁰ This is, of course, an interesting fiction when applied to Internet transmissions, which consist of packages that are broken up and passed from router to router as well as from temporary storage to temporary storage. It is a far cry from the interception of a telephone call. It may simply be that in applying the language of the statute, the courts are faced with applying it to a technology that was not really in existence when the statute was amended in 1986.

In recent years, the courts have attempted to apply the contemporaneous transmission requirement to various situations. For example, cookies used to recover personal data from visitors to a Web site constitute an interception of a contemporaneous electronic communication and a violation of the Wiretap Act.¹⁷¹ Noting that electronic communications are generally in transit and in storage simultaneously, the court reasoned that users communicated simultaneously with the pharmaceutical client's Web server and with the software company's Web server and, thus, the information was acquired contemporaneously with its transmission.¹⁷²

Where electronic transmissions are found in RAM or on the hard drive, they are stored communications and can be retrieved because they are outside of the Wiretap Act.¹⁷³ Similarly, an email that is recovered after it has been sent and received does not satisfy the contemporaneous transmission requirement and therefore has not been intercepted under the Wiretap Act.¹⁷⁴ Perhaps in response to these and other decisions, in 2001 Congress amended the Wiretap Act to apply the contemporary transmission requirement to wire communications that could not be retrieved, thereby permitting the recovery of stored wire communications.¹⁷⁵

11.9.4.3 Konop v. Hawaiian Airlines, Inc. The *Konop* decision appears to be the most oft-cited case on the issue of "interception" under the Wiretap Act. Konop, the plaintiff, was an airline pilot who created and maintained a Web site where he posted bulletins critical of his employer, Hawaiian Airlines, Inc., and the airline union. Konop controlled access to his Web site by requiring visitors to log in with a user name and password and by creating a list of authorized users.

An officer of Hawaiian Airlines asked one such authorized user for permission to use his name to access the Web site. The officer logged on several times, and another officer, using the same technique, also logged on to view the information posted on Konop's bulletin. Konop eventually filed suit against Hawaiian Airlines, alleging that it violated the Wiretap Act when its officer gained unauthorized access to Konop's Web site.

The court first reiterated that the act only prohibits *interceptions* of electronic communications.¹⁷⁶ "Interception," the court held, requires that the party acquire the information contemporaneous with its transmission, and not while it is in electronic storage. In this case, the court concluded that the employer did not violate the Wiretap Act because the officers accessed an electronic communication located on an idle Web site, which did not satisfy the contemporaneous transmission requirement.¹⁷⁷

11.9.5 Stored Communications Act. Unlike the Wiretap Act, the Stored Communications Act (SCA),¹⁷⁸ as its name suggests, establishes the limitations of access to stored communications (i.e., communications accessed *after* their

transmission).¹⁷⁹ Specifically, the SCA makes it unlawful to “intentionally [access] without authorization a facility through which an electronic communication service is provided ... and thereby [obtain], [alter], or [prevent], authorized access to a wire or electronic communication while it is in electronic storage.”¹⁸⁰ The SCA defines “electronic storage” as “(A) any temporary, intermediate storage of a wire or electronic communication incidental to the electronic transmission thereof; and (B) any storage of such communication by an electronic communication service provider for purposes of backup protection of such communication.”¹⁸¹ The SCA exempts from liability conduct “authorized ... by the person or entity providing a wire or electronic communications service”¹⁸² or “by a user of that service with respect to a communication of or intended for that user.”¹⁸³

11.9.5.1 Electronic Storage: Backup Files. The essential element that separates the SCA from the Wiretap Act is that the accessed communications reside in electronic storage. Therefore, the first question is what constitutes electronic storage. In *Theofel v. Farey-Jones*,¹⁸⁴ the United States Court of Appeals for the Ninth Circuit attempted to answer this question.

In *Theofel*, overzealous lawyers for Farey-Jones secured, through a subpoena issued to an ISP, emails sent and received by their opponents in the lawsuit, a company called Integrated Capital Associates (ICA). The subpoena requested from the ISP virtually every email ever sent or received by ICA and its employees. In response, the ISP posted a smattering of the emails on a Web site accessible to Farey-Jones and its lawyers. When ICA learned of these activities, it sued Farey-Jones for, among other things, violation of the SCA.

According to the court in *Theofel*, Congress recognized that users of ISPs have a legitimate interest in protecting the confidentiality of communications in electronic storage at a communications facility. Moreover, this legitimate interest cannot be overcome by fraud or by someone who knowingly exploits a mistake that permits access to what is otherwise protected. The court found that the use of the subpoena to access ICA’s emails when it was reasonably plain, at least to counsel, that the subpoena was invalid, negated any apparent authority that Farey-Jones and its lawyers may have had to view ICA’s emails.

Farey-Jones claimed that the ICA emails were not in “electronic storage” and therefore no violation of the SCA occurred. The court disagreed. As stated earlier, electronic storage exists when messages are stored on a temporary, intermediate basis as part of the process of transmitting the message to the recipient, and when messages are stored as part of a backup process. In this instance, the court found that the emails, which had apparently been delivered to their recipients, were stored by the ISP as part of its backup process for retrieval after initial receipt. Access to those emails was therefore protected by the SCA, which Farey-Jones and its lawyers violated.

11.9.5.2 Electronic Storage: Temporarily Stored Communications. Recent cases interpreting the meaning of “temporary, intermediate storage ... incidental to” transmission of the communication have adhered to the letter of the law more than its spirit. In two cases involving the installation of cookies that were subsequently accessed by software companies for commercial gain, the courts have held that cookies are permanently (or at least indefinitely) installed in the consumer’s hard drive and therefore cannot be considered “temporary, intermediate storage.”¹⁸⁵ The *DoubleClick* decision also emphasized that the “temporary, intermediate storage”

element of the SCA means what it says, that is, the prohibited conduct involves only the unauthorized access to communications while they are being temporarily stored by an intermediate and does not include access to stored messages after they have been received.¹⁸⁶ In the context of an employer's right to examine an employee's emails, the employee will have no claim that an employer has violated the SCA when the employer opens emails sent or received by the employee once the email has been either received or discarded.¹⁸⁷

11.10 OPEN SOURCE. With the continued proliferation of the Internet and computer software, the licensing, distribution, and use of open source code has gained publicity and added importance in the practice of intellectual property and computer security. "Open source" describes the distribution of computer code that is available (i.e., open) to all others and therefore allows computer programmers to read, apply, and modify the code, and also redistribute any changes.¹⁸⁸ The open source movement began with Richard Stallman's development of Gnu's Not UNIX (GNU), a freeware form of UNIX that was meant to be free software (free as in the freedom to use, modify, and distribute the software).¹⁸⁹ GNU's development created the first open source license, the General Public License (GPL). Linux, an open source-based operating system and an alternative to Microsoft Windows, experienced tremendous growth through its use of the GPL.¹⁹⁰ The prevalence of open source issues is evidenced by the 1998 formation of the Open Source Initiative (OSI), which not only promotes open source development and encourages its use by business¹⁹¹ but also offers links to and information about most of the available open source licenses.

11.10.1 Open Source Licenses. The author of an open source code holds a copyright that operates as other copyrights do, but the code is released under a certain license on a nonproprietary basis. There are various types of open source licenses. The first open source license was the GPL, as described. It offers the broadest application of free software. In contrast, other licenses do not seek to perpetuate the free nature of a particular program. According to the Open Source Initiative, there are nearly 60 open source licenses now available for authors of source code,¹⁹² all of which assert certain requirements of the software user.

11.10.2 GPL. Licensing under the GPL is premised on Stallman's idea of "copy-left," which basically uses copyright as a tool to ensure the continued free distribution of source code.¹⁹³ In other words, the GPL affords application, modification, and distribution rights to the copyrighted source code only if the user agrees that the distribution terms remain the same. This creates an endless chain of GPLs attached to future distributions of either the original or derived versions, regardless of their form.¹⁹⁴ This endless chain often is referred to as the GPL's "viral effect," as GPL-protected code multiplies from any modifications of original GPL-protected code.¹⁹⁵ The GPL applies not just to an originally protected software program but also to what it broadly defines as the "Program":

[A]ny such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language.¹⁹⁶

Moreover, although the GPL also states that independent and separate sections of a derivative work are not subject to the GPL's terms when they are distributed as separate

works, the GPL does apply when the user distributes those same independent and separate “sections as part of a whole which is based on the Program. ...”¹⁹⁷ The broad application given to the program under the GPL further enhances the viral effect of the license.

Other provisions of the GPL require users who distribute verbatim copies of the source code to publish copyright notices, disclaim warranties, and provide copies of the GPL. In addition, the modifier/user must attach to any modifications a notice that the software was changed, must distribute or license the software free of charge to third parties, and must provide appropriate copyright notices, warranty disclaimers, and GPL terms and conditions. In sum, the GPL’s sweeping terms not only seek to achieve the free software goals of the FSF but also to impact whether authors chose the GPL, and whether businesses utilize software subject to the GPL.

11.10.3 Other Open Source Licenses. The Berkeley Software Distribution (BSD) License and the Massachusetts Institute of Technology (MIT) License are very similar in that they both require copyright notices, disclaimers of warranties, and liability limitations. The BSD further prohibits contributors or similar organizations from endorsing the program and also requires a copy of the BSD’s terms to be distributed with the software.

11.10.4 Business Policies with Respect to Open Source Licenses. The issue of whether distribution of a proprietary work that incorporates a small portion of GPL-protected code subjects that proprietary work to the terms of the GPL has never been litigated.¹⁹⁸ This is one risk of using open source software. Another risk is that failure to comply with the GPL’s terms could lead to litigation.¹⁹⁹ For instance, MySQL sought to enjoin Progress Software Corporation from distributing MySQL’s Gemini program without a GPL-compliant agreement.²⁰⁰ Because there was a factual dispute as to whether Gemini was a derivative work or an independent work under the GPL, and because Progress stipulated that it disclosed Gemini’s source code and would withdraw the end user license for commercial users, the court did not grant the injunction as to the GPL.²⁰¹

Given the expanding use of open source, businesses need to develop comprehensive policies addressing their use of open source to avoid liability and publicly releasing their own proprietary technology.²⁰² Concerns generally involve license requirements regarding the distribution of the software and its modifications,²⁰³ since those activities usually require the company to release the source code for any distributed modification, and modifications often terminate vendors’ support agreements.²⁰⁴ In addition, distributing unmodified open source as part of a proprietary program may require the company to release its own proprietary open source code.²⁰⁵ It is more likely, however, that the company would be enjoined from distributing the open source or would have to pay damages.²⁰⁶ These considerations should be addressed not only through company policy but also by choosing the best source code to use in programming, given the company’s internal and external needs and the specific licensing requirements of that source code.

11.11 APPLICATION INTERNATIONALLY. Because the laws of the United States are the laws of just one nation among many, the enforcement of U.S. law and the protection of intellectual property rights in large part depend on international treaties. To the extent that the infringing acts or acts of piracy may be deemed to occur in the United States, or the infringers can be found in the United States, then the United States

has sufficient jurisdiction over these acts to enforce its laws. In other words, such actors can be sued directly in the courts of the United States for violation of the laws of the United States.

Apart from direct enforcement, international protection is usually a vehicle of bilateral agreements between the United States and individual countries or a function of international protocols or treaties to which the United States is a signatory. Thus, for example, the Paris Convention for the Protection of Industrial Property²⁰⁷ establishes a system for recognizing priority of invention, but only among member countries. In addition, there is the Patent Cooperation Treaty (PCT), a multilateral treaty with more than 50 signatories. The PCT permits the filing of an international application that simplifies the filing process when a patent is sought in more than one nation. For copyright protection, there is also a series of international treaties and agreements that include the Berne Convention,²⁰⁸ the Universal Copyright Convention, and the World Trade Organization (WTO) Agreement.²⁰⁹ Canada, Mexico, and the United States also signed the North American Free Trade Agreement (NAFTA) in December 1992. NAFTA addresses intellectual property and requires that member states afford the same protections to intellectual property as members of the General Agreement on Tariffs and Trade (GATT). At a minimum, members of GATT must adopt four international conventions, including the Paris Convention and the Berne Convention.

These agreements, conventions, and treaties in large part do not attempt to reconcile the differences in the national laws of intellectual property. The particular national rules and nuances are simply too complicated, and there are too many differences of opinion to expect that these differences could be internally reconciled. Rather, in large measure, these international accords attempt to codify comity between the member nations so that each will recognize the legitimacy of the intellectual property rights in the other.

11.11.1 Agreement on Trade-Related Aspects of Intellectual Property Rights. On December 8, 1994, the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) was signed into law in this country. The signing of TRIPS required changes to be made in United States statutes and regulations to bring them into conformity with international norms. TRIPS, however, was a product of the United States and other industrial countries pressing for stronger, more uniform standards for international treaties concerning intellectual property. The basic structure of TRIPS is to set the minimum standard of protection for intellectual property with each member nation free to adopt more stringent standards. Under the rubric used in the United States, TRIPS applies to copyrights, patents, trademarks, service marks, mask works (integrated circuit designs), and trade secrets. It also covers geographical indications²¹⁰ and industrial designs.²¹¹ Not addressed by TRIPS, although part of the international jargon for intellectual property, are breeder's rights²¹² and utility models.²¹³ Thus, TRIPS establishes no standards as applied to these concepts, leaving each nation to set the parameters of protection unimpeded by TRIPS.

It is not by accident that TRIPS was negotiated within the context of GATT, which had set the international standards for trade tariffs and had provided remedies of trade retaliation if such standards were not adhered to. The structure of GATT provided the means under which developing countries agreed to reduce their trade tariffs in exchange for the right to export innovative products under an exclusive monopoly conveyed by intellectual property rights. The second benefit to the GATT format was to provide a means for trade retaliation if, under the dispute resolution provisions of TRIPS, the WTO determines that there is noncompliance. In reality, it is obvious that TRIPS

benefits those industrial nations that are more likely to be at the forefront of innovation and more concerned with the protection of their citizens' intellectual property.²¹⁴ The major concession wrung by the developing countries under TRIPS was obtaining a period of 4 to 11 years to implement TRIPS and to bring their national laws into conformity.

TRIPS generally reflects the U.S. view that focuses on the economic underpinnings for intellectual property rights as serving the greater societal interests. There is thus a shift from "societal" interests to "enterprise" interests. In particular, TRIPS adopts high minimum standards for patents, which will require significant legislative changes in developing countries. The copyright section, however, affords less protection than may be afforded by European nations, but it is in line with treatment in the United States. In short, TRIPS responds to the concern of enterprises in the United States that too loose a system of international protection has enabled imitation of U.S. innovations through copying and outright piracy.

11.11.2 TRIPS and Trade Secrets. Under its category for "Protection of Undisclosed Information," TRIPS provides protection for the type of information routinely referred to as trade secrets in the United States. Member nations are required to implement laws that safeguard lawfully possessed information from being disclosed to, acquired by, or used by others without consent and contrary to "honest commercial practices" if such information is (a) a secret in that it is not in the public domain, (b) has commercial value because it is a secret, and (c) has been subject to reasonable steps to maintain its secrecy.

Because discussions that led to TRIPS are not institutionally preserved, unlike the United States Congressional Record, there is no negotiating history to be consulted to flesh out the meaning of the spare paragraphs instituting trade secret protection. There do, however, appear to be differences from the total panoply of protections afforded in the United States. The concept of public domain articulated by TRIPS is information that is "not, as a body or in the precise configuration and assembly of its components, generally known among or readily accessible to persons within the circles that normally deal with the kind of information in question." This articulation appears to be addressing technological formulations of information, as opposed to general commercial information, such as financial information, that is generally considered proprietary and confidential in the United States. The focus on a technology formulation for protected information is bolstered by the TRIPS requirement that the information have commercial value. Thus, other types of information that are not part of a traded article may be deemed to have no commercial value and therefore to fall outside of the scope of protection. Depending on the particular jurisdiction in the United States, there is a distinction between confidential information and trade secrets based on the requirement that a trade secret must have commercial value. This, in turn, has been held to mean that information that is not exploited commercially is unprotectable under the law of trade secret. For example, the results of failed experiments that never resulted in a commercial product lack commercial value, even though such experiments are certainly helpful in the next round of exploration, in that they are signposts of what not to do.

The lesson to be drawn is that one should not assume symmetry of protections just because of the TRIPS provision. Instead, as part of the reasonable steps to maintain secrecy, enterprises need to consider carefully thought out and structured contractual provisions as well as a system of data caching that leaves truly confidential data in the United States, even if access is permitted outside. Improper takings of such data are,

arguably, acts that occur in the United States, and such acts are subject to enforcement and punishment under the laws of the United States.

11.11.3 TRIPS and Copyright. TRIPS embraces the U.S. general model for copyright protection in its opening statement that “[c]opyright protection shall extend to expressions and not to ideas, procedures, methods of operation or mathematical concepts as such.” All member nations agree that, as to the protection of copyrights, the Berne Convention will apply. Under the Berne Convention, the duration of a copyright is the life of the author plus 50 years. If the life of a natural person is not involved, then it is ordinarily 50 years from publication. In addition, computer programs, whether in source or object code, are to be protected as literary works under the Berne Convention. TRIPS also recognizes that compilations of data can be protected as creative works. Article 10, ¶ 2 explicitly provides:

Compilations of data or other material, whether in machine readable or other form, which by reason of the *selection* or *arrangement* of their contents constitute *intellectual creations* shall be protected as such. Such protection, which shall not extend to the data or material itself, shall be without prejudice to any copyright subsisting in the data or material itself. (Emphasis added.)

TRIPS, therefore, does establish some minimum standard in the growing debate over what protections will be afforded a database. In the United States, the clear demarcation point for unprotected information is compilations that represent no more than “sweat-of-the-brow” efforts. Such compilations cannot be copyrighted.²¹⁵ The classic example of a sweat-of-the-brow effort is the copying and alphabetical organizing of names, addresses, and telephone numbers that are in telephone books. In the United States, the key for copyright protection is the creator’s original contribution of selection and arrangement. Thus, arguably, the TRIPS provision mimics the law of the United States.

The European Union (EU) has taken a more protective path. In its 1996 European DataBase Directive, the EU granted databases *sui generis* protection as their own unique form of intellectual property. Under the EU Directive, a database is “a collection of independent works, data or other materials arranged in a systematic or methodical way and individually accessible by electronic or other means.” A database may be protected either because it represents a work of “intellectual creation” or because it was compiled through “substantial investment.” The EU Directive protects such databases from unauthorized extraction or use for a period of 15 years, with the ability to extend the period for an additional 15 years if there was a “substantial new investment” in the database. Such protection extends to databases of EU members and to databases of nationals of other countries that offer protections similar to the EU.

The United States, despite a number of legislative proposals, has not adopted a concomitant rule. The result, at least for multinationals, is that entities that rely on databases should consider “locating” such databases within an EU member to take advantage of the EU’s database protections.

11.11.4 TRIPS and Patents. TRIPS requires that all members recognize the right to patent products or processes in all fields of technology. A patentable invention must be new, inventive, and have an industrial application. The patent application must fully and clearly disclose the invention so that a person skilled in the art could carry out the invention. The best mode for carrying out the invention as of the filing date must also be disclosed. Patent rights are to be enforced without discrimination as to

place of invention or whether the product is imported or produced locally. The patent of a product conveys the exclusive right to prevent, without consent of the inventor, the making, using, offering for sale, selling, or importing of the product. The patent of a process conveys the exclusive right to prevent all of the above for products that result from the process as well as the use of the process itself. The holder of a patent also has the rights to assign, transfer, or license the patent. The minimum period for a protecting a patent is 20 years from filing.

TRIPS gives each member state the right to carve out from patentability certain subject matters that have as their purpose the protection of human, animal, or plant life, or to avoid serious prejudice to the environment. In addition, TRIPS permits a member state to allow other use without authorization from the patent holder. The section defining when such use is permissible is the most detailed section among the patent provisions of TRIPS. In general, it permits such use only (a) after an effort to obtain a license from the patent holder on reasonable commercial terms and conditions, (b) with adequate remuneration to the patent holder, (c) if such use is limited predominantly to the domestic market of the member nation, and (d) if there is a review of the decision to permit, as well as the compensation, by a “higher authority in that Member.”

One of the circumstances envisioned by TRIPS is the grant of a second patent that cannot be exploited without infringing an earlier (first) patent. In such cases, a member nation may grant authority if the invention embodied in the second patent represents an “important technical advance of considerable economic significance” with respect to the first patent’s invention and a cross-license on reasonable terms is granted to the holder of the first patent to use the second patent. For process patents, TRIPS creates a limited burden on the alleged infringer to prove that the identical product was produced using a different process. In particular, a member state can create a presumption that the process patent was violated in circumstances where the product is new, or where the patent holder is unable to demonstrate what process was actually used.

11.11.5 TRIPS and Anticompetitive Restrictions. TRIPS acknowledges that some licensing practices or other conditions with respect to intellectual property rights may restrain competition, adversely affect trade, and impede the transfer and dissemination of technology. Accordingly, TRIPS permits member nations to specify practices that constitute an abuse of intellectual property rights and to adopt measures to control or limit such practices, so long as the regulation is consistent with other provisions of TRIPS. In the event that a national of a member nation violates another member’s laws and regulations regarding anticompetitive activity, TRIPS provides for the right of the involved nations to exchange information confidentially regarding the nationals and their activities.

11.11.6 Remedies and Enforcement Mechanisms. Each member nation is expected to provide an enforcement mechanism under its national laws to permit effective action against any act of infringement. Such procedures are to include remedies to prevent acts of infringement as well as to deter future acts. TRIPS imposes the obligation that all such procedures be “fair and equitable” and not be “unnecessarily complicated or costly” or involve “unwarranted delays.”²¹⁶ In general, these remedies mean access to civil judicial procedures with evidentiary standards that shift the burden of going forward to the claimed infringer, once the rights holder has presented reasonably available evidence to support its claim. Damages may be awarded sufficient to compensate the rights holder for the infringement if the “infringer knew or had reasonable grounds to know that he was engaging in infringing activity.” This means

that vigilance and notice are essential to have meaningful protection for intellectual property rights, since notice is the best means for setting up a damage claim. TRIPS permits its members to allow the recovery of lost profits or predetermined (statutory) damages even when the infringer did not know that it was engaged in infringing behavior. Although injunctive relief is to be provided for, remedies may be limited in circumstances involving patent holders, as discussed, where adequate compensation is paid, and the alleged infringer has otherwise complied with the provisions of its national law permitting such use upon payment of reasonable compensation. In order to deter further infringement, infringing materials may be ordered destroyed or noncommercially disposed of.

In addition to civil remedies, TRIPS requires criminal penalties in cases of “willful trademark counterfeiting or copyright piracy on a commercial scale.”²¹⁷

11.12 RECENT DEVELOPMENTS IN INTELLECTUAL PROPERTY LAW²¹⁸

11.12.1 AIA. Peter E. Heuser of Schwabe, Williamson, & Wyatt summarized the Leahy-Smith America Invents Act (AIA) of 2011²¹⁹ as follows: “The AIA is the most important legislative patent reform in over 50 years. The AIA will change how patents are granted, how patent litigation will proceed and what kinds of inventions are eligible for patents, among other things.”²²⁰ The author summarized the main features of the AIA in detailed discussions of the following areas:

- First-to-file will now establish priority of invention
- Prior commercial user defense is established
- New post-grant proceedings for patent validity challenges
- The Patent and Trademark Office (PTO) will no longer grant patents on tax strategy
- Special transitional review for certain patents related to financial products and services
- Most PTO fees will increase by 15 percent
- Limited prioritized examination will be available
- New rules will affect litigation by nonpracticing entities
- False patent marking claims are curbed
- Other provisions will make it more difficult to attack patent validity

Complete information about the legislation is available through the Library of Congress THOMAS database.²²¹

11.12.2 The PROTECT IP Act (PIPA). The PROTECT IP Act (Preventing Real Online Threats to Economic Creativity and Theft of Intellectual Property Act)²²² or PIPA, was introduced in the U.S. Senate in May 2011 but failed to make it to the floor of the Senate.²²³ After extensive public opposition, including a worldwide temporary blackout of thousands of Web sites in protest of PIPA and the Stop Online Piracy Act (SOPA, below),²²⁴ the bill was suspended in January 2012 pending further analysis.²²⁵

PIPA’s main points include the following (quoting several sections from the THOMAS database):

- Preventing Real Online Threats to Economic Creativity and Theft of Intellectual Property Act of 2011 or the PROTECT IP Act of 2011—(Sec. 3) Authorizes the Attorney General (AG) to commence: (1) an in personam action against a registrant of a nondomestic domain name (NDN) used by an Internet site dedicated to infringing activities (ISDIA) or an owner or operator of an ISDIA accessed through an NDN; or (2) if such individuals are unable to be found by the AG or have no address within a U.S. judicial district, an in rem action (against a domain name itself, in lieu of such individuals) against the NDN used by an ISDIA.
- Defines ISDIA as a site that: (1) has no significant use other than engaging in or facilitating copyright infringement, circumventing technology controlling access to copyrighted works, or selling or promoting counterfeit goods or services; or (2) is designed, operated, or marketed and used to engage in such activities.
- Defines NDN as a domain name for which the registry that issued the domain name and operates the relevant top level domain, and the registrar for the domain name, are located outside the United States.
- Allows the court, upon application by the AG after an NDN-related in personam or in rem action is commenced under this section, to issue a temporary restraining order or an injunction against the NDN, registrant, owner, or operator to cease and desist further ISDIA activity if the NDN is used within the United States to access an ISDIA directing business to U.S. residents and harming U.S. intellectual property right holders.
- Directs the AG to identify and provide advance notice to operators of nonauthoritative domain name system servers (NDNSSs), financial transaction providers (FTPs), Internet advertising services (IASs), and providers of information location tools (ILTs), including search engines, online directories, and other indexes with hypertext links or referrals to online locations, whose action may be required to prevent such NDN-related ISDIA activity.
- Sets forth the preventative measures required to be taken by NDNSSs, FTPs, IASs, and ILTs upon being served with a court order in such an NDN-related action commenced by the AG.
- (Sec. 4) Authorizes the AG or an intellectual property right owner harmed by an ISDIA to commence: (1) an in personam action against a registrant of an ISDIA's domain name or an owner or operator of an ISDIA accessed through a domain name; or (2) if such individuals are unable to be found or have no address within a U.S. judicial district, an in rem action against a domain name used by an ISDIA.
- Allows the court, upon application by the relevant plaintiff after an in personam or in rem action concerning a domain name is commenced under this section, to issue a temporary restraining order or injunction against a domain name, registrant, owner, or operator to cease and desist further ISDIA activity if the domain name is: (1) registered or assigned by a domain name registrar or registry located or doing business in the United States, or (2) used within the United States to access an ISDIA directing business to U.S. residents and harming U.S. intellectual property right holders.
- Directs the relevant plaintiff to identify and provide advance notice to FTPs and IASs whose action may be required to prevent such ISDIA activity.

- Requires, upon being served with a court order after such an in personam or in rem action concerning a domain name is commenced by the AG or a private right owner under this section: (1) FTPs to take reasonable specified preventative measures, and (2) IASs to take technically feasible and reasonable measures.
- Sets forth provisions regarding the entities that may be required to take certain preventative measures in actions concerning both domain names and NDNs: (1) granting immunity to such entities for actions complying with a court order, (2) authorizing the relevant plaintiff to bring an action for injunction relief against a served entity that knowingly and willfully fails to comply with a court order, and (3) permitting such entities to intervene in commenced actions and request modifications, suspensions, or terminations of related court orders.
- (Sec. 5) Provides immunity from liability for: (1) FTPs or IASs that, in good faith, voluntarily take certain preventative actions against ISDIAs, and (2) domain name registries and registrars, FTPs, ILTs, or IASs that, in good faith, withhold services from infringing sites that endanger public health by distributing prescription medication that is counterfeit, adulterated, misbranded, or without a valid prescription. ...

11.12.3 The Stop Online Piracy Act (SOPA). The Stop Online Piracy Act (SOPA), H.R. 3261,²²⁶ is summarized in the THOMAS database as follows:

- ... Authorizes the Attorney General (AG) to seek a court order against a U.S.-directed foreign Internet site committing or facilitating online piracy to require the owner, operator, or domain name registrant, or the site or domain name itself if such persons are unable to be found, to cease and desist further activities constituting specified intellectual property offenses under the federal criminal code including criminal copyright infringement, unauthorized fixation and trafficking of sound recordings or videos of live musical performances, the recording of exhibited motion pictures, or trafficking in counterfeit labels, goods, or services.
- Sets forth an additional two-step process that allows an intellectual property right holder harmed by a U.S.-directed site dedicated to infringement, or a site promoted or used for infringement under certain circumstances, to first provide a written notification identifying the site to related payment network providers and Internet advertising services requiring such entities to forward the notification and suspend their services to such an identified site unless the site's owner, operator, or domain name registrant, upon receiving the forwarded notification, provides a counter notification explaining that it is not dedicated to engaging in specified violations. Authorizes the right holder to then commence an action for limited injunctive relief against the owner, operator, or domain name registrant, or against the site or domain name itself if such persons are unable to be found, if: (1) such a counter notification is provided (and, if it is a foreign site, includes consent to U.S. jurisdiction to adjudicate whether the site is dedicated to such violations), or (2) a payment network provider or Internet advertising service fails to suspend its services in the absence of such a counter notification.
- Requires online service providers, Internet search engines, payment network providers, and Internet advertising services, upon receiving a copy of a court order relating to an AG action, to carry out certain preventative measures including withholding services from an infringing site or preventing users located in

the United States from accessing the infringing site. Requires payment network providers and Internet advertising services, upon receiving a copy of such an order relating to a right holder's action, to carry out similar preventative measures.

- Provides immunity from liability for service providers, payment network providers, Internet advertising services, advertisers, Internet search engines, domain name registries, or domain name registrars that take actions required by this Act or otherwise voluntarily block access to or end financial affiliation with such sites.
- Permits such entities to stop or refuse services to certain sites that endanger public health by distributing prescription medication that is adulterated, misbranded, or without a valid prescription.
- Expands the offense of criminal copyright infringement to include public performances of: (1) copyrighted work by digital transmission, and (2) work intended for commercial dissemination by making it available on a computer network. Expands the criminal offenses of trafficking in inherently dangerous goods or services to include: (1) counterfeit drugs; and (2) goods or services falsely identified as meeting military standards or intended for use in a national security, law enforcement, or critical infrastructure application.
- Increases the penalties for: (1) specified trade secret offenses intended to benefit a foreign government, instrumentality, or agent; and (2) various other intellectual property offenses as amended by this Act.
- Directs the U.S. Sentencing Commission to review, and if appropriate, amend related Federal Sentencing Guidelines.
- Requires the Secretary of State and Secretary of Commerce to appoint at least one intellectual property attaché to be assigned to the U.S. embassy or diplomatic mission in a country in each geographic region covered by a Department of State regional bureau.

Critics of the legislation include the American Civil Liberties Association, some educators, some law professors, and the United States Student Association.²²⁷ Arguments included the following:

- The bill would lead to removal of much noninfringing content from the Web, resulting in infringement of free speech.
- Eliminating the focus articulated in PIPA about concentrating on sites dedicated to infringing activity would waste government resources on an enormous range of sites.
- ISPs, search engine providers, payment network providers, and advertising services would all have to obey the Attorney General's orders to block all access to sites with infringing content, thus blocking access to all the sites' noninfringing content as well.
- Educational uses could be severely constrained if a single infringing document led to the shutdown of an entire site.
- Sites with a single link to infringing content could be classified as "facilitating" infringement and thus be shut down.

- The bill would violate standards of due process by allowing administrative shut-down without providing an opportunity for the owners of the accused sites a chance to defend themselves.
- SOPA's potential barriers to access could severely affect the worldwide movement to pressure dictatorial regimes such as that of the People's Republic of China in their consistent suppression of free access to information.
- Librarians, educators, and students could be subject to administrative shutdown even for what could be justified as fair use of copyright materials.

The proposed bill was dropped at the same time as PIPA (above).

11.12.4 Patent Trolls. Groups aggressively targeting users of little-known patents, often purchased from inventors who have never exercised their rights before, are known as *nonpracticing entities* or *patent trolls*. Some of these companies devote their entire business to suing or threatening to sue on the basis of their acquired patents.²²⁸

In one notorious case, a company bought

...the Canadian patent known as "Automatic Information, Goods, and Services Dispensing System (Canada '216)" whose complete text is available at http://patents1.ic.gc.ca/details?patent_number=1236216&language=EN.CA [and] specifically addresses "a system for automatically dispensing information, goods and services to a customer on a self-service basis including a central data processing centre in which information on services offered by various institutions in a particular industry is stored. One or more self-service information and sales terminals are remotely linked to the central data processing centre and are programmed to gather information from prospective customers on goods and services desired, to transmit to customers information on the desired goods or services from the central data processing centre, to take orders for goods or services from customers and transmit them for processing to the central data processing centre, to accept payment, and to deliver goods or services in the form of documents to the customer when orders are completed. The central data processing centre is also remotely linked to terminals of the various institutions serviced by the system, so that each institution can be kept up-to-date on completed sales of services offered by that institution." [Note that Canadian spelling is used above.] Think about this patent. Does it not remind you unavoidably of what you did the last time you ordered a book or bought something online? Or performed any other commercial transaction on the Web?²²⁹

A study published by the Boston University School of Law²³⁰ found that patent trolls "... cost U.S. software and hardware companies US\$29 billion in 2011. ..."²³¹

In the House of Representatives, Peter DeFazio (D-OR) introduced HR.6245, Saving High-Tech Innovators from Egregious Legal Disputes Act of 2012, in August 2012.²³² It would "[Amend] federal patent law to allow a court, upon finding that a party does not have a reasonable likelihood of succeeding in an action disputing the validity or alleging infringement of a computer hardware or software patent, to award the recovery of full litigation costs to the prevailing party, including reasonable attorney's fees. ...". At the time of writing (May 2013), the bill was still in the hands of the Subcommittee on Intellectual Property, Competition and the Internet of the House Committee on the Judiciary.

In May 2013, Senator Charles Schumer (D-NY) introduced S.866, the Patent Quality Improvement Act, an amendment to the AIA to extend its provisions for challenging patents on business methods.²³³

The Library of Congress THOMAS database describes the substance of the proposal as follows:

11 · 44 FUNDAMENTALS OF INTELLECTUAL PROPERTY LAW

- Amends the Leahy-Smith America Invents Act to remove the eight-year sunset provision with respect to the transitional post-grant review program available to review the validity of covered business method patents, thereby making the program permanent.
- Expands the term “covered business method patent” to include a patent that claims a method or corresponding apparatus for performing data processing or other operations used in the practice, administration, or management of any enterprise, product, or service, except technological inventions. (Current law limits the program to financial products or services.)²³⁴

11.13 CONCLUDING REMARKS. Data security ultimately involves the protection of proprietary or personal data and intellectual property. The competition to acquire and retain intellectual property legally is invariably met by unethical and illegal efforts to deprive legitimate owners of their rights. It is necessary, therefore, to be fully aware of the mechanisms and procedures required to protect these rights as part of any computer security program.

This chapter has attempted to delineate the most important aspects of the problem. However, many facets of the legal questions remain unanswered or have been answered generally rather than in the context of a particular problem. Prudent guardians of intellectual property should monitor relevant judicial determinations continuously and be certain to integrate them into a planned approach to protect these most valuable assets.

11.15 NOTES

1. For the uninitiated, a tort is a civil wrong (i.e., an act or failure to act that violates common law rules of civil society, and is distinguished from criminal wrongdoing).
2. See *ProCD, Inc. v. Zeidenberg*, 86 F.3d 1447 (7th Cir. 1996) (product could be returned if shrink-wrap terms were unacceptable).

8. It is easy to confuse the notion of common law trade secret law with protection of confidential information. There is a distinction, however. At its core, trade secret law requires commercial application and utility, which is not true of confidential information that is generally protected as a matter of contract. For example, a failed experiment has no commercial utility and is not generally considered a trade secret, although it easily could be deemed confidential information.
9. The need to protect the information from general dissemination is what, in part, has given rise to the practice of Non Disclosure Agreements.

That doctrine is now codified as part of the copyright statute in 17 U.S.C. § 107.

63. The theoretical nature of the relationship between actual and statutory damages is illustrated dramatically when the copyright owner demonstrates that the infringement was willful. *See Peer International Corp. v. Luna Records, Inc.*, 887 F. Supp. 560 (S.D. N.Y. 1995), where the music publisher's president willfully infringed licensed and unlicensed works and was assessed \$10,000 for the licensed works, \$15,000 for the unlicensed works, and \$25,000 that the president used in derivative format without permission even though actual damages were \$4,107. Presumably, this resulted from the court's attempt to find a way to punish the infringer since the statute makes no provision for punitive damages.

114. The church raised a question of fact about the impact of the ISP's activity on the church's potential market by asserting that the posting of the church's materials on the bulletin board discouraged active participation by existing and potential congregants. Therefore, the court could not find for the ISP as a matter of law.
115. 373 F.3d 544, 555 (4th Cir. 2004). The court went on to state, however, that an ISP "can become liable indirectly upon a showing of additional involvement sufficient to establish a contributory or vicarious violation of the Act. In that case, the ISP could still look to the DMCA for a safe harbor if it fulfilled the conditions therein."
116. *See, e.g., Playboy Enterprises, Inc. v. Frena*, 839 F. Supp. 1552 (M.D. Fla. 1993). The *Frena* decision, insofar as it holds the bulletin board service provider liable for infringement, has been expressly overruled by Title II of the DMCA. *See* House Rep. 105-551(I), at 11.

The FBI has in its arsenal a program known as Carnivore that essentially tracks a target's online activity. Recently, Freedom of Information inquiries by the Electronic Privacy Information Center (EPIC, www.epic.org) suggests that the FBI has discontinued use of Carnivore because ISPs, in light of the PATRIOT Act, may be providing information regarding a user's internet traffic directly to the government.

207. The Paris Convention was initially concluded in 1883 and updated in 1967. It is administered by the World Intellectual Property Organization, an agency of the United Nations. The Paris Convention has provisions that apply to patents, trademarks, service marks, industrial designs (similar to design patents), and unfair competition. Approximately 174 nations are now signatories to the Paris Convention.
208. Until the adoption of TRIPS, the Berne Convention was the other major international agreement. Like the Paris Convention, it is administered by the World Intellectual Property Organization. The Berne Convention, first adopted in 1886, has undergone a series of revisions. The Convention includes "every production in the literary, scientific and artistic domain whatever may be the mode or form of its expression." Berne Convention, Art. 2, ¶ 1. Essentially, it assures that a work protected within a member state will also be protected outside of the member state without being subject to discriminating formalities. The number of signatories to the Berne Convention is presently 165 nations.

209. The WTO effectively began operating on July 1, 1995, as a result of the 1994 Uruguay Round Agreements. The WTO replaces GATT (General Agreement on Tariffs and Trade), which had been in operation since 1950. Congress ratified the Uruguay Round Agreements in December 1994. The WTO has approximately 132 member nations. In 1995, the WTO and the World Intellectual Property Organization (WIPO) signed a joint agreement that provides, among other things, for cooperation in providing legal technical assistance and technical cooperation related to the TRIPS Agreement for developing country members of either of the two organizations. The WIPO has approximately 171 members and is responsible for international cooperation in promoting intellectual property protection around the world. In particular, it looks after various international conventions, such as the Paris Convention and the Berne Convention.
210. Geographical indications are marks or other expressions that state the country, region, or place in which a product or service originates.
211. Industrial designs protect the aesthetic look of the product and are similar but not identical to the United States notion of trade dress. Products may be afforded protection based on novelty or originality of design, depending on national law.
212. Breeder's rights confer protection on new and different plant varieties.
213. Utility models protect the manner in which a product works or functions and as such are different from industrial design, which protects only the aesthetics of the product. Generally, utility models address mechanical functioning, which in the United States is not protectable unless patentable. Thus, the innovation in the United States must be significant to warrant protection.
214. Until 1989, the developing countries largely refused to negotiate standards. Threats by the United States of trade sanctions under the United States Trade Act played a significant role in altering the positions of economically weaker developing countries. In particular, China, India, Taiwan, and Thailand were all investigated.

INTRODUCTION TO PART II

THREATS AND VULNERABILITIES

What are the practical, technical problems faced by security practitioners? Readers are introduced to what is known about the psychological profiles of computer criminals and employees who commit insider crime. The focus is then widened to look at national security issues involving information assurance—critical infrastructure protection in particular. After a systematic review of how criminals penetrate security perimeters—essential for developing proper defensive mechanisms—readers can study a variety of programmatic attacks (widely used by criminals) and methods of deception, such as social engineering. The section ends with a review of widespread problems such as spam, phishing, Trojans, Web server security problems, and physical facility vulnerabilities (an important concern for security specialists, but one that is often overlooked by computer-oriented personnel).

The chapter titles and topics in Part II include:

- 12. The Psychology of Computer Criminals.** Psychological insights into motivations and behavioral disorders of criminal hackers and virus writers
- 13. The Insider Threat.** Identifying potential risks among employees and other authorized personnel
- 14. Information Warfare.** Cyberconflict and protection of national infrastructures in the face of a rising tide of state-sponsored and non-state-actor industrial espionage and sabotage
- 15. Penetrating Computer Systems and Networks.** Widely used penetration techniques for breaching security perimeters
- 16. Malicious Code.** Dangerous computer programs, including viruses and worms, increasingly used to create botnets of infected computers for spreading spam and causing denial of service
- 17. Mobile Code.** Analysis of applets, controls, scripts, and other small programs, including those written in ActiveX, Java, and Javascript
- 18. Denial-of-Service Attacks.** Resource saturation and outright sabotage that brings down availability of systems and that can be used as threats in extortion rackets by organized crime

II · 2 THREATS AND VULNERABILITIES

- 19. Social-Engineering and Low-Tech Attacks.** Lying, cheating, impersonation, intimidation—and countermeasures to strengthen organizations against such attacks, which have increased drastically in recent years
- 20. Spam, Phishing, and Trojans: Attacks Meant to Fool.** Fighting spam, phishing, and Trojans—trickery that puts uninformed victims at serious risk of fraud such as identity theft
- 21. Web-Based Vulnerabilities.** Web servers, and how to strengthen their defenses
- 22. Physical Threats to the Information Infrastructure.** Attacks against the information infrastructure, including buildings and network media

12.1 INTRODUCTION. Symantec's Internet Security Threat Report for 2011 indicated an 81 percent increase in network attacks compared to 2010; this, coupled with a reported 187 million identities that were exposed due to outsider attacks, suggests that the threat of computer crime is growing to unprecedented levels.¹ For the most part, the industry has relied upon legal and technological solutions to reduce the risks to information security. An alternate approach is to target the human element;

12 · 2 THE PSYCHOLOGY OF COMPUTER CRIMINALS

to try to understand the psychological motivations behind those who would exploit these technologies and to design security system accordingly.² The main drawback to this approach is that the information security field has traditionally relied on outdated stereotypes of computer criminals, which have lead to convoluted, overgeneralized, and inaccurate portrayals of these individuals. Contributing to this is the industry's oversimplification of computer crime and its reliance on a generic, all-encompassing view of the computer criminal. The computer underground is a vast and varied landscape that comprises many different subgroups, some of which are infantile and benign, and others that are criminal and destructive. The purpose of this chapter is to identify the various subgroups of computer criminals and to examine their differing motivations from a psychological perspective. Using theoretical perspectives from social, personality, and clinical psychology, we will review current research on the various subsets of computer criminals, ranging from script kiddies to malicious insiders, and provide recommendations for addressing the problem of computer crime at its source.

The National Institute of Justice defines a *computer criminal* as any individual who uses computer or network technology to plan or perpetrate a violation of the law.³ Although the term *computer hacker* is often used interchangeably with computer criminal, they are not synonymous. The term *hacker* was originally used as an umbrella term to refer to a computer programmer who changes or alters code (i.e., hacks) in a unique or unorthodox fashion to solve a problem or to enhance its use. Such interventions may be legal or illegal depending on the circumstances, intent, outcome, or use of the hacked program.

Although a computer criminal, or *cracker*, sometimes also referred to as a *malicious or criminal hacker*, may fall under this broad definition, these individuals typically alter or exploit technology for destructive purposes or financial gain rather than for benign or creative functions. Common examples of computer crimes include Web page defacements, creation and distribution of viruses, unauthorized access of technology, theft of information, distributed denials of service (DDoS), and so on.

In recent years, computer security analysts have reported that many computer criminals are moving away from the hacking-for-fun-and-notoriety mindset to hacking for profit.⁴ More recently, activist groups (*hacktivists*) have used the Internet as a way of spreading their messages of social and political discord by engaging in digital harassment of their targets. According to the 2012 "Verizon Data Breach Report," hacktivist groups represent a significant threat to network security, accounting for the majority of data thefts occurring in 2011.^{5,6}

Computer crime is an obvious financial and societal problem that shows no signs of slowing. Researchers suggest that computer attacks will continue to grow in frequency and sophistication as technology continues to evolve. More specialized threats to social networks, peer-to-peer networks (P2P), handheld mobile devices, and nontraditional hardware systems (e.g., networked gaming consoles and point of sale devices), have been identified in the wild with increasing regularity.⁷ Douglas Campbell, president of the Syneca Research Group Inc., states that "the dominant threat to the United States is not thermonuclear war, but the information war."^{8,9}

One solution that has been offered as an effort to slow this disturbing trend is to examine the motivations of computer criminals from a psychological perspective. Computer-crime researchers suggest that understanding the psychological motivations behind cyber criminals would aid in both cybercrime prevention and protection.^{10,11} Generating a psychological profile of the various subtypes of computer criminals would aid in creating preventive initiatives as well as more effective countermeasures in the fight against computer crime. Since computer crime is not solely a technological

issue but one involving human agents, psychological theories regarding anonymity, aggression, social learning, and individual difference factors may enable us to better understand the behaviors and motivations of the computer criminal.

Information security consultant Donn Parker asserts that the creation of an effective malicious hacker profile still remains an elusive goal in the information security field.¹² Therefore, the goal of this chapter is to survey past and current literature surrounding the psychological motivations of computer criminals. Theories from criminology, as well as social, personality, and clinical psychology, will be presented in an attempt to explain some of the possible motivations behind computer criminals. Based on these psychological research studies, we will conclude by offering recommendations for attenuating computer crime from the perspective of the perpetrator.

12.2 SELF-REPORTED MOTIVATIONS. Perhaps the simplest approach to understanding the mindset of computer criminals is having the perpetrators describe their motivations in their own words. Using various self-reporting measures, including surveys, open-ended questionnaires, and first-person interviews, researchers have consistently found a number of common accounts used by computer criminals to explain and justify their illicit and sometimes harmful behaviors.^{13,14,15,16}

According to sociologist Paul Taylor, computer criminals report that they are motivated by an interacting mix of six primary categories: addiction, curiosity, boredom, power, recognition, and politics.¹⁷ Using a phenomenological-interpretive interview approach that emphasizes the interviewee's perception of reality, sociologist Orly Turgeman-Goldschmidt similarly found that computer criminals reported curiosity, thrill seeking, the need for power, and the ideological opposition to information restrictions among the motivations for their behaviors.¹⁸ Taylor suggests that the extensive use of computers by these criminals may result from a combination of both compulsive behaviors and intellectual curiosity. From an outsider's perspective, an advanced computer user's need to meet the swiftly changing demands of the computer industry may appear to be an indicator of computer abuse, when in actuality the constant use of technology is a consequence of the field. A relentless curiosity and desire for technological improvement is often used by computer criminals as a motivation for their behaviors.¹⁹ Anecdotal evidence has also suggested that the frustrations that result from restrictive computing environments (e.g., network or Internet filters), coupled with a lack of sufficient intellectual stimulation, contribute to some computer criminals' unauthorized access attempts. Some reformed computer criminals have indicated that once they were provided with more liberal access to technology, they were able to focus their skills on practical and legal endeavors rather than illicit undertakings.²⁰

In one of the most ambitious efforts to understand the mindset of criminal hackers, computer security consultant and reformed computer criminal Raoul Chiesa and colleagues created the Hacker's Profiling Project (HPP).²¹ The aim of the HPP was to utilize criminal profiling techniques to develop a comprehensive profile of criminal hackers. Chiesa developed a questionnaire that was judiciously distributed to known criminal hackers and asked questions regarding personal demographics, technological skill, criminal history, and social relationships. The research revealed again that some of the main motivations of criminal hackers are curiosity, proving their self-worth to themselves and others, and feelings of adventure. These relatively benign motivations are also coupled with feelings of anger, frustration, and rebellion against authority. For many of these individuals, the Internet is viewed as the great equalizer. Because of the reduced social context cues that guide face-to-face interactions, Internet users are judged more on their technological skills rather than their social skills, gender, or

12 · 4 THE PSYCHOLOGY OF COMPUTER CRIMINALS

ethnicity. For a more comprehensive look at the results of the HPP, see the recently published book *Profiling Hackers*.²²

Contrary to their stereotypical portrayals in the news media and in fiction, computer criminals appear to have wide-ranging social networks that exist in both their online and offline environments.^{23,24} Taylor indicates that both the need for power and recognition by their peers may be motivating factors for some cybervandals. Computer criminals report feelings of enjoyment and satisfaction when they prove themselves better than system administrators and their peers. Communications researchers Hyung-jin Woo, Yeora Kim, and Joseph Dominick report in their analysis of Webpage defacements that 37 percent of the prank-related defacements contained messages that bragged or taunted the system administrators. Twenty-four percent of these types of defacements contained statements aimed at obtaining peer recognition and 8 percent contained boastful and self-aggrandizing verbiage.²⁵

12.3 PSYCHOLOGICAL PERSPECTIVES ON COMPUTER CRIME. Although self-reporting analyses can give us some insight into the motivations behind computer criminals, these types of descriptive methodologies typically yield incomplete and sometimes inaccurate results. Unless the causes for our behaviors are obvious, our explicit or consciously held explanations for our actions are often misguided. Research has found that our behaviors are frequently controlled by subtle situational variables and implicit attitudes of which we are not typically aware, and may be distinctly different from the conscious mechanisms we use to explain our actions.²⁶ Therefore, our conscious justifications for our actions may be inaccurate if we are unaware of more subtle cognitive processes. The next section examines more empirically based psychological theories of aggression and deviance to gain a further understanding of the factors that may be influencing the behaviors of computer criminals.

12.4 SOCIAL DISTANCE, ANONYMITY, AGGRESSION, AND COMPUTER CRIME. Many acts of computer crime can be categorized as demonstrations of aggressive behaviors. For example, cracking into a company's Web server and defacing a Web page, or launching a DDoS attack on an organization's computer network, thereby crippling its Internet connection, are common malicious and aggressive acts engaged in by computer criminals. Social psychological theories on hostility and violence suggest that people are more likely to commit acts of aggression when the perpetrator of these acts is anonymous and the threat of retaliation is low.²⁷ Since cybervandals frequently use nicknames (*nicks* or *handles*), stolen accounts, and spoofed Internet Protocol (IP) addresses when they engage in illegal activities, their behaviors may be more aggressive than when they are more easily identifiable. Computer criminals are overly confident that their crimes cannot and will not be traced back to their true identities. Computer criminals who deface Web pages are so confident that they are anonymous that they regularly *tag* the hacked Website by leaving their handles and the handles of their friends, and in some cases, even their Internet email addresses and Web page links.²⁸

Due to the relative anonymity of the Internet and the technical abilities of cybercriminals, which enable them to further obfuscate their identities, the resulting emotional distance may be another factor that contributes to increased aggression online. For example, it is an extremely difficult and tedious task to identify computer criminals who launch DDoS attacks against computer networks. The attacker plants denial-of-service (DoS) programs into compromised shell accounts controlled by a master client. The master client will instruct every slave DoS program to *cooperatively* launch an

attack at the victim's host at a configurable time and date. Thus, the DoS attacks are not launched by the criminal's own computer; rather, the attacks come from innocent networks that have been compromised by the cracker. This additional layer makes it all the more difficult for information-security professionals to locate the attack's perpetrator. Much like the Website vandals, DDoS attackers are also confident that the attacks will not be traced back to their actual identities. Frequently, DDoS attackers will even brag on Internet Relay Chat (IRC) channels and Twitter about how many host nodes they have compromised and against which domain they are planning to launch new attacks.²⁹

Situational influences on behaviors and attitudes work on the Internet much as they do in the real world. However, computer criminals who commit aggressive acts against their innocent victims do not see the immediate consequences of their actions. The computer screen and increased social distance that characterize interactions online can act as an electronic buffer between the attacker and victim. Like the participants in psychologist Stanley Milgram's famous obedience experiment, computer criminals are physically and emotionally removed from their victims while they are committing their harmful actions.³⁰ They do not witness firsthand the consequences of their computerized attacks. Automated cracking and DDoS scripts, coupled with the lack of social presence in computer-mediated interactions, may make it easier to attack an entity that is not only emotionally and physically distant, but also depersonalized (e.g., a system administrator working for a large corporation).

Consistent with social psychologist Albert Bandura's theory of moral disengagement, individuals who engage in unscrupulous behaviors will often alter their thinking in order to justify their negative actions.³¹ According to Bandura, most individuals will not commit cruel or illicit behaviors without first engaging in a series of cognitive justification strategies that allow the person to view those actions as moral and just. Immoral behaviors can be justified by comparing them to more egregious acts, minimizing the consequences of the actions, displacing responsibility, and by blaming the victim themselves. Criminologist Marc Rogers posits that computer criminals may rely on a number of these disengagement strategies in an attempt to reduce the dissonance associated with their malicious activities.³²

Studies conducted by sociologists Paul Taylor and Orly Turgeman-Goldschmidt suggest that many computer criminals are, in fact, engaging in forms of moral disengagement.^{33,34} Their interviewees report that computer crime is driven by a search for answers and spurs the development of new technologies. They further indicate that their electronic intrusions cause no real monetary harm or damage to the victims, and that larger corporations that can afford any financial losses that are incurred from their digital transgressions. Web page crackers will often criticize and publicly taunt the system administrators for not properly securing their computers, suggesting that the victims deserved to be attacked.³⁵ Rogers suggests that this victim-blaming strategy is likely the most common form of moral disengagement that is employed by computer criminals.³⁶

A study conducted by information technology researcher Randall Young and colleagues confirmed that computer criminals have a morally distorted view of their deviant activities, enabling them to socially justify their digital exploits.³⁷ Self-identified computer criminals attending a computer conference reported significantly higher levels of moral disengagement than a control group of university students. The self-identified criminals strongly felt that their digital intrusions were actually helpful to the companies that they invaded and that their friends and families would not think negatively of them if they were caught engaging in illegal computer hacking.

12 · 6 THE PSYCHOLOGY OF COMPUTER CRIMINALS

12.4.1 Social Presence and Computer Crime. Social psychologist Sara Kiesler and colleagues found that during face-to-face (FTF) interactions, conversants implicitly attend to social context cues (e.g., facial expressions and intonations) and use them to guide their social behaviors. Since these social context cues are absent or reduced during computer-mediated interactions, digital communication may be more deregulated than FTF discussions.^{38,39} Kiesler and Lee Sproull suggest that the absence of social-context cues in computer-mediated communication hinders the perception of and adaptation to social roles, structures, and norms.⁴⁰ The reduction of social-context cues in computer-mediated communication can lead to deregulated behavior, decreased social inhibitions, and reduced concern with social evaluation. The most common variables examined in their experiments were hostile language in the form of “flaming” (aggressive, rude, and often ad hominem attacks) and post hoc perceptions of group members (i.e., opinions formed after interacting with members). One empirical study found that group members communicating via computer-mediated communication were more hostile toward one another, took longer to reach decisions, and rated group members less favorably than comparable face-to-face groups.⁴¹ Another experiment reported that there were 102 instances of hostile communication during computer-mediated interactions, compared to only 12 instances of hostile commentary during comparable FTF discussions.⁴²

Based on Kiesler’s findings, computer criminals may be engaging in hostile behaviors partly due to this reduction of available context cues. Crackers who harass and victimize system administrators and Internet users may be engaging in these antisocial activities due to the reduced attention to and concern with social evaluations. There are numerous anecdotal accounts of computer criminals “taking over” IRC channels, harassing people online, deleting entire computer systems, and even taunting system administrators whose networks they have compromised.⁴³ Their criminal and aggressive behaviors may be partially attributed to the reduced social context cues in computer-mediated communication and the resulting changes in their psychological states (i.e., deindividuation) while online.

12.4.2 Deindividuation and Computer Crime. Disinhibited behaviors have also been closely linked to the psychological state of deindividuation. Deindividuation is described as a loss of self-awareness that results in irrational, aggressive, antinormative, and antisocial behavior.^{44,45} The deindividuated state traditionally was used to describe the mentality of individuals who comprised large riotous and hostile crowds (e.g., European soccer riots, mob violence, etc.). Social psychologist Phillip Zimbardo suggested that a number of antecedent variables, often characteristic of large crowds, lead to the deindividuated state. The psychosocial factors associated with anonymity, arousal, sensory overload, loss of responsibility, and mind-altering substances may lead to a loss of self-awareness, lessening of internal restraints, and a lack of concern for social or self-evaluation.⁴⁶

The factors associated with deindividuation also appear to be present during some online activities. For instance, Internet users are relatively anonymous and often use handles to further obscure their true identities. Many of the Websites, software programs, and multimedia files that typify the computing experience are sensory arousing and in some cases can be overstimulating. The Internet can be viewed as a large global crowd that individuals become submersed in when they go online. It is possible that the physical and psychological characteristics associated with the Internet that make it so appealing may also lead individuals to engage in antisocial and antinormative behaviors due to psychological feelings of immersion and deindividuation.⁴⁷

Deindividuation is brought about by an individual's loss of self-awareness, and psychological immersion into a crowd due to the aforementioned antecedents.⁴⁸ The aggressive, hostile, and antinormative actions of computer criminals may be linked to the deindividuated state. Zimbardo found that when participants were deindividuated, operationalized by anonymity, darkness, and loud music, they would administer higher levels of electric shocks to subjects, and for longer lengths of time, than individuated participants. Like Zimbardo's participants, computer criminals may be engaging in hostile and aggressive behavior due to deindividuation—that is, as a direct result of anonymity, subjective feelings of immersion, and the arousing nature of computer and Internet use.^{49,50}

12.4.3 Social Identity Theory and Computer Crime. Social psychologists Martin Lea, Tom Postmes, and Russell Spears have recently developed a social identity model of deindividuation effects (SIDE) to explain the influence of deindividuating variables on behaviors and attitudes during computer-mediated communications.^{51,52,53} According to social identity theory, an individual's self-concept resides on a continuum with a stable personal identity at one end and a social identity at the other. Depending on whether the social self, usually in group situations, or individual self is salient, the beliefs, norms, and actions associated with that particular self-concept will have the greatest influence on the individual's actions and attitudes.⁵⁴ When one of our social identities is salient, the norms associated with that group identity tend to guide and direct our behaviors.

According to the SIDE model, the isolation and visual anonymity that characterizes our online environment serves to enhance our social identities. This increase in social identification with a group may polarize our behaviors and attitudes toward the prevailing norms of that collective.^{55,56,57} Contrary to popular media stereotypes, computer criminals appear to have large social networks and frequently form groups and friendships with other like-minded individuals.⁵⁸ The use of handles and pseudonyms by these individuals combined with their physical isolation from each other may increase their aggressive and criminal tendencies depending on the overall norms associated with their online social groups. If the criminal collective values electronic intrusions and defacements more than programming and coding, then these behaviors will be exhibited to a greater extent by members who strongly identify with that group.

According to Henri Tajfel and John Turner's social identity theory (SIT), we tend to identify with ingroups, or those with whom we share common bonds and feelings of unity.⁵⁹ We have a bias toward our own group members and contrast them with outgroups, whom we perceive as different from those in our ingroup. While this ingroup bias or favoritism may benefit and protect our self-concepts, it may cause us to dislike and unfairly treat outgroup members (e.g., network administrators).

Communications researcher Hyung-jin Woo and colleagues used SIT to explain the motivations behind some Web page defacements.⁶⁰ SIT predicts that when groups are in competition for scarce resources, or feel threatened by outgroup members, there is a tendency for groups to respond aggressively toward each other. Ingroup members see improvements in collective self-esteem and enhanced feelings of group unity when they engage in attacks against outgroup members. Based on these predictions, Woo and colleagues hypothesized that computer criminals who are motivated by outgroup threats will express more aggressive and varied communication in Web page defacements than nonthreatened defacers.⁶¹

A content analysis of 462 defaced Web pages indicated that the majority of the defacements (71 percent) were classified as nonmalicious pranks. The most common

12 · 8 THE PSYCHOLOGY OF COMPUTER CRIMINALS

motivations behind these prankster attacks were to beat the system or its administrator, to gain peer recognition, to brag about accomplishments, and for romantic purposes. Twenty-three percent of the defacements were classified as militant attacks. The motivations behind these attacks were to promote groups associated with nationalism, ethnicity, religion, freedom of information, and anti-pornography.⁶² Consistent with the predictions made by SIT, the militant attacks were characterized by significantly more varied content, obscene language, insults, severe threats, and violent images. SIT may be useful in predicting the frequency and severity of attacks by computer criminals. Although only a minority (23 percent) of Web page defacements in this study resulted from intergroup conflict, those attacks *were* more severe in nature.⁶³

12.4.4 Social Learning Theory of Computer Crime. Criminologist Marc Rogers suggests that social learning theory (SLT) may offer some insight into the behavior of computer criminals.⁶⁴ According to psychologist Albert Bandura, individuals learn behaviors by observing the actions of others and their associated consequences.⁶⁵ SLT draws from B. F. Skinner's operant-conditioning model of learning where behaviors are learned or extinguished through schedules of reinforcement and punishment. However, Bandura's theory suggests that social learning occurs when an individual simply observes others' behaviors and reinforcements and forms a cognitive association between the two actions. Once the behavior is acquired, the learned actions are subject to external reinforcement, as in operant conditioning or in self-directed reinforcement.⁶⁶ According to the Social Structure and Social Learning model (SSSL), criminals learn deviant behaviors from their associations and subsequent imitations of deviant peers.⁶⁷ Through these peer associations, individuals learn to rationalize criminal behaviors. As Bandura suggests, if these criminal activities are rewarded (e.g., money, increased status, etc.), then the behavior will be strengthened.

Recently, there has been a growing amount of social and media attention focused on information security and computer criminals. Newspapers, magazines, and electronic news sources have reported thousands of incidents, interviews, and commentary related to computer crime. A number of these articles appear to glamorize hacking and the Internet underground.⁶⁸ The articles compare computer criminals to rock-and-roll superstars, James Bond-like spies, and international freedom fighters. Motion pictures and television shows like *The Matrix Trilogy*, *Mission Impossible*, *Hackers*, *Swordfish*, and *The X-Files* have all bestowed mythical qualities on rebellious computer criminals, while media outlets report computer criminals being recruited for high-paying government and industry jobs.⁶⁹ The media's glorification and glamorization of hacking and computer criminals, teaches some individuals that it pays to commit computer crime—at least, from a social learning perspective.

Many crimes involving computers are difficult to investigate and prosecute. The public learns via the media that computer criminals often are afforded fame and notoriety among their peers, and in the information security field, for their illegal activities. There are very few instances of computer criminals' being convicted and serving jail time as a consequence of their actions; usually the criminals are given light sentences. Their notoriety leads to media interviews, book and movie deals, even consulting and public speaking jobs.⁷⁰ Once an action is learned, SLT states that the behavior will be maintained via self-directed and external reinforcement. If computer criminals are rewarded for their illegal activities via the acquisition of knowledge and their elevated status in the hacker community, and the popular media continues to glamorize and focus on the positive consequences associated with computer crime, then the cost and prevalence of these illicit actions will continue to grow. Lending empirical support

to the social learning model, criminologist Thomas Holt found that the four tenets of the SSSL model reliably predicted cyberdeviance in a college population. Students who associated with cybercriminals, imitated cyberdeviants, held morally ambiguous definitions regarding cybercrime, and had their computer-based deviance reinforced, were more likely to engage in online criminal activities.⁷¹

SLT may offer one explanation for the illegal behaviors of computer criminals, especially the marked increase in recent years.⁷² Instead of focusing on the supposedly positive consequences of computer crime, media outlets should stress the negative repercussions of computer crime for both the victims and the perpetrators. Social learning theorists would suggest modeling *appropriate* use of computers and the immediate negative ramifications of cyberdeviance as one element for fighting computer crime.

12.5 INDIVIDUAL DIFFERENCES AND COMPUTER CRIMINALS. Although situational factors can account for some of the behaviors of some computer criminals, one must not discount the impact of personality factors on their illicit activities. Attitudes and behaviors are often the product of both situational influences and individual personality traits.⁷³ It should be noted that there are few empirical studies that engage in a scientific examination of the personality traits of computer criminals, so without concrete evidence, the anecdotal claims regarding pathological traits of cybercriminals should be interpreted with caution. In addition, simply having traits that are *consistent* with a psychological disorder does not mean that one actually *has* the disorder.

12.5.1 Antisocial and Narcissistic Personalities. According to M. E. Kabay, some computer criminals exhibit insincerity and dishonesty in combination with superficial charm and an enhanced intellect, traits that are consistent with the *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV) criteria for *antisocial personality disorder*.⁷⁴ He also notes that some computer criminals commit their illegal behavior for little or no visible rewards despite the threat of severe punishment.

Another central characteristic of antisocial personality disorder is lack of clear insight by perpetrators regarding their behaviors.⁷⁵ Researchers have noted that computer criminals do not view their criminal actions as harmful or illegal.^{76,77} These criminals sometimes rationalize or externalize their behaviors by blaming the network administrators and software designers for not properly securing their computers and programs.

Computer crime researchers Eric Shaw, Keven Ruby, and Jerrold Post also have suggested that some computer criminals demonstrate personality characteristics consistent with some elements of *narcissistic personality disorder*.^{78,79} According to DSM-IV criteria, narcissistic individuals are attention seekers with an exaggerated sense of entitlement.⁸⁰ Entitlement is described as the belief that one is in some way privileged and owed special treatment or recognition.

Shaw and associates suggest that entitlement is characteristic of many “dangerous insiders,” or information technology specialists who commit electronic crimes against their own organizations.⁸¹ When corporate authority does not recognize the work or achievements of an employee to their satisfaction, the criminal insider seeks revenge via electronic criminal aggressions. Anecdotal evidence suggests that outside network intruders also may demonstrate an exaggerated sense of entitlement, as well as a lack of empathy for their victims, also characteristic of narcissistic personality disorder.

One self-identified computer criminal states, “we rise above the rest, and then pull everyone else up to the same new heights ... We seek to innovate, to invent. We, quite seriously, seek to boldly go where no one has gone before.”⁸² Narcissistic individuals

12 · 10 THE PSYCHOLOGY OF COMPUTER CRIMINALS

also frequently engage in rationalization to justify and defend their behaviors.⁸³ Computer criminal Toxic Shock writes, “We are misunderstood by the majority. We are misunderstood, misinterpreted, misrepresented. All because we simply want to learn. We simply want to increase the flow of knowledge, so that everyone can learn and benefit.”⁸⁴ Although it would be a mistake to generalize these hypotheses to the entire population without any empirical support, certain subsets of computer criminals may demonstrate characteristics that are consistent with aspects of both narcissistic and antisocial personality disorders.

12.5.2 Five-Factor Model of Personality and Computer Criminals. In one of the rare empirical studies looking at computer criminals, criminologist Marc Rogers examined the relationship between the five-factor model of personality and self-reported “criminal computer activity.”⁸⁵ The five-factor model formulated by psychologists Robert McCrae and Paul Costa in 1990 suggests that an individual’s personality can be accurately described using five core dimensions: extraversion (e.g., sociable), neuroticism (e.g., anxious), agreeableness (e.g., cooperative), conscientiousness (e.g., ethical), and openness to experience (e.g., nonconforming).⁸⁶

Rogers hypothesized that individuals engaging in computer crime would demonstrate higher levels of:

- exploitation,
- hedonistic morality,
- manipulation,
- antagonism,
- undirected behaviors,
- introversion,
- openness to experiences, and
- neuroticism

than noncriminals would. Three hundred eighty-one psychology students from an introductory psychology class were administered the computer-crime index (CCI), which is a self-report measure of computer-crime activity, along with measures of exploitation, manipulation, moral decision making, and a five-factor personality inventory. Contrary to the researcher’s expectations, individuals who committed computer crimes did not significantly differ from the nonoffenders on any of the five-factor personality measures. However, students who reported engaging in illegal computer activities did demonstrate more exploitive and manipulative tendencies.⁸⁷

In contrast, in a follow-up study Rogers did find that extraversion was a reliable predictor of computer crime behavior. The less extraverted an individual (i.e., more introverted), the more likely they were to engage in illicit computing activities. He suggests that the differences in populations between the two samples, the latter being a Canadian liberal arts college and the former being U.S. students from a technology program, may have contributed to the discrepant findings.⁸⁸ It is clear that further research will need to be conducted in this area in order to clear up the discrepant findings. One possible limitation in both of these studies is that the questionnaires were administered using a pencil-and-paper format, which assesses attitudes and traits when the participants’ *offline* identities are salient.⁸⁹ Internet researchers have long suggested that there is a distinct difference between our online and offline identities.⁹⁰ Therefore,

had the participants been administered measures in an electronic format, when their online identities were more salient, Rogers might have found differing results

12.5.3 Asperger Syndrome and Computer Criminals. Recently researchers have suggested a possible link between criminal hacking and a relatively new developmental disorder named *Asperger syndrome* (AS).^{91,92,93} AS is a disorder that resides at the mild end of the pervasive developmental disorder (PDD) spectrum, with classic autism at the more severe end. PDDs are characterized by primary developmental impairments in language and communication, social relations and skills, as well as repetitive and intense interests or behaviors.⁹⁴ Unlike autism, individuals who are diagnosed with AS have higher cognitive abilities and IQ scores ranging from normal to superior. Individuals with AS also have normal language and verbal skills, although there are noticeable deficits in social communication. Those diagnosed with AS typically have severe and systematic social skill impairment or underdevelopment, difficulties with interpersonal communication, and repetitive patterns of interests, behaviors, and activities.⁹⁵

According to clinical psychologist Kenneth Gergen, AS individuals must demonstrate social impairment. They may have a lack of desire or inability to interact with peers, and may engage in inappropriate or awkward social responses.⁹⁶ These individuals may have extremely limited or focused interests, and are prone to engage in repetitive routines. Although language development is often normal, these individuals may demonstrate unusual speech patterns (e.g., rate, volume, and intonation). Individuals with AS also may demonstrate clumsy motor behaviors and body language, as well as inappropriate facial expressions and gazing.⁹⁷

One of the noted features of AS that is anecdotally linked to computer criminals is the obsessive or extremely focused area of intellectual interest that the individuals demonstrate. Children with AS often show a preoccupation in areas such as math, science, technology, and machinery. They strive to learn and assimilate as much information as possible about their specialized interest. Researchers have indicated that their preoccupation may last well into adulthood, leading to careers associated with their intellectual interests.⁹⁸ Much of their social communication is egocentric, revolving around their obsessive interests, often leading to strained and difficult social interactions. Although children with AS desire normal peer interaction, their egocentric preoccupations, lack of appropriate social behaviors, and difficulties empathizing with others often leave them frustrated, misunderstood, teased, and sometimes ostracized.⁹⁹

Researchers have noticed similarities in the characteristics associated with AS and traits stereotypically associated with computer hackers.¹⁰⁰ Tony Atwood, an Australian clinical psychologist, suggests that some computer hackers may have a number of characteristics that are associated with AS.¹⁰¹ He notes that many diagnosed AS patients are more proficient at computer programming languages than social language, and that the intellectual challenges that are presented by restricted computers and networks may override the illegal nature of their actions. AS has been used as a successful defense in at least one landmark U.K. court case.¹⁰²

Based on over 200 personal interviews with computer criminals, cybercrime expert Donn Parker reports finding significant similarities between AS sufferers and criminal hackers. Many of the computer criminals that Parker interviewed demonstrated the social awkwardness, atypical prosody, and lack of social empathy during social interactions that are characteristic of AS.¹⁰³ Anecdotal evidence suggests that computer hackers often have an obsessive interest in technology and computers, similar to that seen in individuals with AS, that forms a salient component of both their individual

12 · 12 THE PSYCHOLOGY OF COMPUTER CRIMINALS

and social identities. Due to their egocentric preoccupations, many computer hackers often feel misunderstood and frustrated in face-to-face social situations.

Although the Autism Diagnostic Interview is the most common assessment tool, a number of self-report instruments have been developed to assist in screening disorders on the autism spectrum. To date, sociologist Bernadette Schell has conducted the only empirical study examining Asperger syndrome in a self-identified hacker population.¹⁰⁴ Schell administered the 50-item Autism-Spectrum Quotient (AQ) Inventory to 136 attendees at various well-known hacker conferences (e.g., Defcon¹⁰⁵) between 2005 and 2007. Previous research using the AQ found that diagnosed AS individuals' mean scores were 35.8 compared to a mean score of 16.4 for a control population. Schell found that the mean score for conference attendees in her study was 19.7. However, 11 percent of males in her sample and 1.5 percent of females had mean AQ scores of 32 or higher. Although this study is limited by due to participants' self-identification as hackers, it does suggest that proposed link between hacker culture and AS may be tenuous at best.¹⁰⁶

To date there has been no clear empirical evidence to suggest a link between AS and computer crime. There is no evidence whatsoever to suggest that Asperger syndrome causes computer hacking. In fact, most sufferers of AS have been characterized as being extremely honest and lawful citizens.¹⁰⁷ It would be a mistake to assume that all computer hackers are suffering from AS or that every AS sufferer is a computer hacker. Characteristics of AS appear more common in computer *hackers* (i.e., those who explore and tinker with computers and technology), rather than in *crackers* who break into computers or use them for illegal activities. At present, there is still no single all-encompassing personality profile that applies to all computer criminals. In fact, many feel that it is inappropriate to try to create a single personality profile that applies to all computer criminals.

12.5.4 Internet Abuse and Computer Crime. Although *technological addiction* is not a disorder recognized by the American Psychological Association (APA), researchers have suggested that some individuals appear to demonstrate disturbed computer use that is similar to other recognized disorders like compulsive gambling or impulse control disorders. Technological addiction is characterized by:

- Excessive use of a particular technology (usually in reference to computers and Internet usage)
- Preoccupation with the technology
- Systematic increase in use
- Failed attempts to curb one's use
- Feelings of malaise and irritation when not using the technology
- Interference with social and professional pursuits due to excessive technology use¹⁰⁸

Information security researchers Kent Anderson and Jerrold Post suggest that some computer criminals appear to have symptoms indicative of potentially pathological computer use.^{109,110} Research by sociologist Bernadette Schell found that hacker conference participants indicated that they spend on average 24 hours a week on hacker-related activities.¹¹¹ Furthermore, Anderson reports that cybercriminals will work for 18 or more hours a day on their computers trying to gain unauthorized access to one

single computer system with little or no external reward for doing so. He also mentions an instance where one U.S. judge even attempted to sentence a computer criminal to psychological treatment for his compulsive computer use.¹¹²

In their interviews with a number of self-identified computer criminals, sociologists Paul Taylor and Tim Jordan indicated that many of their interviewees report experiencing a thrill or rush that isn't comparable to anything that they experience in their real-world interactions when engaging in illegal activities.¹¹³ A number of their respondents reported feelings of depression, anxiety, and impaired social functioning when they are away from their computers. Taylor and Jordan suggest that these abuse-like characteristics may also be combined with feelings of compulsion regarding computers and new technologies. However, the researchers indicated that these compulsive or obsessive-like characteristics may be as much a function of the information technology (IT) field as they are personality traits.¹¹⁴ Unlike most disciplines, the IT field is in a constant state of rapid change. To maintain a level of professional expertise and competence in this area, one must devote a good deal of time and resources to monitoring and adapting to this revolutionary field. This need to keep up with the rapidly changing discipline, combined with the euphoric feelings that some experience when committing illegal activities, may increase the likelihood of technological abuse.

Personality theorists state that for some computer criminals, committing electronic crimes produces an experience similar to that of a chemically induced high. Some computer criminals may commit illegal acts because of the euphoric rush they receive from their actions. Information security researcher August Bequai compares the actions of computer criminals to electronic joyriding.¹¹⁵ Gaining unauthorized access and usage to a computer network is, for these people, similar to that of taking a car on a joyride. One computer cracker interviewed by computer crime researcher Dorothy E. Denning described hacking as "the ultimate cerebral buzz." Other crackers have commented that they received a rush from their illegal activities that felt as if their minds were working at accelerated rates. Some computer criminals have suggested that the euphoric high stems from the dangerous and illegal nature of their activities.¹¹⁶ Lending empirical support to this idea, criminologist Michael Bachmann found that self-identified computer criminals have a heightened propensity to engage in risk behaviors compared to the general population. Computer criminals have compared the feelings they receive from their illegal intrusions and attacks to the rush that is felt by participating in extreme sports like rock climbing and skydiving.¹¹⁷

Researchers have found that some experienced computer users also report sometimes experiencing an altered psychological state known as *flow* while engaging in their technological pursuits. Flow is a psychological state that results in feelings of fulfillment and overall positive affect.¹¹⁸ When individuals become absorbed in a task that matches their skill set, at times they may not be consciously aware of the passage of time or of the differences between the undertaking and their identity. In their study looking at the experience of flow in self-identified computer criminals, psychologists Alexander Voiskounsky and Olga Smyslova found that both inexperienced and highly competent criminals report high levels of flow.¹¹⁹ For the inexperienced criminals, this flow experience may lead them to limit themselves to low-level challenges, and they may remain in this novice stage for a significant amount of time. More experienced crackers who also experience flow may leave the hacking domain once they are no longer presented with suitable challenges for their abilities. Conversely, they may systematically increase their illegal pursuits in attempts to reacquire the flow state, contributing to technological abuse.¹²⁰

12 · 14 THE PSYCHOLOGY OF COMPUTER CRIMINALS

Physical and psychological tolerance can occur when increased amounts of a substance or an activity are needed in order to obtain a *high* or euphoric rush. Tolerance is common in hard drug users who find themselves using increasing amounts of a substance to achieve their original euphoric states. Anecdotal evidence suggests that computer criminals may go through a similar stage of evolution, with each step leading to increased dangerous and riskier behaviors. Many cybercriminals begin by pirating and cracking the copy protection algorithms of software programs. When the *warez* (pirated software) scene loses its thrill, they migrate to chat-room or IRC harassment. The individuals may then begin launching damaging DoS attacks against servers and defacing Websites to obtain that initial rush that originated with simple warez trading. As in a substance abuse, the initial euphoric psychological states and resulting tolerance associated with excessive computer use may explain why some computer criminals repeatedly engage in illicit activities, even after they have been caught and punished.

12.6 ETHICS AND COMPUTER CRIME. Researchers have suggested that computer criminals may have an underdeveloped sense of ethics—a moral immaturity—that contributes to their illegal activities.^{121,122,123,124} Because of this ethical immaturity, criminal hackers may think that many of their illegal actions are in fact ethical or beneficial to some degree. Many computer criminals feel that they are ethically entitled to have access to any and all information regardless of legal ownership. Most of these individuals also feel that it is morally right to use inactive computer processing power and time, regardless of who owns the computer system. Computer criminals do not feel that breaking into a computer network should be viewed in the same light as breaking into an individual's house. Often, computer criminals rationalize their illegal activities and justify their behaviors by blaming the victims for not securing their computer networks properly.¹²⁵

Most computer criminals are adolescents, which may account for the underdeveloped sense of ethics in the community.¹²⁶ Computer scientist Brian Harvey suggests that due to the relative lack of experience and guidance with the computing environment compared to the real world, teenagers and adolescents may be operating at lower levels of moral functioning when online compared to their interactions and decisions in the real world.¹²⁷ Similarly, information security specialist Ira Winkler suggests that computer hackers, because of their generally young age, do not fully understand the repercussions associated with their actions. They also may demonstrate an underdeveloped or complete lack of empathy for their victims.¹²⁸ Computer criminals fail to fully realize the consequences of their electronic intrusions into computer networks. The adolescents do not fully comprehend that their mere presence on a computing network could potentially cost companies thousands of dollars, as well as cost systems administrators their jobs.¹²⁹

Sociologist Orly Turgeman-Goldschmidt further suggests that computer criminals may view their behaviors as nothing more than a new form of social entertainment.¹³⁰ They see their electronic intrusions as a game that provides them with excitement and thrills. The Internet serves an unlimited playground or social center where “netizens” are able to develop new games and forms of social activities. Computer criminals may view their illegal activity as nothing more than fun and thrill seeking, a new form of entertainment that is carried out on an electronic playground.¹³¹

According to Winkler, many criminal hackers learn and develop a sense of computing ethics from their online and offline peers.¹³² In other words, unlike most instruction on morality and ethics that stems from a responsible adult, computing ethics are socially

learned from other adolescents. Computer crackers learn the rules of hacking and computing from elder statesmen in the hacking community who may be no more than a few years older than themselves. Often, in today's society, the younger generation is more knowledgeable about technology than older adults. When adolescents have problems or need guidance in ambiguous situations, many times their parents or other adult role models are unable to offer them the necessary guidance and assistance. Therefore, the youngsters may seek knowledge from their peers, who may or may not offer them the most ethical or wise advice.¹³³ In support of this notion, Vincent Sacco and Elia Zureik found that students who viewed illicit computing behaviors as ethical increased the reported likelihood that they would engage in such actions. Computer crime was least reported when the behavior was seen as being more unethical.¹³⁴

While using the Internet, children are constantly making sophisticated judgments without appropriate adult supervision. Adolescents do not have the same ethical maturity that adults have, yet while using the Internet they are given as much power, authority, and responsibility as ethically mature adults.¹³⁵ Neil Patrick, the leader of one particularly malicious group of phone-system hackers known as the 414s, stated that he did not know that his hacking was illegal or unethical. In fact, asked when, if ever, he began to question the ethics of his actions, Patrick stated that ethics never came into his mind until the Federal Bureau of Investigation agents were knocking on his front door. Patrick and the other young members of the 414s did not see anything wrong with their actions. To them, breaking into proprietary telecommunications networks was more of a game or challenges rather than a criminal act. They saw nothing ethically wrong with their actions.¹³⁶

Psychologist Lawrence Kohlberg developed a three-level theory to explain normal human moral development.

- The first level deals with avoiding punishments and obtaining rewards.
- The second level emphasizes social rules.
- The third level emphasizes moral principles.

Each of his three levels contains two stages that an individual passes through during adolescence on the way to adult moral development.¹³⁷ Computer criminals appear to be operating in the lower three phases of Kohlberg's model: the two stages comprising level 1 and the first stage in level 2. The moral judgments of computer criminals appear to be determined by a need to satisfy their own needs and to avoid disapproval and rejection by others.

In his empirical research on moral development, Rogers found that self-identified computer criminals relied more on hedonistic decision making rather than internal or social morality-based choices, compared to a noncriminal student population. Computer criminals do not appear to be aware of or concerned with the third level of moral development, where moral judgments are motivated by civic respect and one's own moral conscience.¹³⁸ Computer criminals may be functioning at the third level of moral development in the physical world, a level appropriate for teens and adults, and may simultaneously be functioning at lower levels of moral development when their online identities are salient.¹³⁹ Computer criminals acting at these lower levels of morality may be naively engaging in their illegal activities to satisfy their own curiosity and to gain the approval of their peers, without considering larger moral implications of their behaviors.

12 · 16 THE PSYCHOLOGY OF COMPUTER CRIMINALS

According to Shaw and associates, there is a notable lack of ethical regulation and education in organizations, schools, and homes regarding proper computing behavior.¹⁴⁰ Computer criminals who lack ethical maturity fail to realize that their digital actions are sometimes just as damaging as physical aggression. Cybervandals do not see the immediate repercussions of their actions because of the physical distance and lack of social presence in computer-mediated interactions. This ethical immaturity is partially a result of the technology-enhanced knowledge gap between young computer users and their parents. A hacker whose handle was *The Mentor* wrote in the 1986 “Hacker Manifesto,”

This is our world now ... the world of the electron and the switch, the beauty of the baud. We make use of a service already existing without paying for what could be dirt-cheap if it wasn't run by profiteering gluttons, and you call us criminals. We explore ... and you call us criminals. We seek after knowledge ... and you call us criminals. We exist without skin color, without nationality, without religious bias ... and you call us criminals. You build atomic bombs, you wage wars, you murder, cheat, and lie to us and try to make us believe it's for our own good, yet we're the criminals.

Yes, I am a criminal. My crime is that of curiosity. My crime is that of judging people by what they say and think, not what they look like. My crime is that of outsmarting you, something that you will never forgive me for.¹⁴¹

In real-world situations, when parents and teachers strive to instill responsible ethics in adolescents, young adults become capable of making informed decisions regarding ethical dilemmas. However, the same adolescents who demonstrate ethical behavior in the physical world may be ethically bereft in cyberspace, partly due to the lack of adult guidance and instruction. Anecdotal evidence suggests that in today's society, adolescents recreationally use, and are more familiar with, computers and the Internet than their parents. These young adults often learn the about Internet-related behaviors and attitudes on their own, or via peer-to-peer interaction. Adolescents are socialized on the Internet by other adolescents, which may lead to a *Lord of the Flies* scenario, where children construct social rules and guidelines to govern their behaviors.¹⁴² These socially constructed norms and guidelines may be both morally and ethically different from real-world norms. Kabay has argued that technological change can take two to three generations for integration of new moral codes into society; by this reasoning, young adults who are growing up with increased awareness of civil behavior in cyberspace will be teaching their own children more appropriate rules of behavior from the earliest ages of the next generation.¹⁴³

12.7 CLASSIFICATIONS OF COMPUTER CRIMINALS. For both ordinary and abnormal behaviors, it is difficult to find one theoretical perspective that can account for every behavior in a given situation. Attitudes and behaviors are the product of the combined influence of an individual's personality and the current social situation. No single theory or theoretical perspective can account for the various types of computerized crimes and the criminals who engage in these activities. There are also many types of computerized crimes, ranging from trading pirated software to cyberterrorism, and many types of computer criminals, ranging from the novice password cracker to the industrial spy. Any theory that would account for the behavior of computer criminals would have to consider, first, the type of illegal activity the person was engaged in and, second, the type of cybercriminal category that the individual falls into.¹⁴⁴ Computer criminals are by nature paranoid and secretive agents who exist in a similar community. They use handles to conceal their true identities and, except for annual hacker

conventions or local meetings, seldom interact with each other in the real world. Therefore, it is difficult for researchers to identify and categorized the various subgroups that exist.

The term *computer hacker* has been both overused and misused as a way of classifying the entire spectrum of computer criminals.¹⁴⁵ The motivations and actions of one subgroup of computer criminals may be entirely different from those of a second group; therefore, it is imperative that in any psychological analysis of computer criminals, the various subcategories be taken into consideration. Many theories have attempted to account for the motivations and behaviors of computer criminals as a whole when the theorists actually were referring to one specific subgroup in the underground culture.¹⁴⁶ Computer criminals are a heterogeneous culture; therefore, one single theory or perspective cannot sufficiently explain all their actions. The fact that researchers traditionally have treated computer criminals as a homogeneous entity has limited the validity and generalizability of their findings. Even researchers who have taken into account the heterogeneous nature of the computing underground have had difficulty with experimental validity. Experimenters have allowed participants to use their own self-classification schemes or attempted to generalize the results of a single subgroup to the entire underground culture.¹⁴⁷

12.7.1 Early Classification Theories of Computer Criminals. Over the past few decades, several researchers have attempted to develop a categorization system for individuals who engage in various forms of computer crime.^{148, 149, 150, 151, 152} A comprehensive review of this research is beyond the scope of this chapter. For an extensive review, see Rogers's analysis and development of a new taxonomy for computer criminals.¹⁵³ Bill Landreth, a reformed computer cracker, was one of the earliest theorists to develop a classification scheme for computer criminals.¹⁵⁴ His system divided criminals into five categories based on their experience and illegal activities.

1. The *novice* criminals have the least experience with computers and cause the least amount of electronic disruption from their transgressions. They are considered to be tricksters and mischief-makers; for example, AOL users who annoy chat-room members with text floods and DoS-like *punting* programs that crash AOL sessions using specific font or control code strings.
2. The *students* are electronic voyeurs. They spend their time browsing and exploring unauthorized computer systems.
3. The *tourists*, according to Landreth, commit unauthorized intrusions for the emotional rush that results from their actions. This subgroup of computer criminals is similar to Bequai's electronic joyriders.¹⁵⁵ The tourists are thrill-seekers who receive a cerebral buzz from their illegal behaviors.
4. The *crashers* are malicious computer criminals. This subgroup is composed of the darkside criminals that Kabay refers to.¹⁵⁶ The crashers will crack into networks and intentionally delete and destroy data and cause denials of service.
5. Landreth's final classification of computer criminal is the *thieves*. Criminals who fit into this category commit their illegal actions for monetary gain. These individuals are equivalent to the dangerous insiders that Post, Shaw, and Ruby analyzed.¹⁵⁷ Thieves may work alone, or they may be under contract from both foreign and domestic corporations and governments. Examples include the Russian Business Network or RBN.¹⁵⁸

12 · 18 THE PSYCHOLOGY OF COMPUTER CRIMINALS

Former Australian Army intelligence analyst Nicholas Chantler conducted one of the few empirical examinations of computer criminals and their culture.¹⁵⁹ Published in 1995, this survey-based study attempted to gain a deeper understanding of the underground culture as well as to develop a categorization system for cybercriminals. Chantler posted questionnaires to bulletin board systems (BBSs), Usenet newsgroups, and chat rooms owned or frequented by computer criminals. An analysis of the data yielded five primary attributes—criminal activities, hacking prowess, motivations, overall knowledge, and length of time hacking—that Chantler used to create three categories of computer criminals: *lamers*, *neophytes*, and *elites*.¹⁶⁰

1. *Lamers* have the least technical skill and they have been engaged in their illegal activities for the shortest period of time. This group of criminals is primarily motivated by revenge or theft of services and property.
2. *Neophytes* are more mature than lamers. They are more knowledgeable than the previous category and engage in illegal behaviors in pursuit of increased information.
3. Members of the *elite* group have the highest level of overall knowledge concerning computers and computer crime. They are internally motivated by a desire for knowledge and discovery. They engage in illegal activities for the intellectual challenge and for the thrill they receive from their criminal behaviors.

According to Chantler, the largest proportion of computer criminals at that time, 60 percent, fell into the neophyte category. Thirty percent of computer criminals fell into the elite category, while 10 percent were lamers.¹⁶¹

Information security analyst Donn Parker developed a seven-level categorization scheme for computer criminals.^{162,163} He formalized his scheme, through years of interaction and structured interviews with computer criminals, into the following categories:

1. **Pranksters** are characterized by their mischievous nature.
2. **Hacksters** are motivated by curiosity and a quest for knowledge. Pranksters and hacksters are the least malicious computer criminals.
3. **Malicious hackers** are motivated by a need for disruption and destruction. They receive pleasure from causing harm to computer systems and financial loss to individuals.
4. **Personal problem solvers** commit illegal activities for personal gain. Problem solvers, the most common type of computer criminal according to Parker, resort to crime after failing in legitimate attempts to resolve their difficulties.
5. **Career criminals** engage in their illegal cyberbehaviors purely for financial gain.
6. **Extreme advocates** have strong ties to religious, political, or social movements. Recently, these types of cybercriminals have been dubbed “hacktivists,” a combination of computer hackers and activists.
7. **Malcontents, addicts, and irrational individuals** comprise the final category in Parker’s scheme. Individuals in this category usually are suffering from some form of psychological disorder (e.g., antisocial personality disorder).

12.7.2 Rogers's New Taxonomy of Computer Criminals. After an extensive review of past categorization theories, Rogers has advanced an updated continuum of computer criminals based on his previous work.¹⁶⁴ This continuum comprises eight categories based primarily on the criminals' motivations and technological prowess:

1. **Novice (NV)** criminals have the least amount of technical knowledge and skill. Members of this category are relatively new to the scene and use prewritten and precompiled scripts and tools to commit their computerized crimes. They are primarily motivated by the thrill of lawbreaking and making a name for themselves in the underground.
2. **Cyber Punk (CP)** is the group that most fits the traditional stereotype of hacker. Members of this category are slightly more advanced than the novices. These criminals have the ability to create basic attack scripts and programs. Cyber Punks' typical behaviors include Web page defacements, DDoS attacks, carding, and telecommunication fraud. They are motivated by a need for attention, fame, and monetary gain, usually attained by parlaying their crimes into lucrative jobs and book deals. Winkler suggests that the majority of computer criminals fall into either the cyber punk or newbie categories. He estimates that between 35,000 and 50,000 computer criminals, well over 90 percent of their total estimated number, fall into these categories, whom he dubs clueless.¹⁶⁵
3. **Internals (IN)** consist of disgruntled workers or former workers who hold information technology positions in an organization. Members of this category have an advantage over external attackers due to their job and status within the corporation. Research indicates that internals are responsible for the majority of computer crimes and associated financial loss. Their motivation is typically based on revenge for some perceived wrong (e.g., termination, passed over for a promotion).^{166,167} These internal or malicious insiders are examined more fully later in Chapter 13 of this *Handbook*.
4. **Petty Thieves (PT)** are traditional criminals who have turned to technology as a way of keeping up with the times. These individuals are career criminals whose motivation is primarily financial gain from stealing from banks, corporations, and individuals.
5. **Old Guard (OG)** are computer criminals with advanced technical knowledge and skill. These individuals are responsible for writing many of the exploit programs (e.g., stack overflows, rootkits, etc.) that are used by the less knowledgeable novice and cyberpunk crackers in their cyberattacks; however, they are not criminals in the traditional sense. This group has an underdeveloped sense of ethics regarding privacy and intellectual and personal property and engages in behaviors consistent the traditional hacker ethic and ideology described by Levy.¹⁶⁸ Their illegal behaviors are motivated by a quest for knowledge, curiosity, and intellectual stimulation.
6. **Virus Writers (VW)** do not fit neatly into Roger's Taxonomy primarily due to the lack of research on this group of individuals. The demographics and motivations of virus writers are examined more fully later in this chapter.
7. **Professional Criminals (PC)** are traditionally older and more knowledgeable about technology than the previous categories. Members of these categories may be former government and intelligence operatives who are motivated by

12 · 20 THE PSYCHOLOGY OF COMPUTER CRIMINALS

financial gain. They may often have access to advanced technology and can be adept at industrial espionage. According to Rogers, PCs may be comprised of ex-intelligence agents and are one of the most dangerous types of computer criminals. Their motivation is primarily large-scale financial gain.

8. **Information Warriors** are highly skilled employees who conduct coordinated attacks against information systems in an attempt to cripple or destabilize the infrastructure. This group may be motivated by allegiance and patriotism. We examine this group more fully in the following section.

Based on these eight categories, Rogers has created a baseline circumplex model of computer criminals that aims to further classify computer criminals. Rogers' circumplex groups computer criminals in a circular diagram using two continua: technological skill and motivation. Using this circumplex, the eight categories can be further subdivided, following future empirical work, to more accurately represent individual subgroups of the computer underground.

12.7.3 Hacktivists and Cyberterrorists: Hacking for a Cause. With the emerging protests against the economically advantaged 1 percent and the political upheaval in Middle East, new trends in cybercrime have emerged in the form of a revitalized hacktivist ethos. *Hactivism* is defined as cause-based hacking for social, political, patriotic, or religious purposes. In general, the perpetrators engage in technological dissent in order to promote freedom of speech and fair distribution of wealth and to combat censorship. Hactivists will often rally behind a symbol, logo, or flag, whether they are religious, political, or emblematic. The term was first used by groups like Electronic Disturbance Theatre (EDT) and the Cult of the Dead Cow (cDc) in the mid-1990s to establish digital protests and *hack-ins* where the groups would launch coordinated DoS attacks and mass Web page defacements as a means of online protest.^{169, 170, 171, 172} Paralleling the global "Occupy" protest movements, many of these modern hacktivist groups have no central leadership or core philosophy, making their actions and targets difficult to predict. They present an increased danger due to their tendency to single out and target high-profile people and organizations to achieve maximal exposure for their group, cause, and interests. Hacktivists are not motivated by financial gain, but instead prefer to publicize their cause through the harm and embarrassment of their victims.¹⁷³ The methods employed by modern hacktivists have evolved from simple DoS attacks and Web defacements to massive amounts of government, corporate, and personal data theft. The number of hacktivist attacks in 2011 surpassed all of the previous year's attacks combined that were attributed to social and political motivations.¹⁷⁴

According to Rogers, *cyber-terrorists*, along with *professional criminals*, may present the most danger to individuals and organizations. A cyber-terrorist is defined as, "an individual who uses computer or network technology to control, dominate, or coerce through the use of terror in furtherance of political or social objectives."¹⁷⁵ Following the September 11, 2001, attacks in the United States, the term cyberterrorism has been frequently overused and misused by the media. An individual who stumbles upon a vulnerable .mil or .gov Website and decides to deface it should not be considered a cyberterrorist unless there is a premeditated intent to cause panic and fear, with the object of obtaining some social end.

Although most of the Web page defacements and network attacks labeled by the media as cyberterrorism would not fit Rogers's definition, that is not to say that the Internet will not be used as means for terrorist acts in the future.¹⁷⁶ Spurred on by

the specter of cyberterrorism and claims by hackers that they could cripple the Internet in 30 minutes, governments and corporations are investing millions into research aimed at protecting the global computing infrastructure from cyberattacks. Rogers suggests that the relative anonymity of the perpetrator, and the multitude of potential targets that could be simultaneously attacked, makes the Internet a very appealing target for terrorists' actions that will likely be exploited in the near future.¹⁷⁷

Perhaps the most infamous case of cyberterrorism occurred in 2010 when researchers analyzed Stuxnet, one of the most sophisticated electronic worms ever discovered in the wild. Stuxnet was created with the singular goal of creating physical damage to centrifuges in one of Iran's nuclear enrichment facilities. Although no one has taken credit for the Stuxnet worm, computer security researchers suggests that it may have been cyberwarriors working for the United States and/or Israeli governments.¹⁷⁸ Theorists suggest that new breeds of computer criminals, dubbed cyberterrorists and hacktivists, are emerging and are motivated by political or social ideologies related information freedom, nationalism, ethnic pride, and warfare.^{179,180}

12.7.4 Dangerous/Malicious Insiders (DI/MI). Dr. Eric Shaw and associates classify computer criminals into two categories: outside intruders and dangerous insiders.^{181,182,183} The researchers focus on the critical IT insiders who are typically programmers, technical support staff, networking operators, administrators, consultants, and temporary workers in organizations. Malicious insiders (MI) are a subgroup of such employees who are motivated by greed, revenge, problem resolution, and ego gratification. Shaw and colleagues estimate that the theft of trade secrets costs more than \$250 billion annually for U.S. businesses alone.

Shaw's research, based on corporate surveys and hundreds of investigations by the U.S. Secret Service and Carnegie Mellon University's Computer Emergency Response Team Coordination Center (CERT-CC), has attempted to compile an initial profile of dangerous insiders. Their critical-pathway approach identifies psychological and situational precursors that may predispose an employee to engage in insider espionage¹⁸⁴:

- 1. Personal Predisposition:** medical/psychiatric problems, reduced social skills, previous violations of the law or business ethics, social or professional ties with competitors or adversaries
- 2. Personal Life Stressors:** financial burden, relationship problems, medical issues, legal issues
- 3. Professional Stressors:** demotions, failed promotions, poor performance review, transfer, supervisor disagreements, looming layoffs
- 4. Concerning Behaviors:** workplace violations, conflict, intellectual property (IP) disagreements
- 5. Maladaptive Organizational Responses:** failure to detect, investigate, appreciate, and appropriately respond to concerning behaviors of employees

The generic profile for an MI is a male in his late thirties who has a job in a technology-related area within the company. The majority of thefts occur when an MI has accepted a job elsewhere and within a month of starting their new job. Moore, as cited by Shaw, classifies MIs into two categories, the *Entitled Disgruntled Thief* and the *Machiavellian Leader*.

12 · 22 THE PSYCHOLOGY OF COMPUTER CRIMINALS

- The Entitled Disgruntled Thief typically engages in IP theft due to professional stressors. They steal information that they directly worked on or helped to develop. These individuals feel entitled to the information and typically will use it to help them acquire a new job or to enhance their performance at their already acquired position.
- The actions of the Machiavellian Leader are more premeditated. They are driven more by personal ambition rather than personal or professional stressors. These individuals may also recruit coworkers to assist them in their thefts.

According to Shaw and coauthors, these dangerous insiders typically have introverted personalities.¹⁸⁵ They demonstrate a preference for solitary intellectual activities over interpersonal interaction. Members of this subgroup may have had numerous personal and social frustrations that have hindered their interpersonal interactions and contributed to their antiauthoritarian attitudes.

The malicious subgroup of critical information technologists has been characterized as having a loose or immature sense of ethics regarding computers. The dangerous insiders rationalize their crimes by blaming their company or supervisors for bringing any negative consequences on themselves. They feel that any electronic damage they cause is the fault of the organization for treating them unfairly. The researchers also note that many insiders identify more with their profession than with the company for which they work. This heightened identification with the profession undermines an insider's loyalty to an organization. This reduced loyalty is evidenced by the high turnover rates of jobs in the IT industry. According to Shaw and associates, the unstable bond between insiders and their organizations creates undue tension with regard to security practices and IP rights.¹⁸⁶

Researchers also have suggested that dangerous insiders are characterized by an increased sense of entitlement and hostility toward organizational authority. According to Shaw and coauthors, when an unfulfilled sense of entitlement is combined with previous hostility toward authority, malicious acts or revenge against the organization are typical.^{187,188,189}

12.7.5 Virus Creators. Unlike more traditional forms of computer crime, there has been very little research examining the motivations and behaviors of malware writers, usually referred to as *virus writers*.¹⁹⁰ Despite the name, the group writes other forms of malware such as worms and Trojans. The limited number of research reports on this particular subgroup of computer criminal has relied primarily on one-on-one interviews and surveys, in an effort to understand the actions and motivations of virus creators.^{191,192,193,194}

Using case studies and multiple interviews, researchers Andrew Bissett and Geraldine Shipton examined the factors that influence and motivate virus writers.¹⁹⁵ The researchers suggest that it is difficult to generalize their findings to all virus creators because of the limited published literature and research regarding virus writers. Virus creators appear to demonstrate conscious motivations for their potentially destructive actions that are similar to the motivations of traditional computer criminals. The coders create and distribute their software for reasons of nonspecific malice, employee revenge, ideological motives, commercial sabotage, and information warfare.

Bissett and Shipton's review of anti-virus expert Sarah Gordon's interview with Dark Avenger reveals some of the motivations behind one of the most notorious virus writers.¹⁹⁶ They suggest that Dark Avenger consistently denies responsibility for his

creations and, like traditional computer criminals, engages in victim blaming. Dark Avenger states that it is human stupidity, not the computer, that spreads viruses. The virus writer also appears to self-identify with his malicious code. Dark Avenger seems to project his persona onto viruses in a process called projective identification. During the interview, Dark Avenger stated that the United States could prevent him from entering the country, but it is unable to stop his viruses. Dark Avenger also attempted to justify creating destructive viruses by commenting that most personal computers did not store data of any value, and therefore his malicious programs were not doing any real harm. Similar to the motivations spurring dangerous insiders, the researchers suggest that Dark Avenger creates malicious viruses because he is envious of the work and achievements of other computing professionals. In the interview, Dark Avenger commented that he hates it when people have more powerful computing resources than he does, especially when the individuals do not use the resources for anything that he deems constructive.¹⁹⁷

Sarah Gordon has also examined the ethical development of several virus writers using surveys and structured interviews.^{198,199,200} Her initial four case studies involved an adolescent virus writer, a college-age virus writer, a professionally employed virus writer, and an ex-virus writer. The interviews revealed that all four individuals appeared to demonstrate normal ethical maturity and development consistent with Kohlberg's previously reviewed stage theory.²⁰¹ Gordon suggests that there appear to be many different reasons why individuals create and distribute viruses, including boredom, exploration, recognition, peer pressure, and sheer malice.²⁰²

Gordon suggests that the virus underground in the mid and late 1990s was populated by a second generation or next generation of virus writers whose skill and ability at virus construction is comparable to that of the old school, original virus writers.²⁰³ On the surface, these second-generation creators maintain a public façade that suggests that they are extremely cruel, obnoxious, and more technologically advanced than the previous generation. The next-generation virus writers appear to be more aware of the ethical responsibilities surrounding virus creation and distribution; however, the exact definition of "responsible virus creation and distribution" varies from individual to individual. Many of these next-generation virus writers have considerable technical skill and are motivated by the challenge to defeat the malware countermeasures implemented by antivirus vendors.²⁰⁴

According to Gordon, another group of virus creators populating the virus underground in the 1990s was composed of "new-age" virus writers.²⁰⁵ These individuals are motivated by current trends, such as political activism, virus exchange, freedom of information, and challenges to write the most destructive or sophisticated virus, as opposed to technical exploration. These virus writers are motivated by boredom, intellectual curiosity, mixed messages surrounding the legality of virus creation, and increased access to ever-more-powerful technological resources. Gordon suggests that these new-age virus writers may be older and wiser than the second or next-generation creators. They are very selective as to who has access to their creations, and they do not share their findings or accomplishments with members outside their respective group. Unlike the next-generation creators, new-age virus writers will not stop or grow out of writing viruses, as they are most likely already adults. They will continue to write and distribute more sophisticated viruses in part due to the mixed messages concerning the ethical nature of virus creation propagated by the popular media, academia, and popular freedom of information zeitgeist.²⁰⁶

Researchers have stated that we must be careful not to view virus creators as a homogeneous group.^{207,208} Instead, we must monitor the virus-exchange community

while pursuing in-depth case histories that may aid in our understanding of virus writers. Education about the ethical nature of virus creation and distribution, and about the repercussions associated with malicious code, may attenuate these potentially destructive activities.

12.8 RECOMMENDATIONS. Psychological theories offer various explanations that may influence criminal activities on the Internet. These situational influences may interact with various individual personality traits to further contribute to illegal behaviors. The current task for researchers is to untangle these personality and situation influences on electronic behavior. They must determine what situations and characteristics are influencing the various subgroups of computer criminals. There is no simple explanation as to why computer criminals engage in hostile and destructive acts. The answer lies in a complex mixture of factors that depends on the social environment and individual personality factors. There are numerous types of computer criminals ranging from script kids to the professional criminal, each with varying personalities and motivators. The interaction of personality variables and environmental factors will determine how a computer criminal reacts in any given situation.

One underlying theme in reducing the overall prevalence of computer crime has been to remove the tangible and psychological reward system that currently surrounds the culture of the Internet underground. Criminal law researchers A. S. Dalal and Raghav Sharma suggest that the information security field has established a pattern of rewarding criminal hackers for their exploits by offering them employment opportunities that further undermines law enforcement efforts to combat computer crime.²⁰⁹ Preventing cybercriminals from profiting from their transgressions via lucrative jobs and book deals may result in a socially learned deterrent to engaging in cybercrime. Thomas Holt and colleagues found strong support for the social learning model of cybercrime in their research: those who received reinforcement in the form of encouragement, praise, and resources from peers and authority figures were more likely to engage in cybercrime activities. This model suggests that removing this reinforcement would significantly reduce the amount and frequency of cyberdeviance, especially in the case of criminals that fall into Rogers' *novice* and *cyberpunk* categories.^{210,211}

Cautioning parents, teachers, and bosses about the dangers of praising adolescents for cyberdeviance and instead instituting consistent punishments should also help to mitigate computer crime for novices. Also, a more proactive strategy that parents and educators could take would be to engage in moral or ethics training on the use of computers and technology before children begin independently using technology on a regular basis. Then, when confronted with ambiguous decisions while using the computers, children would reflexively rely on adults' moral advice and teachings instead of their peers'. Scholastic Incorporated demonstrated in a recent survey that 48 percent of elementary and middle school students did not consider computer hacking to be a crime.²¹² Recently, the U.S. Department of Justice (DoJ) formed a cybercitizen awareness program in an effort to educate parents, teachers, and children about ethical and unethical computing practices. The program seeks to educate individuals through ethics conferences, multimedia presentations, and speaking engagements at schools around the country. This program and others like it may aid to increase moral responsibility and ethical behaviors of adolescents on the Internet.²¹³

Dalal and Sharma also suggest that punishments take into account the motivation and type of cybercrime that is committed, instead of using a rigid approach to sentencing that precludes adapting punishment to the nature of the criminal. For instance, longer jail terms may be a suitable deterrent for criminals who are motivated by financial

gain or malice (e.g., internals, petty thieves, and malicious insiders), but might not be warranted for those who are motivated by intellectual challenges and curiosity (e.g., old guard hackers).

Another problem may be the relatively light sentences that are typically handed down for computer crimes, and the perpetrators' perceptions that they are unlikely to be caught or prosecuted for their transgressions. One study found that the perceived gains achieved by illegal hacking far outweighed the potential costs associated with digital crime. Furthermore, even though computer criminals feel that the punishments for their crimes are severe enough, their feelings that there is a very low probability that they'll be caught minimizes the effects of punishment severity as a deterrent.²¹⁴ Even still, the notoriety that a computer criminal gets from being handed a jail term can be parlayed into a lucrative job once the individual has paid the price for their criminal endeavors.

A more proactive approach to reducing the motivation to engage in illicit activities while using computers could be to establish legal hacking networks for novices to experiment with and explore. For novices and even cyberpunks, safe hacking spaces where they have unlimited access to networks and programs may reduce the psychological reactance that results from strictly enforced computing access and resources. These legal hacking networks would also serve to redirect the users' focus on the technical aspect of computing and traditional hacking endeavors rather than trying to crack open the system. By redirecting adolescents' curiosity toward traditional hacking and technical pursuits into an open network, the users may be less inclined to engage in criminal pursuits.

To combat the threat of malicious insiders, Shaw suggests that businesses also adopt a proactive approach to threat mitigation.²¹⁵ Developing more comprehensive employee-screening methods that include social-media reviews, background checks, substance abuse tests, honesty/ethical tests, and psychological screenings may serve to mitigate the risks of IP theft. Additionally, a more cost-effective and time-efficient method of reducing IP theft would be increasing employee awareness of IP nondisclosure agreements (NDAs) and ensuring that they are aware of the consequences of violating these agreements. Increasing employees' and managers' awareness of intellectual property rights and risk factors, as well as instituting a systematic reporting system for potential violation could mitigate some of the risks of IP theft. Shaw reports that the majority of IP theft was detected by nontechnical means (e.g., employees noticing suspicious activity or similar products being marketed by competitors).²¹⁶

This chapter summarized research on the psychological motivations of computer criminals. The cybercrime landscape is vast in scope and populated by subgroups of computer criminals with their own patterns of motivations, goals, attitudes, and behaviors. Psychological theory and research is one step in trying to generate effective countermeasures to combat the problem of cybercrime.

Although there is no shortage of theories and anecdotal evidence to account for why cybercriminals engage in network intrusions, there is a marked lack of empirical evidence that serves to test and validate these hypotheses. Information security professionals, criminologists, and psychologists must find ways to begin jointly developing, testing, and examining these ideas in order to find concrete solutions for the problem of cybercrime. Such effort will be facilitated by government and private-sector funding to support research into the psychological and social dynamics of the Internet underground. The information security industry as a whole would do well to support these applied scientific efforts.²¹⁷

13.1 INTRODUCTION. An insider is someone who has been given a role within an organization and has access to premises and/or internal systems and information. There are many types of roles; some are core to the business and performed by employees, while others are non-core and contracted out to service providers such as cleaning, maintenance, or information technology (IT). The categories of insiders may be classified as:

Current staff work directly for and under the control of the organization's management. This category includes employees as well as temporary staff, contractors, and consultants. Most of these people are located on the organization's premises and are connected to the internal network with access to internal information.

Departing staff represent one of the highest risks to an organization. These people consist of employees who have resigned or are planning to do so, temporary staff, contractors or consultants coming to the end of their contract, as well as all the people whose employment or services are being ended by the organization. These people still have access to internal information, and may be motivated to take that information with them when they leave, or to commit sabotage in revenge for perceived wrongs.

Former staff are those who are no longer employed by or providing services to the organization. This group still has insider knowledge, and without mitigating controls, they can do substantial damage long after they have left the organization. Former staff can be highly motivated to attack their former employers.

13 · 2 THE INSIDER THREAT

Service-providers: Organizations have many roles that are necessary for the smooth running of the business but that are not core to the company's mission. Examples of these roles are cleaning services, maintenance, and IT. Over the last 20 years, service providers have steadily moved up the service stack to perform core functions as well. It is now common for service providers to perform business operations and even to be the first point of contact with customers. Although not all service providers will need access to premises or internal systems, there are many roles that do.

The key distinction between service providers and staff is that staff (who can be provided by service providers) are working under the control of the organization's management and subject to its policies and procedures; in contrast, service providers are providing a specified service, and all personnel are the responsibility of the service provider. This situation increases risk to the organization, as it has little control over service-provider staff, but the threats are the same as from internal staff.

Partners: Organizations are partners when they work together on a business venture. Access to information goes up to senior business leaders within the partners. Partnerships may be short or long term, and partners may be competitors at the same time as being partners. This situation creates risk for the organization, which has to share information relevant to the partnership but not other internal information.

The term *partner* is sometimes used where service providers are performing key functions for an organization and success of the service is essential. For these key contracts, it is good practice to treat the service provider more like a partner than a vendor, but for insider threat purposes they are service providers.

13.2 THREATS FROM INSIDERS. Successful organizations need to have people in many different roles, with the primary distinction between business roles (business management, sales, customer services, and product design) and support/infrastructure roles (IT, finance, logistics, human resources, and the like).

The people in each role need access to information and systems to perform their role, and the key point to make at this stage is that the impact an insider attack makes on the organization is related to the insider role. A salesman leaving an organization to join a competitor will have had access to customer- and product-related information, whereas someone in product design is likely to have access to valuable intellectual property on current and future products. Customer service center staff are likely to have access to customers' personally identifiable information (PII) that can be used to commit identity fraud.

IT is a high-risk area, and is essential to the efficient running of the business. Most of an organization's information is stored in its IT systems, and without proper controls, IT administrators could have access to everything.

13.2.1 How Common Are Insider Attacks? According to the 2011 CyberSecurity Watch Survey,¹ 21 percent of electronic crime events were conducted by insiders, 58 percent by outsiders, and 21 percent unknown. Of the insider events, 76 percent were dealt with internally without legal action or law enforcement, which is likely a reason that external attacks are more often in the news.

The 2012 U.K. Information Security Breaches Survey² provides some interesting statistics.

- 6 percent of the responding 447 organizations reported staff sabotage of systems, with some organizations experiencing incidents on a weekly basis

- 19 percent of large organizations reported that staff used systems to commit theft or fraud, and this figure had doubled since the survey in 2010
- With regard to other incidents caused by insiders, large organizations were more likely to experience incidents, with 82 percent reporting incidents versus 45 percent for small organizations
- 61 percent of large organizations reported unauthorized access to systems or data
- 45 percent reported a breach of data protection laws or regulations
- 36 percent reported misuse of confidential information
- 47 percent reported loss or leakage of confidential information

The 2013 U.K. Information Security Breaches Survey³ includes the following relevant information for this chapter (quoting directly from the Executive Summary—note U.K. spelling):

- 36% of the worst security breaches in the year were caused by inadvertent human error (and a further 10% by deliberate misuse of systems by staff)
- 57% of small businesses suffered staff-related security breaches in the last year (up from 45% a year ago)
- 17% of small businesses know their staff broke data protection regulations in the last year (up from 11% [in the 2012 report])
- 14% of large organisations had a security or data breach in the last year relating to social networking sites
- 9% of large organisations had a security or data breach in the last year involving smartphones or tablets
- 4% of respondents had a security or data breach in the last year relating to one of their cloud computing services
- 4% of the worst security breaches were due to portable media bypassing defences

13.2.2 Examples of Insider Attacks. To get an understanding of the types of insider events, a number of organizations maintain databases and publish results. The FBI maintains an Insider Threat page on their Website⁴ containing a list of prosecuted insider theft cases. A short summary of these cases follows:

- Retired research scientist conspired with current and former employees to steal trade secrets from his former employer, and sell them to companies in China.
- Employee working for two different U.S. companies stole trade secrets from both companies which were used to benefit Chinese universities.
- A research scientist stole trade secrets from her employer and made them available for sale through her own company.
- An employee stole customer and employee lists, contract information, and other trade secrets to provide to a foreign government, but instead gave them to an undercover FBI agent.
- A computer programmer working for a financial firm copied proprietary software during his last few days at the company.
- An employee who was fired had kept copies of trade secrets. These trade secrets were then sold to a rival company.

13 · 4 THE INSIDER THREAT

- An employee stole and attempted to sell trade secrets that provided everything needed to start a competing business.
- Over a two-day period, an employee copied hundreds of technical documents from her employer, which were found in her luggage during a check at the airport.
- Spies working for U.S. defense companies stole internal information about the space shuttle, Delta IV rocket, the C-17 military plane, and submarine propulsion systems, along with other information. This information was provided to the Chinese government.

In a summary of the “Top Five Insider Attacks of the Decade,” the Linux.com editorial board listed the following cases⁵:

- Roger Duronio was convicted in 2006 to eight and a half years in federal prison⁶ for his actions in 2002 when, apparently in a fit of pique at not receiving what he considered an adequate annual bonus, he sabotaged the computer systems of his employer, UBS PaineWebber. “UBS was hit on March 4, 2002, at 9:30 in the morning, just as the stock market opened for the day. Files were deleted from up to 2,000 servers in both the central data center in Weehawken, N.J., and in branch offices around the country. Company representatives never reported the cost of lost business but did say it cost the company more than \$3.1 million to get the system back up and running. Duronio worked at UBS as a systems administrator until he quit a few weeks before the attack. Witnesses testified that he quit because he was angry that he didn’t receive as large an annual bonus as he expected. Investigators found copies of the malicious code on two of his home computers and on a printout sitting on his bedroom dresser.”⁷
- In 2005, a sting operation by a *The Sun* reporter from Britain netted him confidential details of more than a thousand “... accounts, passports, and credit cards ...” from NatWest and Barclays banks. This led to investigations of call centers in India, when criminals “... boasted of being able to provide details of as many as 200,000 bank accounts in a month, which, he further said, came from more than one call center.”⁸
- The “Athens Affair” was discovered when investigators looked into the apparent suicide of an electrical engineer, Costas Tsalikidis, in his Athens apartment. The inside job by Tsalikidis, the head of network planning, and unknown others compromised the Vodafone-Panafon company (“Vodafone Greece”) using malware and may have resulted in monitoring and recording of conversations involving “... the prime minister, his defense and foreign affairs ministers, top military and law-enforcement officials, the Greek EU commissioner, activists, and journalists.”⁹
- San Francisco network administrator Terry Childs locked other employees out of the city’s network in July 2008 because he claimed that his supervisor was unqualified to have administrative control. He was sentenced to four years in California state prisons. “Prosecutors characterized the former network administrator as a power hungry control freak who couldn’t be managed.”¹⁰
- Bradley Manning, a 22-year-old U.S. Army intelligence analyst, was arrested in May 2010 and charged in July 2010 with leaking nearly half a million classified U.S. videos and cables to the WikiLeaks project.¹¹ He was charged with “aiding the enemy” in February 2012¹² and accused of aiding the terrorist group al

Qaida through his actions.¹³ In January 2013, the trial was rescheduled until June 2013¹⁴ and Manning was denied the opportunity to justify his actions using a whistleblower defense.¹⁵

- *The Sunday Times* reported in 2012 that “Confidential personal data on hundreds of thousands of Britons is being touted by corrupt Indian call centre workers, an undercover investigation has discovered. Credit card information, medical and financial records are being offered for sale to criminals and marketing firms for as little as 2p.” Records of 500,000 Britons were apparently for sale, many of which were supposedly less than 72 hours old and included “... sensitive material about mortgages, loans, insurance, mobile phone contracts, and Sky Television subscriptions ...”¹⁶

13.2.3 Types of Insider Threats. There are three main classifications of insider threats: accidental, malicious, and nonmalicious.

13.2.3.1 Accidental Threats. Accidental threats are generally caused by mistakes; for example, staff may not follow operating procedures due to carelessness, disregard for policies, or a lack of training and awareness of the right thing to do. An example is a customer service representative who accidentally breaches client confidentiality by emailing client information to the wrong email address. Such errors may be caused by the use of email clients that have an auto-complete feature on the email address; staff under pressure to keep up with the volume of work may not notice the error before they send the data. This error is a particularly high risk for financial services organizations where in some jurisdictions a client confidentiality breach is a criminal offense.

Other typical examples include a database administrator who accidentally deletes a database table during maintenance, a systems administrator allowing a programmer to modify a production system without proper approvals, or an operator reformatting a disk drive without having two full, verified backups.

13.2.3.2 Malicious Threats. Malicious threats deliberately try to damage the organization or to benefit the attacker. Disgruntled IT administrators can sabotage IT systems, bringing an organization to a halt. There have been many incidents where both current and former administrators have deliberately caused system issues for various motives: enjoying the lifestyle of traveling around the world in luxury to fix the problems they created, extorting money from the organization, or simply causing as much damage as possible.

Some company information is highly valuable and specifically targeted by attackers. PII is one category that is sometimes illegally copied by staff to conduct identity theft and fraud, or to sell it to criminals. Another category is intellectual property (IP) such as trade secrets. Staff may take this information to help them with their next job or to sell to competing companies. This crime is thought to be common with IT developers who often seek to take their source code with them. Industrial espionage sponsored by rival companies or foreign governments is another common threat to IP (see Chapter 11 in this *Handbook* for examples).

Information can leave an organization by being copied to removable storage such as USB flash or hard drives and CD/DVD writers. Portable 3TB drives are now readily available, which means entire databases can be copied to a drive measuring less than 7 × 5 inches in size. With gigabit ethernet becoming standard, the time required to copy

13 · 6 THE INSIDER THREAT

this data is rapidly decreasing. Other common channels include emailing attachments to external email addresses, uploading files to external email services and to Internet Websites, and using cloud backup and cloud storage tools. To address these data-leakage channels, products known as data loss prevention (DLP) systems are increasingly being installed in organizations.¹⁷

There are also the common physical threats, such as taking printed information from people's desks or from the office printers. Where logical access controls are strong, staff intent on stealing information can take photographs of documents or information on screen with the high-resolution cameras in today's mobile phones.

There are some incidents where the motive may be conscience based as well as having a desire to damage an organization. Since the financial crisis in 2008, governments have increased their efforts to reduce tax avoidance, and are aggressively pursuing the use of foreign tax havens. There have been a number of publicized incidents where insiders have provided lists of offshore clients and accounts to country tax authorities.^{18,19}

13.2.3.3 Nonmalicious Threats. Nonmalicious threats are actions taken deliberately by people without intent to damage the organization. Often, the motive is to increase productivity, and the mistakes occur due to a lack of training or awareness of policies, procedures, and the risk. There have been many incidents in which staff loaded internal information onto Internet-based systems, some of which have no access controls. This error makes the information available to anyone who uses the sites and is often found and indexed by search engines.

One incident occurred in the early days of cloud computing. A drug researcher was given a lengthy lead time by his internal IT department for the delivery of infrastructure to conduct simulations. What he did instead was use his credit card to buy time on cloud-based systems and ran the simulations there instead. This would have put valuable intellectual property at risk had these Internet systems been compromised. This information was also sitting on the cloud provider's storage systems; what if the cloud vendor were to fail to reinitialize the storage when reallocating released storage to another customer, and the next user of the storage were to understand the value of what came pre-loaded on their system—and be dishonest?

Another example that is often reported in the media is the loss of PII when staff copy information to laptop computers or to removable storage devices such as USB drives or CDs/DVDs, which are then lost or stolen.²⁰

One common insider threat that can happen for both malicious and nonmalicious reasons is to email internal information to their home email address. Once on the staff member's own computer, the information is vulnerable to theft, successful attack on the computer or email account, or recycling of the machine by donating it to charity, or giving it away to family or friends. There have been many media reports of people finding sensitive information on secondhand computer hard disks.²¹

The nonmalicious motive for this practice is often to enable the employee to work from home, or the information is needed for a business trip. The malicious motive is to take the information with them, for reasons covered earlier.

13.2.4 Internet-Based Systems. The growing trend to use outsourced applications available over the Internet rather than internal systems can contribute to insider crime. With internal systems, when someone leaves an organization, they no longer have physical access to premises, and their network and application user-ids are supposed to be disabled immediately, removing access to corporate networks, computers,

and applications. Appropriate action makes it difficult for even maliciously motivated former staff to access confidential systems and their information.

But with Internet-based systems, the former staff member may still have access to confidential data via any Internet connection. It is very difficult to ensure all application accounts are promptly closed when someone leaves, creating a high risk of continued access to these systems. The people concerned may be deterred by the risk of being prosecuted for misusing their rights after leaving the organization, but their risk can be reduced if they use a former colleague's log-on account.

Organizations don't have to avoid using these external services; indeed, these external services are often among the best available, and can be provided at a much lower cost than hosting internally. However, security officers must coordinate closely with their human resources departments and the IT people responsible for maintaining the lists of external providers to ensure that access by former employees to external services is shut down as quickly as access to internal systems.

13.2.5 Service Provider Threats. Even organizations with strong personnel controls that reduce the risk from internal staff may have no protection from external service-provider staff. Although organizations commonly include their policies, standards, and procedures into contracts and treat this precaution as sufficient to address risk, the service provider may not consistently perform all the required controls, either through attempts to maximize profit or through poor management.

For example, a service provider faced with high staff turnover might bypass preemployment checks to get replacement staff quickly onto a service, particularly if there are service performance issues. Similarly, poor standards for handling termination of employment at the service provider could lead to compromise of client information.

In cases where an entire IT service is being provided by a service provider, the service provider's staff and IT administrators may have access to all the client organization's information. Email is a particular risk that may contain a great deal of an organization's intellectual property and that has powerful search facilities to easily target individuals and specific information.

13.2.6 System Administration Threats. System administrators have privileged access to an organization's IT infrastructure and, in poorly managed systems, may have access to critical and sensitive information on the systems. System administrators may deliberately attack the availability of an organization's systems even if they cannot access the data themselves. Administrators may destroy individual data sets, applications, or entire systems and networks—and may be able to destroy system backups to make the organization's recovery more difficult. This risk is most acute in smaller organizations, in which one person may manage the servers, applications, networks, email, backups, and perhaps even user administration. In larger organizations, it is much easier to segregate these roles as they should be, thus limiting access and therefore the damage one person can cause.

Even in large organizations with thousands of servers with effective segregation implemented, an administrator may be able to submit a job that can be run simultaneously on every server to wipe every hard disk. This type of threat highlights the importance of controlling the access and scope of administrators and preventing unauthorized changes from being implemented.

13.3 MITIGATING THE INSIDER THREAT. This section describes at a high level a few of some specific mitigating controls and how they address the insider threat.

13 · 8 THE INSIDER THREAT

For more details on the wider range of controls, refer to the detailed information in other chapters in this *Handbook* such as Chapter 15 (Penetrating Computer Systems and Networks), Chapter 28 (Identification and Authentication), Chapter 31 (Content Filtering and Web Monitoring), Chapter 45 (Employment Practices and Policies), Chapter 52 (Application Controls), Chapter 53 (Monitoring and Control Systems), Chapter 54 (Security Audits and Inspections), Chapter 55 (Cyber Investigation), Chapter 56 (Computer Incident Response Teams), and Chapter 68 (Outsourcing and Security).

13.3.1 System and Asset Inventories. If you don't know what you have, you can't manage it. Without an inventory of servers, you can't ensure they are patched, enabling an insider to compromise them and use them for their own purposes. Without a list of applications running on each server, you may have unnecessary servers sitting on your network being used for unauthorized purposes. The active systems on the network also need to correlate to the inventory. An administrator who doesn't remove a redundant system in your Internet DMZ could use it to bypass all of your network perimeter controls after he has left the organization.

In particular, one of the most dangerous tools for insider crime is the unauthorized and undetected wireless access point—easily purchased from any electronic store for at low cost and capable of transferring data from an internal network to unauthorized devices within the corporate facilities or even to external agents within a modest radius outside the building. See Chapter 33 in this *Handbook* for discussion of wireless network security.

13.3.2 Data Loss Prevention (DLP). There have been technology adoptions over the last 10 years which have made it much easier for staff to either accidentally or deliberately breach the confidentiality of organizational and client information. Data loss prevention (DLP) is a class of IT security system increasingly being implemented by organizations to help address these risks. A typical DLP system needs to address the following vulnerabilities at a minimum:

- Mobile storage devices/removable media, such as USB memory sticks and hard drives, mobile phones, memory cards, CD/DVD writers, along with infrared, Bluetooth, FireWire, and SCSI-connected storage.
- File uploads—including encrypted data—to external Websites via the standard protocols within Web browsers, such as ftp, http, and https. These controls may be enforced at both the Internet gateway as well as on the desktop.
- Detection of when laptops are not on the corporate network and preventing files being copied to noncorporate file shares.

For the majority of staff, the DLP system can be configured to block attempts to copy and upload data to these data-leakage channels. However, for most of these channels, there are going to be some people who have a genuine business need to copy and upload information, resulting in exceptions to the policy. The DLP system can help manage this risk by creating a log of what has been copied to support incident investigation or to enable a review of what a staff member has copied out of the organization. These facilities can be particularly useful when an employee hands in his resignation.

13.3.2.1 Email Data Leakage. Once the low-hanging fruit of removable storage and file uploads are blocked, staff begin to export information via email. The motive may not be malicious, but it still results in the organization's losing control over the information. To address this risk, the DLP system can be configured to report on people sending attachments to home email addresses, which is the usual destination for information, or to any unauthorized email address. These reports can then be used to increase staff awareness about policy or to support disciplinary processes for deliberate data leakage.

However, the true benefit from DLP comes when the business areas are engaged, because DLP can drive a process of identifying and defining the critical information that has to be protected. For example, the IT development group could have a DLP rule that blocks emails containing source code, to prevent developers taking their work with them when they leave. Even if source code is placed in an encrypted zip file to try and avoid detection, the metadata (e.g., filenames and identifiers of file creators) may still be readable and can trigger the rule.

For other areas of the business, client information, business strategy, business results, intellectual property, and PII such as credit card numbers and Social Security numbers can be configured into the DLP system.

13.3.2.2 Data Leakage Using Cloud Storage. Widespread availability of external data storage facilities (e.g., Dropbox and Google Drive) adds to the complexity of DLP. Careful application of Web monitoring and blacklisting specific URLs may be helpful, but determined opponents of the regulations may circumvent such methods using a variety of proxy avoidance Websites which mask the destination of the HTTP request. Security administrators should be on the lookout for new sites so they can add them to the corporate blacklists for outbound communications through their firewalls.

13.3.2.3 Difficulties with DLP. DLP is not a panacea. It is difficult if not impossible to prevent someone determined to leak data, but with a DLP system, one can make it difficult for them to do so without detection, and this barrier usually deters the majority of people.

With email DLP, it is very difficult to identify safe blocking rules that prevent data leakage. For example, if employees routinely send emails to customers, some of these customers are going to be using their home email addresses, which means that a hard block (blacklisting) of emails sent to home email addresses won't be feasible.

13.3.2.4 Legal Issues with DLP. With the implementation of DLP, an organization progresses from investigating reported incidents to actively monitoring for breaches of company policy. One of the major issues with implementing a global DLP system is that active monitoring may be subject to privacy and workplace laws, and failure to comply with these laws in some countries is a criminal offence.

Additionally, with customer and organization information being captured in DLP logs, consideration needs to be given as to where the log files are stored and who will be reviewing them. As an example from the financial services industry, some information is price sensitive and there are strict requirements on who can access it, to prevent insider dealing. Client information within the log files may be covered under banking secrecy laws and regulations. If the log files for one country are stored on a server in another country, then outsourcing regulations need to be complied with as well, and planners must identify the most stringent regulations to ensure efforts for

13 · 10 THE INSIDER THREAT

compliance. Data protection laws have been enacted in many countries that require data subjects to give their agreement to their information being processed and for defined purposes; therefore, monitoring of communications may need to be included in customer contracts and other data protection declarations.

Despite all of these hurdles, for most countries, it is possible to roll out a DLP system. As part of the project planning stage, the organization needs to commission a legal investigation for each country to understand whether it is lawful to actively monitor corporate email, but more importantly, the preconditions for any monitoring to lawfully take place. For countries that forbid email monitoring or any form of workplace surveillance, it is usually possible to implement blocking controls on writing to removable storage along with uploads to external Websites, provided no log files are kept.

13.3.2.5 Remote Access Solution. A commonly implemented remote access solution is the provision of Webmail from home computers. With Webmail you need to configure the system to prevent staff opening attachments within local applications on the home computer. If this is not blocked, staff can copy corporate information by saving the open attachment to their local hard drive. In addition, any use of the Remote Desktop Protocol (RDP) also needs to be properly configured to prevent local USB resources being mapped to the remote computer.

13.3.3 Internal Honeypots. Honeypots are attractive systems or nodes that appear to have valuable confidential data. Roger Grimes, author of a textbook about honeypots,²² writes:

One of the best things you can do to get early warning of internal attackers is to implement honeypots. ... because they're low cost and low noise—and they work!

Because the internal attackers you seek could be trusted IT employees, the entire project must be kept secret. It should be known only to the sponsor, management, and the implementers. Often, we give the project a boring code name like Marketing Business Development, which is used in all documents and e-mails, avoiding terms having anything to do with honeypots. Don't even tell the network security people about it, in so far as you can and still have an operational project. Then take a few computers that are destined for de-provisioning or the scrap heap and turn them into your honeypots.²³

The point of such a honeypot is that there should be zero access to it: It serves no function and there is never a reference to it in any internal or external documentation. Thus, anyone who accesses it is either doing, so by pure accident or is violating policies governing unauthorized access to internal data (there *is* no one authorized to access the honeypot). Detailed logging should be in place at all times to provide forensic information immediately; however, administrators should ensure that they can actually visualize exactly what is being done in real time, not simply rely on the detailed log files for after-the-fact analysis. An early-warning system should immediately alert system administrators to the problem (preferably as the access is in progress) via screen messages, voice messages, and text messages.

13.4 CONCLUDING REMARKS. Fighting the insider threat need not be solely reactive. In addition to the entire spectrum of information assurance measures covered throughout this *Handbook*, maintaining an environment of security awareness and of encouragement, trust, fair-dealing, and long-term commitment to the welfare of employees must remain among the very best approaches to reducing the risk of insider crime.

14 · 2 INFORMATION WARFARE

Information warfare is the offensive and defensive use of information and information systems to deny, exploit, corrupt, or destroy, an adversary's information, information-based processes, information systems, and computer-based networks while protecting one's own. Such actions are designed to achieve advantages over military or business adversaries.

—Dr. Ivan Goldberg, Institute for Advanced Study of Information Warfare

14.1 INTRODUCTION. Until recently, warfare was conducted by armed forces representing adversarial nations, or by revolutionary elements opposing their own governments. Today, although such conflicts still exist around the world, the ubiquitous nature of computers and associated technology has created new forces, new threats, new targets, and an accompanying need for new offensive and defensive weapons. Information warfare (IW), also known as *e-warfare* or *cyberwar*, is actually, or potentially, waged by all U.S. armed forces and by those of other nations, as well as by commercial enterprises, by activist groups, and even by individuals acting alone.

Conventional wars, whether large or small, are regularly reported by the news media. Information war, however, are largely ignored except by those with a professional interest in the field. One reason for this is that conventional warfare is a matter of life or death; photos and eyewitness accounts are dramatic reminders of human cruelty and mortality. In contrast, IW has so far been conducted bloodlessly, with only economic and political consequences. However, it is becoming increasingly evident that IW may soon be conducted in ways that could equal or exceed the death and destruction associated with conventional weapons.

Conventional wars are fought by known combatants with clearly defined allies and antagonists, but IW often is waged by unknown entities with uncertain allegiances and goals. IW may be conducted on many fronts simultaneously, with wars fought within wars, and with both civilian and military targets devastated.

The motives for conventional warfare were almost always territorial, religious, political, or economic. These are still important, but to them must be added the psychological motivations of groups and individuals—groups far more widely distributed and less easily overcome.

This chapter discusses information warfare in terms of the vulnerabilities of targets, participants' objectives, sources of threats and attacks, weapons used, and defenses against those weapons.

14.2 VULNERABILITIES. Until recently, concerns over the security of the technological infrastructure in technologically advanced nations have been viewed with skepticism. However, by the mid-1990s, opinion leaders in government, industry, and the security field were coming to grips with widespread vulnerabilities in the critical infrastructure.

14.2.1 Critical Infrastructure. In 1998, President Bill Clinton circulated Presidential Decision Directive 63, which outlined his administration's policy on critical infrastructure protection:

Critical infrastructures are those physical and cyber-based systems essential to the minimum operations of the economy and the government. ... They include, but are not limited to, telecommunications, energy, banking and finance, transportation, water systems and emergency services, both government and private.¹

Having defined the very broad, vital areas that require protection, the paper went on to describe succinctly their vulnerability:

The United States possesses both the world's strongest military and its largest national economy. Those two aspects of our power are mutually reinforcing and dependent. They are also increasingly reliant upon certain critical infrastructures and upon cyber-based information systems. ...

Because of our military strength, future enemies, whether nations, groups or individuals, may seek to harm us in non-traditional ways including attacks within the United States. Our economy is increasingly reliant upon interdependent and cyber-supported infrastructures and non-traditional attacks on our infrastructure and information systems may be capable of significantly harming both our military power and our economy.

A few examples of specific weaknesses were given by Jack L. Brock, Jr., director, Government-wide and Defense Information Systems, United States General Accounting Office:

In May 1999 we reported that, as part of our tests of the National Aeronautics and Space Administration's (NASA) computer-based controls, we successfully penetrated several mission-critical systems. Having obtained access, we could have disrupted NASA's ongoing command and control operations and stolen, modified, or destroyed systems software and data.

In August 1999, we reported that serious weaknesses in Department of Defense (DOD) information security continue to provide both hackers and hundreds of thousands of authorized users the opportunity to modify, steal, inappropriately disclose, and destroy sensitive DOD data.²

Although these "attacks" were carried out one at a time, and without malicious intent, it is apparent that they, and many others, could have been launched simultaneously and with intent to inflict the maximum possible damage to the most sensitive elements of the national infrastructure.

In a memorandum to its chairman, describing a report of the Defense Science Board Task Force on Defensive Information Operations, Larry Wright stated in 1999 that:

The threats to the DoD infrastructure are very real, non-traditional and highly diversified. ... The vulnerabilities of these United States are greater than ever before, and we know that over twenty countries already have or are developing computer attack capabilities. Moreover, the Department of defense should consider existing viruses and "hacker" attacks to be real "Information Operations or Warfare," what early aviation was to Air Power. In other words, we have not seen anything yet!³

The report concluded that "[i]t is the view of this task force that DoD cannot today defend itself from an Information Operations attack by a sophisticated nation state adversary."

14.2.2 Off-the-Shelf Software. One characteristic of almost all military and civilian infrastructures is that they share, with more than 100 million computers, a single ubiquitous operating system, and many of the same applications programs, such as word processors, spreadsheets, and database software. These commercial off-the-shelf (COTS) products are available around the world, to friend and foe alike, and they appear to be more intensively studied by malefactors than by their security-inadequate producers. Each of these products presents entry points at which one common vulnerability may be exploited to damage or destroy huge portions of the national infrastructure.

14 · 4 INFORMATION WARFARE

Until, and unless, this software is rendered significantly more resistant to attack, all of its users remain at risk.

14.2.3 Dissenting Views. Not every influential observer concurs in these possible scenarios. Dr. Thomas P. M. Barnett, a professor and senior decision researcher at the Decision Support Department, Center for Naval Warfare Studies, U.S. Naval War College, voiced a fairly typical disagreement in 1999:

If absence makes the heart grow fonder, network-centric warfare is in for a lot of heartbreak, because I doubt we will ever encounter an enemy to match its grand assumptions regarding a revolution in military affairs. The United States currently spends more on its information technology than all but a couple of great powers spend on their entire militaries. In a world where rogue nations typically spend around \$5 billion a year on defense, NCW is a path down which only the U.S. military can tread.⁴

14.2.4 Rebuttal. It may be of some benefit to have spokespersons for this unworried viewpoint, but their opinions must be weighed against those, for example, of Scott Henderson, of the Navy-Marine Corps intranet, who said: “One of our critical capabilities will be how we are to defend our information and our information systems from an adversary’s attack.”⁵ He stated that successful intrusions, or attacks, on Navy computer systems increased from 89 in 2000 to 125 by mid-2001, an annualized increase of 80 percent. Those figures did not include successful attacks that went undetected or unsuccessful attempts that may have identified a weak point from which to launch future and probably more successful, attacks.

A highly significant factor in IW is its asymmetric nature. The barriers to entry for attackers are low; their weapons can be inexpensive, easily obtained, highly effective, easily automated, and used with negligible risk of personal harm. In contrast, defensive measures are extremely costly in time, money, and personnel and they may be ineffective against even unsophisticated attackers using obsolete computers.

The 2013 *Annual Report to Congress: Military and Security Developments Involving the People’s Republic of China* from the U.S. Office of the Secretary of Defense includes the following evaluation of China’s “Anti-Access/Area Denial (A2/AD)” capabilities:

An essential element, if not a fundamental prerequisite, of China’s emerging A2/AD regime is the ability to control and dominate the information spectrum in all dimensions of the modern battlespace. PLA authors often cite the need in modern warfare to control information, sometimes termed “information blockade” or “information dominance,” and to seize the initiative and gain an information advantage in the early phases of a campaign to achieve air and sea superiority. China is improving information and operational security to protect its own information structures, and is also developing electronic and information warfare capabilities, including denial and deception, to defeat those of its adversaries. China’s “information blockade” likely envisions employment of military and non-military instruments of state power across the battlespace, including in cyberspace and outer space. China’s investments in advanced electronic warfare systems, counter-space weapons, and computer network operations (CNO)—combined with more traditional forms of control historically associated with the PLA and CCP systems, such as propaganda and denial through opacity, reflect the emphasis and priority China’s leaders place on building capability for information advantage.⁶

Considering the nature and extent of already successful attacks against major elements of U.S. military and civilian infrastructures, there appears to be no justification for discounting the views of those who believe that IW, in both its offensive and defensive roles, must be accorded the attention that surrounds any potentially cataclysmic force. This *Handbook*, especially Chapters 16, 17, 18, 20, and 21, contains many

examples of viruses, worms, and other malware that have created massive disruptions in very large networks. The worst-case scenarios presented here should serve to awaken a measured response in those who may have been unaware or unconcerned.

14.3 GOALS AND OBJECTIVES. Attacking forces, in information warfare, will always have a variety of strategic and tactical motives behind their actions; defensive forces generally have only one tactical goal—to blunt the enemy’s attack and, if possible, to counterattack. Only after this is accomplished, and the nature of the attackers has been studied, can strategies for long-range operations be determined and effected.

14.3.1 Infrastructure. Depending on the target, an attacker’s goals may vary widely, but attackers generally want to damage, subvert, or destroy the infrastructure. In doing so, an attacker would hope to bring government, the economy, and military operations to a standstill or at least to reduce their efficiency and effectiveness to instill fear, uncertainty, and doubt (FUD), and ultimately to induce widespread chaos that could cost many lives.

Although this view is entirely appropriate to wars between nations or to campaigns by terrorists, it must be tempered when considering commercial warfare, whose main goal is competitive financial advantage.

14.3.2 Military. Today, information warfare is a vital concern of area commanders under battlefield conditions. They must obtain complete, accurate, and timely information about their opponents’ actions, intentions, weaknesses, and resources while denying the same to their adversaries. The ultimate objective for all of these activities is to support the military tactics that will maximize the enemy’s body count, or at least to render its defenses ineffective, so that surrender becomes the only viable option. The other side of the coin, defensive tactics, are aimed at preventing enemies from accomplishing their objectives.

In the United States, the Joint Chiefs of Staff (for Army, Navy, Marine Corps, Coast Guard, and Air Force) have formulated the *Joint Doctrine for Operations Security* to be followed by all commanders of combatant commands in planning, preparation, and execution of joint operations. The publication states:

Operations Security (OPSEC) is a process of identifying critical information and subsequently analyzing friendly actions attendant to military operations and other activities, to: (a) identify those operations that can be observed by adversary intelligence systems; (b) determine what indicators adversary intelligence systems might obtain that could be interpreted or pieced together to derive critical information in time to be useful to adversaries; and (c) select and execute measures that eliminate or reduce to an acceptable level the vulnerabilities of friendly actions to adversary exploitation.⁷

OPSEC is a process that could be applied to every element of civilian infrastructure, as well as to the military, although all sources of information commonly used by the military are not available to the civilian sector. Other military code words for intelligence activities are:

- HUMINT (human intelligence) is the most widely used source of information, as it has always been for both the civilian and military sectors. HUMINT is often the only source capable of direct access to an opponent’s plans and intentions. Some

14 · 6 INFORMATION WARFARE

intelligence gathering is quite open, but covert or clandestine operations must be conducted in secrecy, so as to protect the sources of confidential information.

- SIGINT (signals intelligence) is obtained from communications (COMINT), electronics (ELINT), and foreign instrumentation signals (FISINT).
- COMINT (communications intelligence) is information intended for others and intercepted without leaving a trace.
- ELINT (electronic intelligence) derives technical or geographic location data from an opponent's electromagnetic radiations, other than those that arise from communications or from nuclear detonations or radioactive sources. The primary ELINT sources are radars (radio detection and ranging).
- FISINT (foreign instrumentation signals intelligence) is obtained from intercepting and analyzing metered performance parameters electronically transmitted from sources such as a ballistic missile.
- MASINT (measurement and signatures intelligence) is scientific and technical in nature. Its purpose is to identify distinctive features associated with a source, emitter, or sender so as to facilitate subsequent identification or measurement. These features include wavelength, modulation, time dependencies, and other unique characteristics derived from technical sensors.
- IMINT (imagery intelligence) is produced by photography, infrared sensors, lasers, radars, and electro-optical equipment. This equipment, operated from land, sea, air, or space platforms, provides strategic, tactical, and operational information.
- TECHINT (technical intelligence) is derived from the exploitation and analysis of captured or otherwise acquired foreign equipment.
- OSINT (open source intelligence) is available to the general public from news media, unclassified government publications, public hearings, contracts, journals, seminars, and conferences. The World Wide Web has become an important tool of OSINT.

The *Joint Doctrine for Operations Security* lists several generic military activities with some of their associated critical information. It must be the objective of all information warfare to acquire this critical information about their opponents while denying such information to them:

- *Diplomatic negotiations* include military capabilities, intelligence verification, and minimum negotiating positions.
- *Political-military crisis management* includes target selection, timing considerations, and logistic capabilities and limitations.
- *Military intervention* requires information about intentions, military capabilities, forces assigned and in reserve, targets, and logistic capabilities and constraints.
- *Counterterrorism* involves forces, targets, timing, strategic locations, tactics, and ingress and egress methods.
- *Open hostilities* information involves force composition and disposition, attrition and reinforcement, targets, timing, logistic constraints, and location of command and control (C²) nodes.

- *Mobilization* requires information about an intent to mobilize before public announcement, impact on military industrial base, impact on civilian economy, and transportation capabilities and limitations.
- *Intelligence, reconnaissance, and surveillance* information includes purpose and targets of collection, timing, capabilities of collection assets, and processing capabilities.

In addition to the Joint Chiefs' doctrines, the Department of Defense and each individual branch of service have been charged with the responsibility for establishing task forces, advisory groups, training and awareness programs, and virtual information networks to mobilize IW forces and to bring into being a strong defense against enemy attack.

Further evidence of the importance of military information and the vulnerabilities that exist at this time is contained in the 2001 report of the Secretary of Defense to the President and the Congress:

Information superiority is all about getting the right information to the right people at the right time in the right format while denying adversaries the same advantages. The United States enjoys a competitive advantage in many of the technical components of information superiority, but the U.S. also has vulnerabilities stemming from its increasing dependence on high technology. Experiences from Somalia to the Balkans have shown that low technology adversaries also can wage effective information campaigns, especially in urban environments.

In the Information Age, the opportunities and obstacles to achieving national security objectives often are informational in nature. Information superiority is a principal component of the transformation of the Department. The results of research, analyses, and experiments, reinforced by experiences in Kosovo, demonstrate that the availability of information and the ability to share it significantly enhances mission effectiveness and improves efficiencies. Benefits include: increased speed of command, a higher tempo of operations, greater lethality, less fratricide and collateral damage, increased survivability, streamlined combat support, and more effective force synchronization. Kosovo also highlighted the shortage of assets for intelligence, surveillance, and reconnaissance, as well as the need for more secure interoperability and information protection, especially within coalitions.

To ensure that the above prerequisites are in place, DoD is developing appropriate policy and oversight initiatives, actively pursuing opportunities to improve international cooperation in the areas of Command, Control, Communication, Computers, Intelligence, Surveillance, and Reconnaissance (C4ISR) and space-related activities, partnering with industry, and working to anticipate and understand the implications of emerging information technologies.

The quality of DoD's infostructure will be a pacing item on the journey to the future. The ability to conceive of, experiment with, and implement new ways of doing business to harness the power of Information Age concepts and technologies depends upon what information can be collected, how it can be processed, and the extent to which it can be distributed. The ability to bring this capability to war will depend upon how well it can be secured and its reliability. DoD envisions an infostructure that is seamless with security built-in, one that can support the need for increased combined, joint, and coalition interoperability, leverages commercial technology, and accommodates evolution.⁸⁷

Although not as well publicized as are the U.S. defensive efforts, equal attention, time, and resources are being expended on actual and possible offensive operations. Every objective, every tactic, and every recommendation just mentioned, and some too sensitive to discuss here, are subjects for study and implementation of offensive strategies and tactics aimed at enemies, present and future.

14 · 8 INFORMATION WARFARE

14.3.3 Military Offensives. The nature of U.S. offensive planning has been described in detail in a top-secret presidential memo published by *The Guardian* (U.K.) on June 7, 2013.

The memo states that:

The United States has an abiding interest in developing and maintaining use of cyberspace as an integral part of U.S. national capabilities to collect intelligence, and to deter, deny, or defeat any adversary that seeks to harm U.S. national interests in peace, crisis, or war. ... The United States Government shall conduct DCEO [Defensive Cyber Effects Operations] and OCEO [Offensive Cyber Effects Operations] under this directive consistent with its obligations under international law, including with regard to matters of sovereignty and neutrality, and as applicable, the laws of armed conflict. This directive pertains to cyber operations, including those that support or enable kinetic, information, or other types of operation.⁹

In this context, “kinetic operations” are a recognized euphemism for warfare, and this memo provides the U.S. Government with a broad mandate to protect U.S. interests, as it sees them, with any means available to it without a declaration of war.

At the time of this writing (July 2013), the full implications of this serious security breach cannot be evaluated. At the very least, it will provide the critics of U.S. policy with reinforcement for their view of the United States as a militaristic, even terrorist force in international relations. For defenders of U.S. policies, it will represent an ordered, rational, response to threats that must be contemplated and guarded against.

14.3.4 Government. The objectives of government, at every level, must be to protect the lives and welfare of its constituencies. Any breakdown in an essential government function may produce marked unrest, rioting, vandalism, civil disobedience, and possibly much bloodshed.

Just as in the military, government must be able to defend itself against an information attack waged by any enemy of the established order. Although not every element of government is perceived by all to perform a useful function, there are agencies without which it would be virtually impossible to sustain a developed nation’s day-to-day activities.

At the federal level, civil servants’ salaries, Social Security payments, tax collections and disbursements, military expenditures, lawmaking, and a myriad of other functions and activities can be carried out only with the active and pervasive use of computers and computer networks. In the past, some of these computer operations have been penetrated by hackers, crackers, and political dissidents, but only one at a time. It does not require a science fiction writer to imagine what the effect would be if simultaneous attacks were successfully launched against major federal government agencies.

At state levels, although the effects would be more constrained geographically, a great deal of damage could be done to emergency response units, to police and judiciary functions, and to health and welfare services. All of these depend on computerized functions that are protected even less than those of federal agencies.

For municipalities and even smaller governments, zoning enforcements and other local functions can be suspended without serious consequences, but police radio and computer networks are easily penetrated, and their ability to maintain law and order compromised.

As demonstrated by many previous incidents, government functions at any level are susceptible to information warfare. Natural events, Murphy's law (what *can* go wrong *will* go wrong), poorly configured systems, flawed operating systems and application programs, together with inadequate security measures underlie the vulnerability of government systems.

14.3.5 Energy Systems.¹⁰ Oil, coal, and hydroelectric systems are critical elements of the national infrastructure. Supervisory control and data acquisition (SCADA) security in the electric power industry suffers from widespread misconceptions and a breakdown in communications between administrators and security experts. In brief,

- Attacks on electric power plants and the distribution grid may not result in the catastrophic scenarios painted by the promoters of panic, but any interruption in electric power delivery can cause widespread infrastructure disruption.
- SCADA systems controlling electric generators and distribution systems are not, in fact, isolated by air gaps from the Internet.
- On the contrary, vulnerability analysis teams have systematically and repeatedly demonstrated that power companies are unaware of the reality of their interconnectedness and vulnerabilities.
- There are documented cases of industrial espionage, sabotage, denial of service, and malware attacks on electric power grid SCADA systems.
- SCADA systems have been considered too stable to bother updating with current patches; as a result, they are consistently vulnerable to exploits of current (and even ancient) vulnerabilities.
- Many SCADA systems were developed without consideration of security, secure coding, or integration of security dimensions of software quality assurance.
- Government and academia have significant projects in place to advance SCADA security, but acceptance by industry is modest at best. Academics engaged in SCADA security research are doing a good job of reaching other academics through peer-reviewed presentations at academic conferences; they are less successful in reaching managers at power companies.
- Pressure is rising in the public sphere, in government circles, among security practitioners, and within the electric power industry to come to grips with the need for improved cybersecurity.
- The electric power industry must coordinate its efforts to implement well-established standards for protecting computer systems and networks in all its SCADA systems and related networks. In addition, the industry should implement cyber situational awareness solutions to integrate multiple inputs from SCADA and network sensors that will permit intelligent, agile response to attacks and effective forensic analysis of those attacks.

The electric power industry has become a fundamental underpinning of twenty-first century life. In a landmark report on "The Electricity Economy," author Jesse Berst and colleagues describe the convergence of growing demand, an increasing dependence on computerized SCADA systems, and the inevitable complexity of interactions among elements controlled by diverse entities with limited coordination.¹¹ To illustrate the

14 · 10 INFORMATION WARFARE

growth in electricity demands, the report's Table 1 shows global electricity demands of 2.06 terawatts (TW) in 1950 versus 3.8 TW in 2000 and a predicted 6.99 TW in 2050. The proportion of electricity as a percentage of global energy utilization was 10.4 percent in 1950 and 25.3 percent in 2000; by 2050 it may reach 33.7 percent. The authors add,

Today we depend on electricity for basic needs such as food, water, shelter, communication, employment, and health care. Those needs are served by infrastructures for food preservation, water treatment, heat and light, phone service, Internet, offices, factories, hospitals and emergency response, to name a few. Yet all of those essentials degrade or disappear without electricity.¹²

In October 1997, the President's Commission on Critical Infrastructure Protection (the "Marsh Report" named after Commission Chairman Robert T. Marsh) included the following warning:

Prolonged disruption in the flow of energy would seriously affect every infrastructure.

The significant physical vulnerabilities for electric power are related to substations, generation facilities, and transmission lines. Large oil refineries are also attractive targets. The increase in transportation of oil via pipelines over the last decade provides a huge, attractive, and largely unprotected target array. Oil and gas vulnerabilities include lines at river crossings; interconnects; valves, pumps, and compressors; and natural gas city gates. Large metropolitan areas could be deprived of critical fuel for an extended period by a properly executed attack.

The widespread and increasing use of Supervisory Control and Data Acquisition (SCADA) systems for control of energy systems provides increasing ability to cause serious damage and disruption by cyber means. The exponential growth of information system networks that interconnect the business, administrative, and operational systems contributes to system vulnerability.¹³

Electrical power systems have been harmed through data leakage, industrial espionage, insider threats and sabotage.¹⁴ Incidents described in the reference include

- 2006 Japan's Power Plant Security Info Leaked Onto Internet
- 2007 Egypt Accuses Nuclear Employee of Spying
- 2007 Former Nuclear Plant Engineer Allegedly Took Data to Iran
- 2007 Saboteur of California Power Grid Gained Access Despite Warning
- 2009 Fired Nuclear-Power-Plant Employee Arrested for Hacking Systems
- 2009 (Former) IT Consultant Confesses to SCADA Tampering

Hackers and malware writers and distributors have also attacked power systems.¹⁵ Cases summarized in the reference include

- 2000 Hacker Shocks Electric Company
- 2003 Slammer Worm Crashes Ohio Nuclear Plant Network
- 2006 National Nuclear Security Administration Computers Hacked; Info on 1500 Taken
- 2010 Stuxnet Worm Attacks SCADA Vulnerabilities

The Stuxnet incident is a significant development in information warfare. The European Network and Information Security Agency (ENISA) published a detailed analysis of the case in 2010:

Stuxnet is a specialised malware targeting SCADA systems running Siemens SIMATIC® WinCC or SIMATIC® Siemens STEP 7 software for process visualisation and system control. SCADA in general refers to computer systems that monitor and control industrial processes, such as, e.g., those in nuclear power plants, or in facilities for water treatment.

This highly sophisticated malware uses several vulnerabilities in the underlying Windows® operating system for infection and propagation. Infection works via USB-drives or open network shares. A root kit component hides the content of the malware on infected WinCC systems. An infected system can usually be controlled remotely by the attacker. In the end this means that the attacker has full control of the respective facility.¹⁶

ENISA also published a report on securing computer-controlled energy-distribution systems (*smart grids*) in December 2012.¹⁷

14.3.6 Transportation. Airplanes, trains, trucks, and ships are all likely targets for physical and information warfare. Because all of them are necessary to support the infrastructure by transporting personnel and materials, any disruption can cause severe problems. Because all of these transportation systems increasingly rely on sophisticated telecommunications and computing resources, they are subject to information warfare.

14.3.6.1 Aviation. The most visible, and potentially the most vulnerable, component of the transportation infrastructure is the aviation industry. Unlike the fly-by-the-seat-of-your-pants technology of aviation's early days, today's airplanes and the systems that dispatch and control them in flight are almost totally dependent on electronic communications and instruments, both analog and digital.

To a great extent, almost every airplane depends on its global positioning system (GPS) to determine its position in space, its course, speed, bearing to an airfield, and other important functions. Airplanes generally are required to fly at certain altitudes, in specific corridors, avoiding restricted areas, bad weather, and other aircraft. These requirements are met by a combination of GPS, ground and airborne radar, internal instruments, and communications from ground controllers. In the original design of these types of equipment, little or no consideration was given to security; as a result, all of them are susceptible to information warfare attacks.

The accuracy and reliability of GPS and airborne radar, however, has led federal aviation authorities to consider implementing a system wherein ground controllers and published restrictions would no longer determine altitude, speed, clearance distances, and other flight parameters. Instead, pilots would have the option to choose any flight parameter that they believed to be safe. This new system is intended to increase the number of flights that can safely traverse the limited airspace. It is undoubtedly capable of doing so, but at the same time, it will greatly increase the dangers of flight should information warfare be waged against airplanes and the aviation infrastructure.

14.3.6.2 Railroads. Less so than airplanes, but not to a negligible degree, trains are possible targets of IW. Train movements; switch settings, communications between engineers, trainmen, and control centers are all carried on by insecure radio communications and wired lines. Attacks against any or all of these can prevent the railroads from carrying out their important functions, possibly by causing disastrous wrecks.

14 · 12 INFORMATION WARFARE

14.3.6.3 Trucking. The great majority of domestic goods shipments are carried by tractor-trailer trucks. Foodstuffs, especially, depend on this relatively fast, reliable means of transportation. If even a short disruption were to be caused by IW, untold quantities of foodstuffs would rot in the fields, as would additional stockpiles awaiting distribution from central warehouses. Data for scheduling, routing, locating trucks, setting times and locations of pickup and delivery, and performing maintenance could be prevented from reaching their destinations.

14.3.6.4 Shipping. Ships are indispensable means for transporting vast quantities of materials over long distances. Navigational data, such as position, speed, course to steer, and estimated time of arrival, are a few of the parameters determined by computers and GPS on virtually every ship afloat. Conventional radar and communications by VHF and high-frequency radio are in common use, with satellite communications becoming more prevalent, despite an early start that met with technical and economic difficulties.

Radar and communications jamming are old established weapons of IW, as is interception of critical information. Little attention has been paid to security in designing or operating this equipment, and that places ships at great risk, as does the threat of physical attacks.

14.3.6.5 Other Transportation Vulnerabilities. Recognizing the importance of transportation to a nation's infrastructure, IW attackers could create wide-ranging disruptions if they were to intercept and successfully prevent receipt of critical information within the transportation industry. Recently, as a leader in new technology, the Port Authority of New York and New Jersey has begun converting to a wireless infrastructure at its many airports, train stations, bus terminals, tunnels, bridges, and shipping facilities. It requires no stretch of the imagination to predict what a determined attacker might accomplish in damaging or destroying such an infrastructure. The danger is especially great in light of the general lack of security from which wireless transmissions suffer.

When the World Trade Center (WTC) was destroyed by terrorist action, the Port Authority's offices in the WTC were completely destroyed, and more than 70 of its employees were officially listed as deceased or missing. Although that catastrophe pointed up the need for greater physical security, it also demonstrated how the Internet can be used in emergency situations. The Port Authority site, www.panynj.gov, was used to convey operational messages to the public as well as information for tenants, employees and prospective employees, vendors, suppliers, contractors, and the media.

14.3.7 Commerce. In 1924, in an address to the American Society of Newspaper Editors, President Calvin Coolidge said: "After all, the chief business of the American people is business. They are profoundly concerned with producing, buying, selling, investing, and prospering in the world. I am strongly of the opinion that the great majority of people will always find these are moving impulses of our life. ..." ¹⁸

Now, 90 years later at the time of writing, these statements are no less true. Producing, buying, selling, and investing are the commercial means by which U.S. citizens and guest workers can hope to achieve prosperity. Although not recognized earlier, infrastructure is the glue that ties these functions together and permits them to operate efficiently and economically.

If these bonds were to be broken, American business would come to a virtual standstill; it is that reality which makes the commercial infrastructure so inviting a target. Without complete, accurate, and current information, no investors would put their money at risk, and no transactions would take place among producers, buyers, and sellers.

In a populace lacking food, utilities, prescription drugs, money, and other necessities, civil disorder would be widespread. With the breakdown of commerce and the citizenry's unwillingness or inability to perform their customary functions, government at every level might cease to operate. This, in turn, would make military defensive actions highly problematic, and an enemy that combined IW with conventional force attacks would be difficult to resist.

On a less catastrophic level, there have been several cases of deliberate stock manipulation by means of insertion of false information into various news channels; an enemy could cause significant disruption in the stock market by forcing a few key stocks into unwarranted declines. In addition, the widespread use of automated trading tools that respond to significant drops in specific shares or in particular aggregate stock indexes could precipitate major economic problems in the developed world.

14.3.8 Financial Disruptions. Money is the lifeblood of every developed nation. For an economy to be healthy, its money supply, like the body's blood supply, must be strong, healthy, and free flowing. For an IW attacker, disruptions in the enemy's money supply and in its free flow are important objectives. Likely targets in the financial infrastructure include payment systems, investment mechanisms, and banking facilities.

14.3.8.1 Payment Systems. Every government employee, every member of the armed forces, every office worker, factory hand, service worker, engineer, and retired person—in fact, almost every individual in the United States—depends on regular receipt of funds necessary for survival. Paychecks, dividends, welfare and unemployment benefits, commissions, payments for products, and fees for services comprise most of the hundreds of millions of daily checks, direct deposits, and wire transfers without which most people would be unable to purchase their essential needs—assuming that products and services were available to meet those needs.

The great majority of payroll systems are computerized. Many of them, including those of the federal and state governments, depend on a few centralized computer payroll services. Even if those services were not damaged by infrastructure attacks, the banks on which payroll funds are drawn might be. This would halt, or at least impede, the cutting of physical checks, the direct deposits, cash withdrawals, wire transfers, and any other means by which payments are made. Such a situation has never occurred within the United States except in small local areas and for only brief periods of time. No one can predict what the consequences would be for a widespread attack, and surely no one would want to find out.

For more on banking payment systems, see Section 14.3.8.3.

14.3.8.2 Investment Mechanisms. Various stock, bond, and commodity exchanges provide the principal means by which individual, institutional, and corporate entities easily and expeditiously can invest in financial instruments and commodity goods.

With few exceptions, each exchange has all of its computers and communications located within a single facility, with connections to tens of thousands of terminals

14 · 14 INFORMATION WARFARE

worldwide. Disruption in these systems would not have as disastrous an effect as would a payment system disruption, but it would not be long before a breakdown in investment mechanisms would produce a commercial meltdown.

Because of the vast sums of money involved, exchange systems largely have been hardened against intrusion, and some have remote, redundant facilities, but there have been instances where hardware and software problems as well as physical exploits have brought down an exchange infrastructure.

14.3.8.3 Banking. The banking industry is the foundation of the modern financial system and, by extension, both American and foreign capitalist economies. At some point, every important financial transaction is conducted through the banking system. As such it is vital to economic health. With the advent of information warfare, the electronic, interdependent nature of banking—and finance in general—combined with its critical nature, makes the banking system a likely target for a strategic attack against a country. This is a new viewpoint for an industry focused on crime, traditional financial crises, and the more recent phenomenon of low-level hacking. It is critical, however, that we master this viewpoint and adapt our banking industry to it, for the threats information warfare poses are different from traditional bank security threats and will increase as the age of information warfare develops. Focused correctly, a well-prepared attack could cause chaos throughout the international system.¹⁹

The ubiquitous banking system is as highly automated and as security conscious as any element of the world's infrastructure. With ATMs, online banking, funds-transfer networks, and check clearing, banks are integral to virtually every commercial transaction.

As an example of the scope of banking operations involving money transfers, FEDWIRE, operated by the Federal Reserve Board, serves approximately 9,000 depository institutions as of January 2012, providing transfers that are immediate, final, and irrevocable.²⁰ In 2011, it processed 127 million transactions with a total value in excess of \$663 trillion. The average daily volume in 2011 was over 506,000 transactions valued at more than \$2.6 trillion.²¹

The Clearing House Interbank Payment System (CHIPS) “is responsible for over 95% of USD cross-border transactions, and nearly half of all domestic wire transactions, totaling \$1.5 trillion daily [in 2012].”²²

The Society for Worldwide Interbank Funds Transfer (SWIFT) “is a member-owned cooperative through which the financial world conducts its business operations with speed, certainty, and confidence. More than 10,000 financial institutions and corporations in 212 countries trust us every day to exchange millions of standardized financial messages. This activity involves the secure exchange of proprietary data while ensuring its confidentiality and integrity.”²³ Information about dollar value is not made public, but the amounts are known to be huge and the traffic enormous. For example, by the end of September 2012, the annualized number of messages transferred for the year was over 339 million and the annualized volume of files transferred among institutions was over 22 million.²⁴

If any of these systems were to be attacked successfully, the consequences for the financial well-being of many nations would be disastrous. Despite intensive efforts to safeguard the networks, attacks could be launched against the central computers, the computers of each user, and the networks that connect them.

14.3.9 Medical Security. In hospitals, as in group and private medical practice, the primary functions are carried out in a decentralized mode, making large-scale

attacks impracticable. However, ancillary functions, such as sending invoices to the government, to health maintenance organizations, and to individuals, for services provided, and placing orders for drugs and supplies, all require interconnections with centralized computers.

Although the medical profession is often slow to adopt new infrastructure elements, network-connected computers have been mandated at least for payments, and they are becoming increasingly popular for maintaining patient data, for research, and for other functions. There have been reports that hospital systems have been penetrated, with prescriptions switched and HIV-negative patients advised that their test results were positive.

See Chapter 71 of this *Handbook* for more detail about medical information security.

14.3.10 Law Enforcement. The objectives of law enforcement are to facilitate the apprehension of criminals and wrongdoers. To accomplish this, facilities in common use include computers in every squad car connected to precinct headquarters and networks that interconnect local, state, federal, and international databases. With local law enforcement, it is clear that jamming, or noise interference on emergency channels, or denial of computer services would greatly exacerbate the effects of physical attacks. At worst, a state of panic and chaos might ensue.

Another attack on law enforcement could be flash crowds—groups of people gathered into a single physical location through instructions sent electronically.²⁵ One commentator wrote in 2004,

... [T]raining people to assemble on command in large numbers at, say, shoe stores, piano showrooms or restaurants for no good reason other than the fun of being part of a huge crowd is a perfect setup for creating an army of willing, mindless drones who will congregate on command at the site of a terrorist attack or at places where their presence will interfere with response to criminal or terrorist activities. Want to rob a bank in peace and quiet? Set up a conflict between two instant crowds to draw the police to an instant riot.²⁶

14.3.11 International and Corporate Espionage. Espionage has been a recognized military activity since at least the biblical story of Joshua, one of 12 spies sent to explore the land of Canaan.²⁷ However, its application to civilian commerce dates only from the Industrial Revolution. Since then, industries and indeed nations have prospered to the extent that they could devise and retain trade secrets. In the United States, the unauthorized appropriation of military secrets has been legally proscribed since the country's inception, with penalties as severe as death, during wartime.

Only recently have economic espionage and the theft of trade secrets become the subjects of law, with severe penalties whether the law is broken within or outside of the United States or even via the Internet.

The Economic Espionage Act of 1996 was signed into law by President Clinton on October 11, 1996. Section 1832 provides that:

- (A) Whoever, with intent to convert a trade secret, that is related to or included in a product that is produced for or placed in interstate or foreign commerce, to the economic benefit of anyone other than the owner thereof, and intending or knowing that the offense will injure any owner of that trade secret, knowingly—
 - (1) Steals, or without authorization appropriates, takes, carries away, or conceals, or by fraud, artifice, or deception obtains such information;
 - (2) Without authorization copies, duplicates, sketches, draws, photographs, downloads, uploads, alters, destroys, photocopies, replicates, transmits, delivers, sends, mails, communicates, or conveys such information;

14 · 16 INFORMATION WARFARE

- (3) Receives, buys, or possesses such information, knowing the same to have been stolen or appropriated, obtained, or converted without authorization;
- (4) Attempts to commit any offense described in any of paragraphs (1) through (3); or
- (5) Conspires with one or more other persons to commit any offense described in any of paragraphs (1) through (3), and one or more of such persons do any act to effect the object of the conspiracy,

Shall, except as provided in subsection (b), be fined under this title or imprisoned not more than 10 years, or both. (b) Any organization that commits any offense described in subsection (a) shall be fined not more than \$5,000,000.²⁸

Although the foregoing lists all of the actions that are proscribed, it is not specific as to which assets are to be protected as trade secrets. For this, see the Defense Security Service paper, “What Are We Protecting?”²⁹ There, the five basic categories of People, Activities/Operations, Information, Facilities, and Equipment/Materials are expanded into 42 specific assets, with the admonition that every company official must clearly identify to employees what classified or proprietary information requires protection. Only if the owner has taken reasonable measures to keep such information secret, and the information derives actual or potential economic value from not being generally known to or readily obtainable through proper means, will the courts view it as a trade secret.

For further information on intellectual property, including trade secrets, see Chapters 11 and 42 in this *Handbook*.

14.3.12 Communications. Communications are the means by which all elements of a civilization are tied together. Any significant destruction of communications media would disrupt the most important segments of society. Without adequate communications, transactions and services would come to a complete halt. In the United States, communications have been disrupted frequently, but fortunately, the infrastructure has been so vast and so diverse that the consequences have rarely been more than temporary. Even after the World Trade Center disaster of September 11, 2001, when Verizon’s downtown telephone facilities centers were heavily damaged, service was restored within four days to the New York Stock Exchange and to other important users in the area.

Contrary to popular belief, the Internet is so widely used and concentrated in so few backbone points that a coordinated attack actually could destroy its functioning. For many years, backup facilities have included redundant computers and all of their associated peripherals, often in remote locations. Too often, however, alternate communications facilities are not provided. Unless this is rectified, the same disaster that brings down one installation could disable all.

14.3.13 Destabilization of Economic Infrastructure. A major difference between wealthy, developed nations and poor, undeveloped countries lies in the strength of their economic infrastructures. The existence of strong capital markets, stable banking and lending facilities, and efficient payment processes, all tied together by fast, technically advanced communications capabilities, is essential to healthy, growing economies.

At opposite ends of this spectrum lie Afghanistan and the United States. The perpetrators of the attacks on the World Trade Center and the Pentagon, identified as Osama bin Laden and his Al-Qaeda organization, operating out of Afghanistan, chose as their targets the symbols and the operating centers of America’s military operations and of its economic infrastructure.

The recession of the late 2000s and early 2010s has illustrated the vulnerability of global economic systems to disruption. With hundreds of thousands thrown out of work and with investment capital drying up, the entire economic infrastructure of the world has already suffered a great blow without direct cyberattacks. Every effort must be bent toward preventing attacks that imperil the economic infrastructure of the world. Security can no longer be the duty of a few technical people; it has become everyone's responsibility.

14.4 SOURCES OF THREATS AND ATTACKS. The actual and potential originators of information warfare are numerous and powerful. One need not be paranoid to feel that an attack may come from any direction. This section lists sources that have already proven their capabilities for conducting cyberwar.

14.4.1 Nation-States. U.S. military preparations for cyberwar have been described in Section 14.3.2. This section details some of the measures that another great power—China—is effecting toward the same ends. Most of the material is from a paper entitled “Like Adding Wings to the Tiger: Chinese Information War Theory and Practice.”³⁰

14.4.1.1 China and Information Warfare. Although China is a nuclear power, it does not yet have the arsenal necessary to threaten a superpower like the United States. However, it can do so with its IW forces; adding wings to the tiger makes it more combat worthy. Nor is Chinese IW entirely theoretical. On August 3, 2000, the *Washington Times* reported that hackers suspected of working for a Chinese government institute took large amounts of unclassified but sensitive information from a Los Alamos computer system. A spokesman stated that “an enormous amount of Chinese activity hitting our green, open sites” occurs continuously.³¹

According to an article in the Chinese Armed Forces newspaper, the *Liberation Army Daily*, their first attack objectives will be the computer networking systems that link a country's political, economic, and military installations, as well as their general society.³² A further objective will be to control the enemy's decision-making capability in order to hinder coordinated actions.

Expanding on Mao Zedung's theory of a People's War, IW can be “carried out by hundreds of millions of people using open-type modern information system.”³³ In this war, combatants can be soldiers or teenagers, or anyone who has a computer as a weapon.³⁴ Ironically, China, with its long-standing fear of outside information as a possible spur to counterrevolutionary action, now views arming large numbers of intelligent people with computers and access to the Internet as a necessary survival measure. It remains to be seen just how many personal computers will be made available and how China will ensure that they will be used only as the government intends.

The “Annual Report to Congress on the Military Power of the People's Republic of China” from the U.S. Department of Defense has been issued every year since 2002. Reading through all the reports provides valuable perspective on the DoD view of information warfare capabilities of the People's Republic of China (PRC) and the People's Liberation Army (PLA). The 2011 edition included the following analysis:

- **Cyberwarfare Capabilities.** In 2010, numerous computer systems around the world, including those owned by the U.S. Government, were the target of intrusions, some of which appear to have originated within the PRC. These intrusions were focused on exfiltrating information. Although this alone is a serious concern, the accesses and skills required for these intrusions are similar to those necessary to conduct computer network attacks. China's 2010 *Defense*

14 · 18 INFORMATION WARFARE

White Paper notes China's own concern over foreign cyberwarfare efforts and highlighted the importance of cybersecurity in China's national defense.

- Cyberwarfare capabilities could serve PRC military operations in three key areas. First and foremost, they allow data collection through exfiltration. Second, they can be employed to constrain an adversary's actions or slow response time by targeting network-based logistics, communications, and commercial activities. Third, they can serve as a force multiplier when coupled with kinetic attacks during times of crisis or conflict.
- Developing capabilities for cyberwarfare is consistent with authoritative PLA military writings. Two military doctrinal writings, *Science of Strategy* and *Science of Campaigns*, identify information warfare (IW) as integral to achieving information superiority and an effective means for countering a stronger foe. Although neither document identifies the specific criteria for employing computer network attack against an adversary, both advocate developing capabilities to compete in this medium.
- The *Science of Strategy* and *Science of Campaigns* detail the effectiveness of IW and computer network operations in conflicts and advocate targeting adversary command and control and logistics networks to impact their ability to operate during the early stages of conflict. As the *Science of Strategy* explains,

—In the information war, the command and control system is the heart of information collection, control, and application on the battlefield. It is also the nerve center of the entire battlefield. [Emphasis ours.]³⁵

In parallel with its military preparations, China has increased diplomatic engagement and advocacy in multilateral and international forums where cyberissues are discussed and debated. Beijing's agenda is frequently in line with the Russian Federation's efforts to promote more international control over cyberactivities. China has not yet agreed with the U.S. position that existing mechanisms, such as International Humanitarian Law and the Law of Armed Conflict, apply in cyberspace. China's thinking in this area is evolving as it becomes more engaged."

14.4.1.2 Strategies. The People's Liberation Army (PLA) with 1.5 million reserve troops has been carrying out IW exercises on a wide scale. One such exercise, in Xian Province, concentrated on conducting information reconnaissance, changing network data, releasing information bombs, dumping information garbage, disseminating propaganda, applying information deception, releasing clone information, organizing information defense, and establishing spy stations.³⁶ The antecedents of these tactics can be found in a book of unknown authorship, first mentioned about 1,500 years ago, entitled *The Secret Art of War: The 36 Stratagems*. Strategy 25 advises:

Replace the Beams with Rotten Timbers. Disrupt the enemy's formations, interfere with their methods of operations, change the rules which they are used to following, and go contrary to their standard training. In this way you remove the supporting pillar, the common link that makes a group of men an effective fighting force.³⁷

The 36 stratagems deserve close study; many of them are obviously in use even today by China and others. For example, strategy 3 says:

Kill with a Borrowed Sword. When you do not have the means to attack your enemy directly, then attack using the strength of another.

Lacking the weapons to attack the United States directly, the perpetrators of the WTC attack used the airliners belonging to their targets.

Strategy 5 says:

Loot a Burning House. When a country is beset by internal conflicts, when disease and famine ravage the population, when corruption and crime are rampant, then it will be unable to deal with an outside threat. This is the time to attack.

Some of the strategies might well be employed by the United States. For example, strategy 33 advises:

The Strategy of Sowing Discord. Undermine your enemy's ability to fight by secretly causing discord between him and his friends, allies, advisors, family, commanders, soldiers, and population. While he is preoccupied settling internal disputes his ability to attack or defend, is compromised.

To accomplish this, IW may prove to be an effective weapon.

14.4.1.3 Training. Several high-level academies and universities have been established to conduct IW instruction for the PLA. In addition, training is planned for large numbers of individuals to include:

- Basic theory, including computer basics and application, communications network technology, the information highway, and digitized units
- Electronic countermeasures, radar technology
- IW rules and regulations
- IW strategy and tactics
- Theater and strategic IW
- Information systems, including gathering, handling, disseminating, and using information
- Combat command, monitoring, decision making, and control systems
- Information weapons, including concepts, principles of soft and hard destruction, and how to apply these weapons
- Simulated IW, protection of information systems, computer virus attacks and counterattacks, and jamming and counterjamming of communications networks³⁸

It is doubtful that all of these training objectives have been accomplished, but there seems to be a major commitment to do so, and sooner rather than later.

China and the United States are only two of the nations that are openly preparing for, and actually engaged in, information warfare. It is obvious that many others are similarly involved and that these measures, combined with conventional weapons or weapons of mass destruction, have the potential to elevate warfare to a destructive level never before possible and hardly conceivable.

14.4.2 Cyberterrorists

"Cyberterrorism" means intentional use or threat of use, without legally recognized authority, of violence, disruption, or interference against cybersystems, when it is likely that such use would result in death or injury of a person or persons, substantial damage to physical property, civil disorder, or significant economic harm.³⁹

Cyberterrorists, those who engage in cyberterrorism, generally are able to carry out the same sort of cyberwar as nation-states; in fact, they may be state-sponsored. The major difference is that terrorist attacks are usually hit-and-run, where nations are capable of sustained and continuous operations. Although conventional warfare always was carried out in an overt fashion, it is the nature of IW that it can be engaged in without a declaration of war and without any clear indication of who the attacker actually is. In fact, it may not be recognized that a war is being conducted; it may

14 · 20 INFORMATION WARFARE

seem only that a series of unfortunate, unconnected natural failures of computers and communications are disrupting an economy.

Terrorists, especially when state-sponsored, would be very likely to conceal their IW activities in this manner, so as to avoid the retribution that would inevitably follow. However, some terrorists would publicly take credit for their actions, in order to bolster their apparent strength and to gather added support from like-minded individuals and organizations.

The seriousness of terrorist threats after 9/11 resulted in Executive Order 13228 of October 8, 2001, establishing the Office of Homeland Security and the Homeland Security Council.⁴⁰ The mission of the Office was to “develop and coordinate the implementation of a comprehensive national strategy to secure the United States from terrorist threats or attacks.” Its function was “to coordinate the executive branch’s efforts to detect, prepare for, prevent, protect against, respond to, and recover from terrorist attacks within the United States.”

The Department of Homeland Security was mandated by Congress on January 24, 2003, and was fully formed on March 1, 2003. Celebrating its tenth anniversary in 2013, the department employs more than 200,000 people dedicated to fulfilling its mission.

On February 15, 2005, Michael Chertoff was sworn in as the second secretary. His five goals:

1. Protect our Nation from Dangerous People
2. Protect our Nation from Dangerous Goods
3. Protect Critical Infrastructure
4. Strengthen our Nation’s Preparedness and Emergency Response Capabilities
5. Strengthen and Unify Operations and Management⁴¹²⁶

On April 30, 2008, Secretary Chertoff, recognizing new realities, said:

[T]he technology of the 21st Century is changing so rapidly that many of our rules and procedures, which were built at a time that we had a certain kind of communication system and a certain kind of analog set of processes, that legal structure seems woefully inadequate to a digital age when the movement of communications is not rooted in any one place and when it’s very difficult to take the concepts which made a lot of sense in the days of the rotary telephone and apply them in the world of voice over internet protocols.⁴²

In March 2010, a report on comments by FBI Director Robert Mueller and former White House “terrorism czar” Richard Clarke included this summary:

“As you well know, a cyber-attack could have the same impact as a well-placed bomb,” Mueller said. “In the past 10 years, Al-Qaeda’s online presence has become as potent as its in-world presence.”

Al-Qaeda uses for the Internet range from recruiting members and inciting violence to posting ways to make bio-weapons and forming social-networks for aspiring terrorists, according to Mueller. “The cyber-terrorism threat is real and rapidly expanding,” Mueller said. “Terrorists have shown a clear interest in hacking skills and combining real attacks with cyber attacks.”

Threats are also rising from online espionage, with hackers out for source code, money, trade, and government secrets, according to the FBI. “Every major company in the U.S. and Europe has been penetrated—it’s industrial warfare,” said Richard Clarke, who was a White House adviser under three prior U.S. presidents. “All the little cyber-devices that the companies here sell have been unable to stop them. China and Russia are stealing petabytes of information.”

Clarke, now a partner at Good Harbor Consulting firm, was among the RSA panelists discussing cyber-warfare. “Nation states have created cyber-warfare units. They are preparing the battlefield,” Clarke said. “We have the governments of China and Russia engaging in daily activities successfully that the U.S. government and private industry are not stopping and they are stealing anything worth stealing. ...

Mueller urged computer security professionals to join in a united, international alliance with law enforcement agencies to battle enemies in cyberspace. He credited such teamwork with resulting in the recent arrest of three men in Spain suspected of running a network of nearly 13 million computers secretly infected with malicious software and used for nefarious deeds.

Mueller called on victims of cyber-attacks to break the pattern of remaining silent out of fear that reporting crimes would hurt their positions in the marketplace. “Maintaining the code of silence will not benefit you or your clients in the long run,” Mueller said. “We must continue to do everything we can together to minimize and stop these attacks.”⁴³

The challenges faced by the Department of Homeland Security are multitudinous and complex. Whether it proves effective in reducing or eliminating terrorism within the United States will depend on solving the problems of overlapping authorities, inertia, incompatible databases, turf wars, funding, management, the predictability of terrorist actions, and a host of political and technological issues.

14.4.3 Corporations. The threats aimed at or directed by corporations are far less deadly than those of the military or of terrorists, but they are no less pervasive. Thefts of data, denial of service, viruses, and natural disasters traditionally have been at the heart of individual corporate security concerns. These concerns have not abated, but to them have been added fears that attacks on large segments of the information infrastructure are more likely to create damage than is an attack against any single enterprise. To guard against this, every installation should operate behind strong firewalls and effective access controls.

In the wake of the September 11 attacks, Richard Clarke, who had been National Coordinator for Security, Infrastructure Protection, and Counterterrorism since May 1998, was appointed to a new post. As special advisor to the president for cyberspace security, Mr. Clarke warned that terrorists are out to hurt our economy and that they can use viruses in massive, coordinated attacks against corporate IT systems. He recommended, at a minimum, that disaster recovery plans include near-online, offsite backup facilities and redundant communications paths.

14.5 WEAPONS OF CYBERWAR. The weapons used in information warfare have existed for many years, but newer and more malevolent versions are produced with increasing frequency. For this reason, system security cannot be considered as static, but rather as part of an ongoing process that must be continuously monitored and strengthened. This section briefly describes the most common and most dangerous IW weapons, with references to other chapters where more detailed information is available.

14.5.1 Denial of Service and Distributed Denial of Service. Denial of service (DoS) and distributed denial of service (DDoS) are means by which computers, network servers, and telecommunications circuits can be partially or completely prevented from performing their designated functions. Any computer element that has been designed for a specific maximum capacity, if flooded by messages or data inputs that greatly exceed that number, can be slowed or even brought to a complete halt.

14 · 22 INFORMATION WARFARE

A DoS attack is carried out by a single computer that has been programmed to overwhelm the target system's capacity, usually by generating, automatically, a very large number of messages. A DDoS attack is implemented by planting a small program on hundreds or thousands of unaware computers. At a signal from the attacker, all of the agents (sometimes called zombies or daemons) are caused to send many messages simultaneously, thus flooding the victim's system or preempting all of its bandwidth capacity.

On April 26, 2007, a page-one article in the *New York Times* reported on what some Estonian authorities described as the first war in cyberspace. It was precipitated by the removal from a park in Tallinn of a bronze memorial to the Soviet soldiers of World War II. It was believed, but not proven, that the Russian government, or individual activists, had used DDoS attacks to bring down computers propagating the Websites of the Estonian president, prime minister, and Parliament as well as of banks and newspapers. The attacks were finally brought under control with the help of experts from NATO, the European Union, the United States, Finland, Germany, Slovenia, and Israel. Details of many DoS and DDos attacks and the recommended defenses are contained in Chapter 18 of this *Handbook*.

14.5.2 Malicious Code. Malicious code includes viruses, worms, and Trojan horses, as described in Chapter 16. Mobile code, such as Java, ActiveX, and VBScript, was developed to increase the functionality of Websites, but all three, as described in Chapter 17, also can be used maliciously.

There have been innumerable instances where malicious code has been used to damage or deface Websites, both civilian and military. Apparently, all of these exploits have been perpetrated by single individuals or by very small groups of unaffiliated crackers. However, in the event of actual cyberwar, it seems certain that large groups of coordinated, technically knowledgeable attackers will attempt to wreak havoc on their opponents' infrastructures through the use of malicious code.

In 2012, news reports indicated that Flame, malware with a relationship to Stuxnet, may, similarly, have been developed by U.S. and Israeli cyberwarfare specialists. Flame was not used for sabotage but rather for data theft.⁴⁴ It was held to be responsible for stealing Iranian passwords, network descriptors, and even data files. Armed with this information, Stuxnet was allegedly used to destroy Iranian centrifuges enriching uranium as a component of atomic weapons. It accomplished this by controlling the controllers that set the speed of the centrifuges. When the speeds were set excessively high, they damaged or destroyed the centrifuges.

Because most of the hardware elements of these systems are commercially available, and because the software is readily duplicated, the threats to military and commercial applications are imminently capable of extensive and costly attacks. Just as U.S. military and governmental agencies, and most of their allies, are engaged in large-scale operations to develop defensive capabilities, it is essential that all commercial enterprises exert major efforts to do the same. Initiatives have begun to form close working relationships between government and the private sector. Also, industry groups have begun advocating relaxation of those laws that prohibit close cooperation between competitors. This will be necessary before information can be shared as required to strengthen the infrastructure. Similarly, groups are requesting that shared information be protected from those who would use the Freedom of Information Act to force disclosure.

Every prudent organization will support these initiatives and will work with appropriate government agencies and industry groups to ensure its own survival and the welfare of the country itself.

14.5.3 Cryptography. Military operations, since the earliest recorded times, have utilized cryptography to prevent critical information from falling into enemy hands. Today, information is a vastly more important resource than ever before, and the need for cryptography has increased almost beyond measure. Not only the military, but indeed every financial institution, every competitive commercial enterprise, and even many individuals feel impelled to safeguard their own vital information. At the same time, access to the secret information of enemies and opponents would provide inestimable advantages.

Recognizing this, powerful supercomputers, directed by mathematicians, theoretical scientists, and cryptographers, are being applied to improving the processes of encryption and decryption. The most notable achievement in the recent past was the British construction of a computerized device to break the German Enigma code. The information thus obtained has been widely credited with a significant role in the outcome of World War II.

The development of effective mechanisms for spreading computations over millions of personal computers has greatly reduced the time required for brute force cracking of specific encrypted messages; for example, messages encrypted using the 56-bit Digital Encryption Standard (DES) were decrypted in four months using 10,000 computers in 1997, 56 hours using 1,500 special-purpose processors in 1998, and 22 hours using 100,000 processors in 1999.⁴⁵

A major issue, yet to be resolved, is the strength of cryptographic tools that may be sold domestically or exported overseas. The contending forces include producers of cryptographic tools who believe that if the strength of their product is in any way restricted, they will lose their markets to producers in other countries with more liberal policies. Similarly, proponents of privacy rights believe that unbreakable cryptographic tools should be freely available.

The countervailing view is that virtually unbreakable cryptographic tools shipped overseas will inevitably find their way into the hands of unfriendly governments, which may use them in conducting cyberwars against us. Domestically, law enforcement agencies believe that they should have “back-door” entry into all cryptographic algorithms, so that they may prevent crimes as wide-ranging as embezzlement, drug trafficking, and terrorism.

As domestic crimes and terrorist attacks grow in number and intensity, it seems certain that at least a few civil liberties, including privacy rights, may be infringed. The hope is that an optimum balance will be struck between the need for security and the core values of our democracy.

For more on privacy in cyberspace, see Chapter 69 in this *Handbook*.

14.5.4 Psychological Operations. Psychological operations (PSYOP) may be defined as planned psychological activities directed to enemy, friendly, and neutral audiences in order to influence their emotions, motives, attitudes, objective reasoning, and behaviors in ways favorable to the originator. The target audiences include governments, organizations, groups, and individuals, both military and civilian.

One of the most potent weapons in information warfare, PSYOP attempts to:

- Reduce morale and combat efficiency within the enemy’s ranks
- Promote mass dissension within, and defections from, enemy combat units and/or revolutionary cadres

14 · 24 INFORMATION WARFARE

- Support our own and allied forces cover and deception operations
- Promote cooperation, unity, and morale within one's own and allied units, as well as within friendly resistance forces behind enemy lines⁴⁶

The information that accomplishes these ends is conveyed via any media: by printed material such as pamphlets, posters, newspapers, books, and magazines, and by radio, television, personal contact, public address systems, and of increasing importance, through the Internet.

A classic example of successful PSYOP application was the deception practiced prior to the Allied invasion of the European mainland. Through clever “leaks,” false information reached Germany that General Patton, America’s most celebrated combat commander, was to lead an army group across the English Channel at Pas de Calais. As a consequence, German defensive forces were concentrated in that area. For weeks after the Normandy invasion was mounted, Hitler was convinced that it was just a feint, and he refused to permit the forces at Calais to be redeployed. Had this PSYOP failed, and had more of Germany’s defensive forces been concentrated in Normandy, the Allied landing forces might well have been thrown back into the sea.

Although generally considered not to involve a PSYOP action, the September 11 attacks and the subsequent spread of anthrax spores made clear that a physical action can have the greatest and most far-reaching psychological effects. Beyond mourning the death of almost 3,000 innocent civilians, the new sense of vulnerability and powerlessness caused great psychological trauma throughout the nation and much of the Western world. The full consequences to the travel, entertainment, and hospitality industries, as well as to every segment of the world economy, are likely to be both disastrous and long-lasting.

A major, integrated, expert PSYOP mission to restore morale and encourage behavior can halt or reverse a downward spiral, but worldwide recessions and acts of nature, such as cyclones, hurricanes, and earthquakes, can do more than PSYOP actions to demoralize a nation.

14.5.5 Physical Attacks. Prior to September 11, 2001, physical attacks, as a part of cyberwar, were generally considered in the same light as attacks against any military objective, and defensive measures were instituted accordingly. In the civilian sector, starting with student attacks against academic computers in the 1960s and 1970s, there have been occasional reported physical attacks against information processing resources. Although access controls have been almost universally in place, their enforcement often has been less than strict.

Another indication of the susceptibility of the information infrastructure to physical attack is the prevalence of “backhoe attacks” in which construction crews accidentally slice through high-capacity optic cables used for telecommunications and as part of the Internet backbones.⁴⁷ The signs indicating where not to dig can serve as markers for those targeting single points of failure.

A related vulnerability is undersea telecommunications cables, which are unprotected against accidental—or deliberate—damage from ship anchors and from other objects or tools. Breaks in these cables can interrupt the Internet and telephone networks on a global scale.⁴⁸

The destruction of the WTC and a portion of the Pentagon have brought the possibility of additional physical attacks very much into the forefront of cyberwar thinking, for both the military and the civilian infrastructures. Car bombings and packaged bombs

had become almost commonplace, especially in the Mideast. Successful attacks had been launched against U.S. embassies and troop barracks, as well as against Israel, England, Spain, and France. To guard against such actions, perimeter defenses were widened, and in some areas personal searches at strategic points were instituted.

These defenses have proven to be of limited value, and suicide bombers seem to be increasing in numbers and in the effectiveness of their weapons. The use of commercial aircraft, fully loaded with fuel, as manned, guided missiles was apparently never considered prior to 11 September. After that date, there has been widespread recognition that protective measures must be taken that will prevent a recurrence of those tragic events. Airport security has become a direct federal responsibility, under a new Transportation Security Administration in the Department of Transportation. On November 11, 2001, President Bush signed a bill that requires all airport baggage screeners to be U.S. citizens and to undergo criminal background checks before becoming federal employees. At many airports, security is provided by private contractors. The protective measures in common use are considered to be pointless, inconvenient, and ineffective by many travelers. Although even minimal safeguards against known weapons are being debated, there appears to be little thinking directed toward other types of attacks that might even now be in the planning stage.

14.5.6 Biological and Chemical Weapons and Weapons of Mass Destruction. Although the use of these weapons can affect every element of society, they have a particular potency in destroying the infrastructure of a targeted nation. The WTC attacks have had long-lasting psychological effects, but the results of the anthrax dissemination may be even more deeply traumatic. Already, the presence of anthrax spores has interfered with the functioning of the Congress, the Supreme Court, the U.S. Postal Service, hospitals, and other institutions. Although the furor over these attacks, as well as their incidence, has dissipated, there may be even more such attacks in the future. Unless any future culprit is apprehended quickly, and countermeasures taken immediately, damage to the infrastructure could be extensive.

14.5.7 Weapons Inadvertently Provided. There are many widespread vulnerabilities to computer systems that are not created as weapons, but whose presence makes the targets of cyberwar highly vulnerable. Poor software designs and inadequate quality control create opportunities for attackers to damage or destroy information, and the information systems themselves. Chapters 38 to 40 of this *Handbook* are especially useful in identifying and eliminating these sources of security vulnerabilities.

14.6 DEFENSES. A variety of defenses may be employed both to prevent attacks and to mitigate their effects. Because each of these defenses may have only limited utility, it is evident that new and more effective defenses must be developed.

14.6.1 Legal Defenses. As a defense against IW attacks or as a framework for apprehending and prosecuting attackers, the international legal system has been generally ineffective. The reasons for this include:

- Information warfare is not prohibited under the United Nations (UN) Charter, unless it directly results in death or property damage.
- Laws that are not recognized and enforced lose their power to compel actions.
- There is little or no police power to enforce those few laws that do exist.

14 · 26 INFORMATION WARFARE

- The issue of sovereignty as it relates to transborder communications is unresolved.
- Neither the United States nor any other major power has pressed for international laws to govern information warfare. This may be attributed to the fact that such laws, while desirable for defense, would impair the nation's own offensive operations.
- Many nations do not recognize cyberwar attacks as criminal actions.
- In many lands, political considerations determine judicial outcomes.
- Few countries support extradition of their citizens even when indicted for terrorist or criminal activities.
- Terrorists, drug cartels, the international mafia, and even individual hackers have every reason to circumvent the law, and usually possess the resources that enable them to do so.
- Identifying attackers may be difficult or even impossible.
- New technologies arrive at a rate much faster than appropriate legislation.

Further acting to constrain law as a deterrent is the fact that there has been no universal acceptance of definitions for IW-relevant terminology: Attacks, acts of war, aggression, hostilities, combatants, crimes, criminals—all remain vague concepts. Until such terms, as applied to IW, are clearly defined, there can be no legal strictures against them.

The difference between acceptable and unacceptable targets is obscured by the dual-use, civilian and military, characteristics of infosystems and infrastructures. Similarly, it is difficult to condemn denial of service, when peacetime boycotts and economic sanctions are widely applied to further economic or political ends.

Clearly, legal defenses against cyberwar are inadequate at this time. Whether the United States will pursue effective international legislation remains doubtful, until the question of building adequate defenses, without hobbling offensive operations, is resolved.

14.6.2 Forceful Defenses. If IW attacks are accepted as acts of war, the use of retaliatory military force would be highly likely. The strategic and tactical decisions that would follow are well beyond the scope of this chapter, but six considerations are relevant.

1. The United States is growing reluctant to engage in combat without the sanction of the United Nations and without the concurrence of major allies. If the provocation is limited to an IW attack, it may be difficult to build a coalition or even to avoid UN condemnation.
2. The identity of the attacker may be unclear. Even after the September 11 attacks, the United States had no enemy that admitted culpability. As a consequence, the United States could not declare war on any nation or state but could only declare a war on "terrorism."
3. The attacker may be misidentified. Through the use of "spoofing" and routing an attack through unaware nations, the anonymous culprit may escape detection, while blame falls on an innocent victim.
4. There may be difficulty in determining whether a particular event is an act of information warfare or simply the result of errors, accidents, or malfunctions.
5. The attackers may not be a foreign government, against whom war can be declared, but a criminal organization, a disaffected group, activists, commercial competitors, or even individuals bent on mischief.

6. The United Nations, and international sentiment in general, requires that military force only be used in response to armed attack and, further, that the response be proportional to the attack that provoked it.

In light of these considerations, it seems unlikely that information warfare, unless it results in catastrophic injuries and deaths, will be met by a forceful reaction. The top secret Presidential memo leaked on June 7, 2013, and discussed in Section 14.3.3 clearly indicates that armed actions may now be initiated without the impetus of injuries and deaths.

14.6.3 Technical Defenses. The technical defenses against IW are many and varied. Almost the entire contents of this volume are applicable to safeguarding against cyberwar attacks. These same measures can prove equally effective in defending against IW, criminals, activists, competitors, and hackers.

14.6.4 In-Kind Counterattacks. A cyberwar defense that has been used often is an in-kind counterattack, where flaming is met by flaming, DDoS by DDoS, site defacement by site defacement, and propaganda by propaganda. Recent examples include exchanges between Israelis and Arabs, Kashmiris and Indians, Serbs and Albanians, Indians and Pakistanis, Taiwanese and Chinese, and Chinese and Americans.

Although there may be personal satisfaction in originating or responding to such attacks, the net effect is usually a draw, and, therefore, in-kind attacks generally have been short-lived. In the future, such attacks may no longer be the output of only a few individuals, but may be mounted by large numbers of similarly minded cyberwarriors, organized into coordinated groups, with sophisticated tools and with covert or overt state sponsorship.

In that event, the asymmetric nature of the adversaries' infrastructures would be telling. Clearly, if the Taliban, for example, were to mount another full-scale cyberterrorist attack against the United States with the help of their supporters throughout the world, the effects could be devastating. Although the United States might mount a highly sophisticated in-kind response, it probably would have no effect on the Taliban's organization, its economy, its military effectiveness, or its ability to carry out suicide missions, biological warfare, or other physical attacks. A great and powerful nation may lack the ability to destroy a small, primitive, almost nonexistent infrastructure.

A serious problem with any kind of counterattack is that the origins of cyberattacks through the Internet using Internet Protocol version 4 (IPv4) are easily masked, or *spoofed*, because of the lack of mandatory, verifiable source authentication. It is possible that poorly analyzed data about the supposed attackers could lead to a counterattack against innocent victims.

14.6.5 Integration of Cyberwarfare into Military Planning. The United States Cyber Command (USCYBERCOM) was initiated in 2009 as a subset of the United States Strategic Command and became fully operational in its Fort Meade headquarters in 2010.⁴⁹ Its mission and focus are defined as follows:

- Mission: USCYBERCOM is responsible for planning, coordinating, integrating, synchronizing, and directing activities to operate and defend the Department of Defense information networks and when directed, conducts full-spectrum military cyberspace operations (in accordance with all applicable laws and regulations) in order to ensure U.S. and allied freedom of action in cyberspace, while denying the same to our adversaries.

14 · 28 INFORMATION WARFARE

- Focus: The command is charged with pulling together existing cyberspace resources, creating synergy that did not previously exist and synchronizing war-fighting effects to defend the information security environment.
- The Command centralizes direction of cyberspace operations, strengthens DoD cyberspace capabilities, and integrates and bolsters DoD's cyberexpertise. USCYBERCOM improves DoD's capabilities to ensure resilient, reliable information and communication networks, counter cyberspace threats, and assure access to cyberspace. The command works closely with interagency and international partners in executing the cybermission.

USCYBERCOM has initiated training exercises for U.S. military forces. The first *Cyber Flag* exercise was held in 2011 at Nellis Air Force Base; the second was in 2012.⁵⁰ The 2012 "... exercise saw approximately 700 participants, up from last year's 300, and doubled the network size. All participants had a specific role to play, playing the part of a U.S. team or role-playing an adversary."

In January 2013, plans surfaced for a major investment by the Pentagon in cybersecurity:

The expansion would increase the Defense Department's Cyber Command by more than 4,000 people, up from the current 900, an American official said. Defense officials acknowledged that a formidable challenge in the growth of the command would be finding, training, and holding onto such a large number of qualified people.

The Pentagon "is constantly looking to recruit, train and retain world class cyberpersonnel," a defense official said Sunday.

"The threat is real and we need to react to it," said William J. Lynn III, a former deputy defense secretary who worked on the Pentagon's cybersecurity strategy.

As part of the expansion, officials said the Pentagon was planning three different forces under Cyber Command: "national mission forces" to protect computer systems that support the nation's power grid and critical infrastructure; "combat mission forces" to plan and execute attacks on adversaries; and "cyberprotection forces" to secure the Pentagon's computer systems.⁵¹

14.6.6 Cooperative Efforts. Although the United States has been moderately successful in building coalitions in support of military operations, it has shown little inclination to build an international consensus dealing with information warfare. This may be so because of the legal difficulties outlined in Section 14.6.1 or because any prohibitions against offensive cyberwar will limit United States options. Nevertheless, whether by treaty, convention, agreement, or UN directive, technical people, diplomats, and statesmen of all well-intentioned countries should work together to define unacceptable and harmful actions and to devise means for detecting, identifying, and punishing those who transgress.

In June 2013, the North Atlantic Treaty Organization (NATO) representatives participated in a discussion of "how best to defend against cyber threats."⁵² NATO posted this summary of its stance:

Against the background of rapidly developing technology, NATO is advancing its efforts to confront the wide range of cyber threats targeting the Alliance's networks on a daily basis. NATO's Strategic Concept and the 2012 Chicago Summit Declaration recognise that the growing sophistication of cyber attacks makes the protection of the Alliance's information and communications systems an urgent task for NATO, and one on which its security now depends.

In June 2011, NATO adopted a new cyber defence policy and the associated Action Plan, which sets out a clear vision of how the Alliance plans to bolster its cyber efforts. This policy

reiterates that any collective defence response is subject to decisions of the North Atlantic Council, NATO's principal political decision-making body.

The revised policy offers a coordinated approach to cyber defence across the Alliance. It focuses on the prevention of cyber attacks and building resilience. All NATO structures will be brought under centralised protection and NATO will enhance its capabilities to deal with the vast array of cyber threats it currently faces, including through integrating them into the NATO Defence Planning Process. This way Allies will ensure that appropriate cyber defence capabilities are included as part of their planning to protect information infrastructures that are critical for core Alliance tasks. The revised cyber defence policy also stipulates NATO's principles on cyber defence cooperation with partner countries, international organisations, the private sector and academia.⁵³

14.7 SUMMARY. The potential for information warfare to damage or destroy the infrastructure of any nation, any corporation, or, in fact, any civilian, governmental, or military entity is unquestionable. Until now, the only incidents have been isolated and sporadic, but the possibility of sustained, coordinated, simultaneous attacks is strong. If these attacks are combined with physical, chemical, or biological warfare, the effects are certain to be devastating.

Although the types of potential attackers, and the probable weapons they will use, are well known, the available defenses do not at this time offer any great assurance that they will be effective. The United States and many of its allies are engaged in great efforts to remedy this situation, but formidable obstacles are yet to be overcome. The military is generally better prepared than the civilian sector, but much of the military's infrastructure is woven into and dependent on transportation, communications, utilities, food production and distribution, and other vital necessities that are owned by private enterprises.

Recent terrorist attacks and the probability of future offensives should serve as an immediate impetus to devote whatever resources are needed to combat the threats to our way of life and, in fact, to our very existence.

15.1 MULTIPLE FACTORS INVOLVED IN SYSTEM PENETRATION. Although penetrating computer systems and networks may sound like a technical challenge, most information security professionals are aware that systems security has both technical and nontechnical aspects. Both aspects come into play when people attempt to penetrate systems. Both aspects are addressed in this chapter, which is not an instruction guide on how to penetrate systems, but rather a review of the methods and means by which systems penetrations are accomplished.

15 · 2 PENETRATING COMPUTER SYSTEMS AND NETWORKS

15.1.1 System Security: More than a Technical Issue. The primary non-technical factor in system security and resistance to system penetration is human behavior, which can defeat just about any technical security measure. More than anything else, security depends on human beings to understand and carry out security procedures. Consequently, information system (IS) security must be integral to the culture of any organization employing an information system. Without security, systems and networks will not be able resist attempts at penetration.

Often security is represented as a structure of concentric circles. Protection of the central, secured element is then dependent on the barriers imposed by each successive ring. These barriers can be physical or figurative, but the goal of IS security is to protect the integrity, confidentiality, and availability of information processed by the system. This goal is reached using identification, authentication, and authorization. *Identification* is a prerequisite, with each user required to proffer an identifier (ID) that is included in the authorization lists of the system to be accessed. *Authentication* consists of proving that the user really is the person to whom the ID has been assigned. *Authorization* consists of defining what a specific user ID, running specified programs, can legally do on the system. The security perimeter can be penetrated by compromising any of these functions. Chapters 28 and 29 in this *Handbook* discuss identification and authentication in detail.

The trend toward distributed and mobile computers, often utilizing the global networking capability of the Internet, makes it hard to know where to draw these concentric circles of protection. Indeed, the barriers to penetration need to be extended along lines of communication, encompassing end points of the network, which may be geographically dispersed.

15.1.2 Organizational Culture. An organization's general attitude toward security is the key to an effective defense against attack. Security is difficult to sell, especially to an organization that has never experienced a significant problem. (Ironically, the better the defenses, the less evidence there is of their utility.) A basic principle of security is that practitioners must act as if they are paranoid, continuously on guard against attacks from any direction. Many organizations view security precautions as an attack on the integrity of employees. Wearing badges, for example, sometimes is viewed as dehumanizing and offensive. This attitude leads to absurdities, such as having only visitors wear badges. If only visitors wear badges, then taking off the badge automatically reduces the likelihood that a dishonest intruder will be challenged.

Some individual employees also consider security precautions as personally offensive. For example, locking a terminal or workstation when leaving it for a few minutes may be seen as evidence of distrust of other employees. Refusing to allow piggybacking—that is, permitting several colleagues to enter a restricted area on one access card—may be seen as insufferably rude. Where employees are taught to be open and collegial, securing removable computer media and paperwork at night can seem insulting.

These conflicts occur because years of socialization, starting in infancy, are diametrically opposed to the tenets of information security. Politeness in a social context is a disaster in a secure area; for instance, piggybacking into a computer room impairs the accuracy of audit trails kept by the access-control computers. Lending someone a car is kind and generous, but lending someone a user ID and a personal password is a gross violation of responsibility. Chapters 49 and 50 in this *Handbook* discuss psychological aspects of changing corporate culture to support information security.

Carrying out effective security policies and procedures must resolve these conflicts between normal standards of politeness and the standards required in a secure environment. Organizations must foster open discussion of the appropriateness of security procedures, so that employees can voluntarily create a corporate culture conducive to protection of corporate information. Chapters 44, 45, 48, and 51 in this *Handbook* specifically discuss policy issues.

Beyond this, organizations need to be aware of the security posture and attitudes of those with whom they network. These days it is quite possible for one organization's system to be operated, or even owned, by another. And people from many different organizations may be using the same network. A culture of security must permeate all of the organizations that have access to a system, otherwise points of weakness will exist, thus increasing the probability that attempts to penetrate the system will succeed.

15.1.3 Chapter Organization. Section 15.2 looks at methods of tricking people into allowing unauthorized access to systems (Chapter 19 in this *Handbook* explores social engineering in more depth). Section 15.3 examines technical measures for overcoming security barriers and specific techniques (*exploits*) for penetration, while Section 15.4 describes legal and political aspects of system penetration.

15.2 NONTECHNICAL PENETRATION TECHNIQUES. Although the penetration of information systems is often portrayed as the work of the technically adept, many successful penetrations have relied on human factors, such as gullibility and venality. Both are exploited by would-be system penetrators.

15.2.1 Misrepresentation (Social Engineering). Social engineering relies on falsehood. Lies, bribes, and seduction can trick honest or marginally dishonest employees into facilitating a penetration. An attacker might trick an employee into revealing login and authentication codes or even into granting physical access to an otherwise secure site. System penetration can then be accomplished by numerous means, from walking up to an unsecured workstation, to installing Trojan code or a network packet-sniffing device. (Both of these technologies are discussed in more detail later in this chapter.)

15.2.1.1 Lying. Telling lies is a technique often used by persons intent on obtaining unauthorized access to a system. One can obtain valuable information about a system and its defenses by telling lies. Many lies work by playing on the natural human tendency to interpret the world by our internal model of what is most likely. Social psychologists call this model the *schema*. Well-dressed businesspeople who walk briskly and talk assertively are probably what they seem. In a phone conversation, a person who sounds exasperated, impatient, and rude when demanding a new password is probably an exasperated, impatient, and rude employee who has forgotten a password. Unfortunately, many criminals know, sometimes instinctively, how to exploit these interpretations to help get them into secured systems.

Another technique, often used in concert with lying, is to escape notice and avoid suspicion by simply blending in. The way we perceive, or fail to perceive, details are referred to by social psychologists as the figure-ground problem. The normal becomes the background, and the objects of our attention become figures standing out from the ground. The schema influences what is noticed; only deviations from expectation spark figure-ground discrimination. Criminal hackers take advantage of this effect by fading into the background while penetrating security perimeters.

15 · 4 PENETRATING COMPUTER SYSTEMS AND NETWORKS

15.2.1.2 Impersonating Authorized Personnel. Criminal hackers and unscrupulous employees call security personnel, operators, programmers, and administrators to request user IDs, privileges, and even passwords. (This is one reason that the telephone is a poor medium for granting security privileges; if staff members were trained to refuse requests made over the phone, many attempts to penetrate systems could be thwarted.) In sites where employees wear ID badges, intruders have a hard time penetrating physical security by posing as employees. However, physical security in these cases depends on the cooperation of all authorized personnel to challenge everyone who fails to wear a badge. This policy is critically important at entry points. To penetrate such sites physically, criminals must steal or forge badges or work with confederates to obtain real but unauthorized badges.

Sites where physical security includes physical tokens, such as cards for electronic access control, are harder for criminals to penetrate. They must obtain a real token, perhaps by theft or by collusion with an employee. Perimeter security depends on keeping the access codes up to date so that cards belonging to ex-employees are inactivated. Security staff must immediately inactivate all cards reported lost. In addition, it is essential that employees not permit *piggybacking*, the act of allowing another person, possibly unauthorized, to enter a restricted zone along with an authorized person. Too often, an employee, in an act of politeness, will permit others to enter a normally locked door as he or she exits. Once inside a building, criminals can steal valuable information that will allow later penetration of the computer systems from remote locations. This is often accomplished by impersonating third-party personnel.

Even if employees are willing to challenge visitors in business suits, it may not occur to them to interfere with people who look as if they are employees of an authorized support firm. For example, thieves often have succeeded in entering a secured zone by dressing like third-party computer technicians or office cleaners. Few employees will think of checking the credentials of a weary technician wearing grimy overalls, an authentic-looking company badge, a colorful ID card, and a tool belt. When a suitable-looking individual claims to have been called to run diagnostics on a workstation, many nontechnical employees will acquiesce at once, seizing the opportunity to grab a cup of coffee or to chat with colleagues. Minutes later, the thief may have copied sensitive files or installed a sniffing device (e.g., a keystroke recorder or a network packet sniffer). In one case known to one of the authors (MK), a criminal was given a workspace and a network connection in a large bank and allowed to work unmolested and unchallenged for several months on a “secret project.” It was only when an alert security guard realized that no one in the office knew who this person was that she challenged the intruder and broke the scam.

15.2.1.3 Intimidation. A technique related to impersonation of authorized or third-party personnel is intimidation. Someone claiming to be a person in a position of authority displays irritation or anger at delays in granting an unauthorized deviation from policy, such as communicating a password over the phone to a person of unauthenticated identity. The attackers indirectly or directly threaten alarming consequences (e.g., delays of critical repairs, financial losses, disciplinary actions) unless they are granted restricted information or access to secured equipment or facilities.

15.2.1.4 Subversion. People make moral choices constantly. There is always a conscious or unconscious balancing of alternatives. Criminal hackers try to reach

their goals by changing the rules so that dishonesty becomes more acceptable to the victim than honesty.

15.2.1.5 Bribery. A lot of industrial and commercial information has a black market value. The same is true of personally identifiable information that can be used to commit fraud and identity theft. The price of a competitor's engineering plans or customer database may be a year's salary for a computer operator responsible for making backups. There is little likelihood that anyone would notice the subverted operator copying a backup at 3:00 A.M. or a secretary taking an extra compact disc out of the office. Many organizations have failed to install software to prevent a manager sending electronic mail with confidential files to a future employer.

That industrial espionage, with or without state sponsorship, is a thriving business is a fact that is now widely—and sometimes quite openly—acknowledged.¹ Building a corporate environment in which employees legitimately feel themselves to be part of a community is a bulwark against espionage. When respect and a sense of exchange for mutual benefits inform the corporate culture, employees will rebuff spies or even entrap them, but the disgruntled employee whose needs are not addressed is a potential enemy.

15.2.1.6 Seduction. Sometimes criminal hackers and spies have obtained confidential information, including access codes, by tricking employees into believing that they are loved. This lie works well enough to allow access to personal effects, sometimes after false passion or drugs have driven the victim into insensibility. It is not unknown for prostitutes to seduce men from organizations that they and their confederates are seeking to crack. Rifling through customers' wallets can often uncover telltale slips bearing user IDs and passwords.

No one can prevent all such abuse. People who are enthralled by expert manipulators will rarely suspect that they are being used as a wedge through a security perimeter. Along with a general increase in security consciousness, staff members with sensitive codes must become aware of these techniques so that they may be less vulnerable. Perhaps then they will automatically reject a request for confidential information or access codes.

15.2.1.7 Extortion. Criminals can threaten harm if their demands are not met. Threaten someone's family or hold a gun to their head and few will, or should, resist a demand for entry to a secured facility or for a login sequence into a network. Some physical access-control systems include a duress signal that can be used to trigger a silent alarm at the monitoring stations. The duress signal requires a predetermined, deliberate action on the part of the person being coerced into admitting unauthorized personnel. This action may be adding an extra number to the normal pass code, pressing the pound sign (#) twice after entering the code, or entering 4357 (H-E-L-P) into the keypad. The duress signal covertly notifies security that an employee is being forced to do something unwillingly. Security can then take appropriate action.

15.2.1.8 Blackmail. Blackmail is extortion based on the threat of revealing secrets. An employee may be entrapped into revealing confidential data, for example, using techniques just described. Classic blackmail includes seduction followed by pictures in flagrante delicto, which the criminals then threaten to reveal. Sometimes a person can be framed by fabricated evidence; a plausible but rigged image of venality can ruin a career as easily as truth. Healthy respect for individuals and social bonds

15 · 6 PENETRATING COMPUTER SYSTEMS AND NETWORKS

among employees, supervisors, and management can make it difficult for blackmailers to succeed. If employees who are victims of a blackmail attempt feel they can inform management without suffering inappropriately negative consequences, the threat may be mitigated to a certain degree. Perhaps the last, best defense against blackmail is honesty. The exceptionally honest person will reject opportunities that lead to victimization through blackmail and will laugh at fabrications, trusting friends and colleagues to recognize lies when they hear them.

15.2.1.9 Insiders. Many of the world's largest and most daring robberies have, upon examination, turned out to be inside jobs. The same is true of system penetrations. Although many of the just-described techniques can be used to obtain help from the inside, some are made possible by people on the inside who decide, for whatever reason, to aid and abet criminal hackers. For example, a dishonest employee may actively seek to sell access for personal gain. Organizations should try to be alert to this eventuality, but there is very little defense against thoroughly dishonest employees when the only overt act needed to open the gates from the inside is to pass system credentials to an outsider. Chapter 13 in this *Handbook* specifically addresses insider crime.

15.2.1.10 Human Target Range. Organizations should not underestimate the range of targets at which the described techniques may be directed. Although the terms *employees*, *authorized personnel*, and *third-party personnel* are used in the preceding paragraphs, the target range includes all manner of vendors, suppliers, and contractors as well as all levels of employees—from software and hardware vendors, through contract programmers, to soft-drink vendors and cleaning staff. It may even include clients and customers, some of whom possess detailed knowledge of the organization's operations. Employees at every level are likely to be computer literate, although with varying degrees of skill. For example, it is quite possible that someone working as a janitor today knows how to operate a computer skillfully and may even know how to surf hacking sites on the Web and download penetration tools. Indeed, a janitor may have obtained the job specifically with the intent of engaging in industrial espionage, data theft, or sabotage.

In short, anyone who comes into contact with the organization has the potential to provide an attacker with information useful in the preparation and execution of an attack. The human targets of a social engineering attack may not, on an individual basis, possess or divulge critical information, but each may provide clues—pieces of the puzzle—an aggregation of which can lead to successful penetration and compromise of valuable data and resources. Use of this process is a hallmark of some of the most successful criminal hackers. The term *incremental information leveraging* was coined for this use of less valuable data to obtain more valuable data.²

15.2.2 Incremental Information Leveraging. By gathering and shrewdly utilizing small and seemingly insignificant pieces of information, it is possible to gain access to much more valuable information. This technique of incremental information leveraging is a favorite tool of hackers, both criminal and noncriminal. One important benefit of the tool that is particularly appreciated by criminal hackers is the low profile it presents to most forms of detection. By accumulating seemingly innocuous pieces of information over a period of time, and by making intelligent deductions from them, it is possible to penetrate systems to the highest level.

A prime example of this approach is seen in the exploits of Kevin Mitnick, who served almost five years behind bars for breaking into computers, stealing data, and

abusing electronic communication systems. Illegal acts committed by Mitnick include the 1981 penetration of Computer System for Mainframe Operations (COSMOS), a Pacific Bell facility in downtown Los Angeles. COSMOS was a centralized database used by many U.S. phone companies for controlling basic recordkeeping functions. Mitnick and others talked their way past a security guard and located the COSMOS computer room. They stole lists of computer passwords, operating manuals for the COSMOS system, and combinations to the door locks on nine Pacific Bell central offices. Mitnick later employed knowledge of phone systems and phone company operations to penetrate systems at Digital Equipment Corp. (DEC).

Since his release in January 2000, Mitnick has spoken about information security before Congress and at other public venues. He described social engineering as such a powerful tool that he “rarely had to resort to a technical attack.”³ As to technique, he stated, “I used to do a lot of improvising . . . I would try to learn their internal lingo and tidbits of information that only an employee would know.” In other words, by building up knowledge of the target, using a lot of information that is neither protected nor proprietary, it is possible to gain access to that which is both proprietary and protected. The power of incremental information leveraging is the equivalent of converting a foot in the door into an invitation to come inside.

Protection against incremental information leveraging and all other aspects of social engineering begins with employee awareness. Employees who maintain a healthy skepticism toward any and all requests for information provide a strong line of defense. Another powerful defense mechanism, highlighted by Mitnick, is the use of telephone recording messages, such as “This message may be monitored or recorded for training purposes and quality assurance.” An attacker who hears a message like this may think twice about proceeding with attempts to use voice calls to social engineer information from the target.

15.3 TECHNICAL PENETRATION TECHNIQUES. Technical penetration attacks may build on data obtained from social engineering, or they may be executed on a purely technical basis. Techniques used include eavesdropping, either by listening in on conversations or by trapping data during transmissions, and breaches of access controls (e.g., trying all possible passwords for a user ID or guessing at passwords). Weaknesses in the design and implementation of information systems, such as program bugs and lack of input validation, also may be exploited in technical attacks. Unfortunately, weaknesses of this nature abound in the realm of the Internet, even as more and more organizations increase their Internet connectivity, thus creating more and more potential penetration points.

15.3.1 Data Leakage: A Fundamental Problem. Unfortunately, for information security (INFOSEC) specialists, it is impossible, even in theory, to prevent the unauthorized flow of information from a secured region into an unsecured region. The imperceptible transfer of data without authorization is known as *data leakage*. Technical means alone cannot suppress data leakage.

Consider a tightly secured operating system or security monitor that prevents confidential data from being copied into unsecured files. Workstations are diskless, there are no printers, employees do not take disks into or out of the secured facility, and there are strict restrictions on taking printouts out of the building. These mechanisms should suffice to prevent data leakage.

Not really.

15 · 8 PENETRATING COMPUTER SYSTEMS AND NETWORKS

Anyone with a penchant for mnemonics or with a photographic memory could simply remember information and write it down after leaving the facility. And it is extremely difficult to prevent employees from writing notes on paper and concealing them in their clothing or personal possessions when they leave work. Unless employees are strip-searched, no guard can stop people with crib sheets full of confidential data from walking out of the building. Indeed, this is how Vasili Mitrokhin, head archivist of the KGB's First Chief Directorate, perpetrated the largest breach of KGB security ever, by smuggling thousands of handwritten copies of secret documents out of the KGB headquarters in Moscow in his shoes, socks, and other garments.⁴

Another means of data leakage is steganography, hiding valuable information in plain sight among large quantities of unexceptional information. For example, a corrupt employee determined to send a confederate information about a chemical formula could encode text as numerical equivalents and print these values as, say, the fourth and fifth digits of a set of engineering figures. No one is likely to notice that these numbers contained anything special. The more digitally inclined can use steganography software, freely available on the Internet, to hide data in image files.

The unauthorized transfer of information cannot be absolutely prevented because information can be communicated by anything that can fluctuate. Theoretically, one could transfer data to a confederate by changing the position of a window shade (slow but possible). Or one could send ones and zeroes by the direction of oscillation of a tape reel; or one could send coded information by the choice of music. Even if a building were completely sealed, it would still leak heat outward or transfer heat inward—and *that* would be enough to carry information. In practical terms, system managers can best meet the problem of data leakage by a combination of technical protection and effective management strategies.

It is also important to realize that a significant amount of data leakage occurs through innocuous intending communications from employees. It is common for employees to discuss small aspects of their jobs and work information without realizing the implications and ability of others to collate this information into far more substantial amounts. This has become particularly prevalent with the modern advent of social media. Significant amounts of information about an organization and its internal workings can be derived from employee social media pages. Consequently, social media has become a rich source of data for attackers wishing to target an organization. This approach is particularly common among attackers that target an organization through its employees using techniques such as spear-phishing.

Data loss prevention (DLP), discussed briefly in Chapter 13 in this *Handbook*, is now an established set of techniques, with numerous tools available to enforce restrictions on unauthorized data transfers to storage devices and external sites. Nonetheless, vigilance over human behavior and the effective configuration and real-time or at least frequent analysis of log records remain essential components of effective DLP.

15.3.2 Intercepting Communications. Criminal hackers and dishonest or disgruntled employees can glean access codes and other information useful to their system penetration efforts by monitoring communications. These might be between two workstations on a local area or wide area network, between a remote terminal and a host such as a mainframe, or between a client and a server on the Internet. Attackers can exploit various vulnerabilities of communications technologies. The shift to Transmission Control Protocol/Internet Protocol (TCP/IP)-based Internet communications over the last decade has brought many more communications streams into the target

range of would-be penetrators. For basic information about data communications, see Chapter 5 in this *Handbook*.

15.3.2.1 Wiretapping. Wiretapping consists of intercepting the data stream on a communications channel (even if that channel is not wire; e.g., fiber optic cable can also be tapped, as can wireless communications, although the latter sometimes are said to be sniffed rather than tapped).

15.3.2.2 Asynchronous Connections. Point-to-point data connections (e.g., using telephone modems or serial devices) have all but disappeared, but they are relatively easy to tap. Physical connection at any point on twisted pair or multiwire cables allows eavesdropping on conversations; if the line is being used for data communications, a monitor is easily attached to display and record all information passing between a node and its host. Asynchronous lines in large installations often pass through patch panels, where taps may not be noticed by busy support staff, as they manage hundreds of legitimate connections. Such communications usually use phone lines for distances beyond a few hundred meters (or about 1,000 feet).

Wiretappers must use modems configured for the correct communications parameters, including speed, parity, number of data bits, and number of stop bits, but these parameters are easy to find out by trial and error.

Countermeasures include:

- Physical shielding of cables and patch panels
- Multiplexing data streams on the same wires
- Encryption of data flowing between nodes and hosts

15.3.2.3 Synchronous Communications. Because synchronous modems are more complex than asynchronous models and because their bandwidths (maximum transmission speeds) are higher, they are less susceptible to attack, but they are not risk-free.

15.3.2.4 Dial-up Phone Lines. Used for both data and voice communications, dial-up lines supplied by local telephone companies and long-distance carriers are vulnerable to wiretapping. Law enforcement authorities and telephone company employees can install taps at central switching. Criminals can tap phone lines within a building at patch panels, within cabling manifolds running in dropped ceilings, below raised floors, or even in drywall. They also can tap at junction boxes where lines join the telephone company's external cables.

The same countermeasures apply to phone lines as to asynchronous or synchronous data communications cables.

15.3.2.5 Leased Lines. Leased lines use the same technology as dial-up (switched) lines, except that the phone company supplies a fixed sequence of connections rather than random switching from one central station to another. There is nothing inherently more secure about a leased line than a switched line; on the contrary, it is easier to tap a leased line at the central switching station because its path is fixed. However, leased lines usually carry high-volume transmissions. The higher the volume of multiplexed data, the more difficult it is for amateur hackers to disentangle the data streams and make sense of them. At the high end of leased line bandwidth

15 · 10 PENETRATING COMPUTER SYSTEMS AND NETWORKS

(e.g., carriers such as T1, T2, etc.), the cost of multiplexing equipment makes interception prohibitively expensive for all but professional or government wiretappers.

Data encryption provides the best defense against wiretapping on leased lines.

15.3.2.6 Long-Distance Transmissions. Dial-up and leased lines carry both short-haul and long-distance transmissions. The latter introduce additional points of vulnerability. Microwave relay towers carry much of the long-distance voice and data communications within a continent. The towers are spaced about 40 kilometers (25 miles) apart; signals spread out noticeably over such distances. Radio receivers at ground level can intercept the signals relayed through a nearby tower, and because microwaves travel in straight lines, rather than following the curvature of the earth, they eventually end up in space, where satellite receivers can collect them. The difficulty for the eavesdropper is that there may be thousands of such signals, including voice and data, at any tower. Sorting out the interesting ones is the challenge. However, given sufficient computing power, such sorting is possible, as is targeting of specific message streams. *Spread-spectrum* transmission, or *frequency hopping*, is an effective countermeasure.

15.3.2.7 Packet-Switching Networks. Packet-switching networks, including historical X.25 carriers such as Telenet, Tymnet, and Datapac, used packet assembler-disassemblers (PADs) to group data into packets addressed from a source to a destination. If data traveled over ordinary phone lines to reach the network, interception could occur anywhere along these segments of the communications link. However, once the data were broken up into packets (whether at the customer side or at the network side), wiretappers had a difficult time making sense of the data stream.

15.3.2.8 Internet Connections. TCP/IP connections are no harder to tap than any others, and they carry an ever-increasing array of data, from e-commerce traffic to television broadcasts and voice communications, the latter using Voice over Internet Protocol (VoIP). (See Chapter 34 in this *Handbook*.) Unless the data stream is encrypted, there are no special impediments to wiretappers. Although the tapping of fiber optic cable requires more specialized equipment than the tapping of copper cables, it is possible.

15.3.2.9 LAN Packet Capture. Local area networks (LANs) are similar to packet-switching networks: both network protocols send information in discrete packages, either over cables or radio waves. Each package has a header containing the address of its sender and of its intended recipient. Packets are transmitted to all nodes on a segment of a LAN. For more information about LANs, see Chapter 25 in this *Handbook*.

Normally a node is restricted to interpreting only those packets that are intended for it alone. However, it is possible to place devices in “promiscuous mode,” overriding this restriction. This can be done with software that surreptitiously converts a device, such as an end user workstation, into a listening device, capturing all packets that reach that node. Of course, network administrators can intentionally create a packet-capturing workstation for legitimate purposes, such as diagnosing network bottlenecks. It is also possible to connect specialized hardware called *LAN monitors* to the network, either with or without permission, for legitimate or illegitimate purposes. Sometimes called *network sniffers*, these devices and programs range from basic freeware to expensive commercial packages that can cost tens of thousands of dollars for a network with

hundreds of nodes. (The term *sniffer*, although in common use, is a registered trademark, as *Sniffer*[®], of Network General Corporation.)

The more sophisticated packet-sniffing programs allow the user to configure profiles for capture; for example, the operator can select packets passing between a host and a system manager's workstation. Such programs allow an observer to view and record everything seen and done on a workstation, including logins or encryption keys sent to a server.

Packet sniffing poses a serious threat to confidentiality of data transmissions through LANs. Most sniffing programs do not announce their presence on the network. Although it may not be apparent to the casual observer that a workstation is performing sniffing, it is possible, as a countermeasure, to scan the network for sniffing devices. Stealthier packet-sniffing technology is constantly improving, and tight physical security may be the best overall deterrence.

LAN users concerned about confidentiality should use LAN protocols that provide end-to-end encryption of the data stream or third-party products to encrypt sensitive files before they are sent through the LAN. Routers that isolate segments of an LAN or WAN (wide area network) can help limit exposure to the threat of sniffers.

15.3.2.10 Optical Fiber. Although optical fibers were once thought to be secure against interception, new developments quickly abolished that hope. An attacker can strip an optical fiber of its outer casing and bend it into a hairpin with a radius of a few millimeters (1/8 inch); from the bend, enough light leaks out to duplicate the data stream. Bryan Betts, writing in *PCWorld*, quoted

Thomas Meier, the CEO of Swiss company Infoguard. . . [who] demonstrated the technique on a fibre carrying a VOIP phone call over Gigabit Ethernet. A section of fibre from inside a junction box was looped into a photodetector called a bend coupler, and the call was recorded and then played back on a laptop.

"People claim optical fibre is harder to tap than copper, but the opposite is true—you don't even have to break the insulation, as you would with copper," Meier said. "You can read through the fibre's cladding with as little as half a dB signal loss."

He claimed that suitable bend couplers can be bought off the shelf—or from eBay—for a few hundred dollars, and connected to the extra fibre that is typically left coiled up in junctions boxes for future splicing needs.

He added that the risk is not imaginary or theoretical—optical taps have been found on police networks in the Netherlands and Germany, and the FBI investigated one discovered on Verizon's network in the United States. Networks used by U.K. and French pharmaceutical companies have also been attacked, probably for industrial espionage, he said.⁵

Luckily, most optical trunk cables carry hundreds or thousands of fibers, making it almost impossible to locate any specific communications channel. (The same is not true of fiber cables used to deliver network connectivity to individual homes and offices.) Equipment for converting optical signals into usable data remains costly, discouraging its use by casual criminal hackers.

15.3.2.11 Wireless Communications. Cable-based communications have the advantage of restricting channel access to at least theoretically visible connections. However, the rapid increase in wireless telecommunications in the last decade of the twentieth century and the first years of the twenty-first has routed increasing

15 · 12 PENETRATING COMPUTER SYSTEMS AND NETWORKS

amounts of information through a broadcast medium in which access—even unauthorized access—may be invisible to users and system administrators.

15.3.2.12 Wireless Phones. Also referred to as cordless phones, conventional wireless phones broadcast their signals, and the traffic they carry can be detected from a distance. Older cordless phones were analog and susceptible to eavesdropping from such basic devices as walkie-talkies and baby monitors. Children sometimes walked around their suburban neighborhoods with a handset from such a phone turned on; once they walked far enough away from their home to lose the signal, any new dial tone belonged to a neighbor, who might be puzzled to discover a call to the Antipodes on the next phone bill. Today's wireless phone models typically use a different set of frequencies, such as 2.4 gigahertz (GHz). These phones generally use frequency-hopping spread spectrum (FHSS) technology to make unauthorized use more difficult, and to impede eavesdropping. FHSS means the signals hop from frequency to frequency across the entire 2.4-GHz spectrum, making tapping their signals harder but by no means impossible. Wireless phones should not be used for confidential voice or data traffic unless encryption is enabled and activated. An added danger lies in hanging up a cordless phone during a conversation, since the cordless phone's base continues to transmit until switched off.

15.3.2.13 Cellular (Mobile) Phones. Early analog cellular (mobile) phone systems had an expectation of privacy equivalent to that of shouting a message through a megaphone from a rooftop. Calls on such phones were easily intercepted using scanners purchased from local electronics stores. Although encryption is possible on the newer digital cell phones that are now widely used, the encryption is not always turned on due to the burden it imposes on the cell company switching equipment. Check with the carrier before assuming that cell calls are encrypted. Also, bear in mind that, although digital cell phone calls are harder to intercept than analog ones, there is a thriving black market in devices that make such interception possible.

As a rule, confidential information should never be conveyed through cellular phones without encrypting the line or the messages first.

Phil Zimmermann, creator of Pretty Good Privacy (PGP, later GPG) in the early 1990s, created a new service in 2012 called Silent Circle to provide encrypted telephony and Internet access to its subscribers.⁶

15.3.2.14 Wireless Networks. The increasingly popular means of networking computers to networks known as WiFi presents many opportunities for interception of communications. In this context, “wireless network” usually means a data network using the 802.11 standard, which comes in a variety of flavors, such as 802.11b, 802.11g (often collectively referred to as WiFi, which stands for “Wireless Fidelity” and is actually a brand name owned by the trade group WiFi Alliance). Typically, this is the sort of local area network created by plugging a wireless access point into an Ethernet network and a WiFi card or adapter into each computer. Most notebook computers now come with a built-in WiFi adapter.

These WLANs, or wireless local area networks, are relatively cheap and easy to create since they do not require network cabling. That helps to explain why more than 200 million WiFi devices were sold in 2006 and more than half of all U.S. companies have been using WLANs to some degree or other since 2002. But cheap WLANs come with hidden costs, namely security. Every WLAN operates, by its very nature, in loose-lips mode. In a sense, the ease of use comes with ease of abuse. They all broadcast

their traffic into the air, whence it may be overheard by someone with the right set of ears, a legitimate user or a criminal hacker, someone looking for free bandwidth or a war driver. War driving, the practice of driving around town to find wireless access points, is a hobby to some people, and probably not illegal unless done with malicious intent—many notebook computers try to find wireless access points whenever turned on—but bear in mind that laws vary from one country to another. (Those contemplating war driving should check the legal status in their jurisdictions.)

To be a war driver, all that is needed is an old laptop, the right WiFi card, some free software (NetStumbler, e.g.), and an empty Pringles[®] potato-chip can wired to the WiFi card as an external antenna to boost reception. (The Pringles[®] can is optional, as is a global positioning system device to mark the location of WiFi access points.) If you drive around with this equipment activated, you will doubtless discover numerous access points in both residential and business districts. If the names of the access points are things like “Linksys” or “netgear,” this is an indication that the owner of the network has not changed the default service set identifier (SSID), which tends to be the brand of the wireless access point, broadcast for the world to see, unless the network owner turns off this feature. The name could also be a person, or place, or company, which helps war drivers figure out whose network they are picking up. (One of the authors detected SCHS near the offices of Sample County Health Services.) A program like NetStumbler will also tell you whether the network is using encryption. There has been a steady rise in the percentage of wireless networks using encryption, but it is far less than 10 percent. According to a survey conducted by AT&T in late 2007, one in six small businesses in America that use wireless technology has taken no precautions against wireless threats, and one-third of small businesses indicated that they were unconcerned about wireless data security.⁷

There is more about wireless network security in Chapter 33 in this *Handbook*, but the point is the relative ease with which networks can be tapped. This means WiFi, whether at home, in the office, or at a hot spot, represents a significant category of data leakage and thus a major avenue for systems penetration.

15.3.2.15 Van Eck Phreaking. This attack is named for Wim Van Eck, a Dutch electronics researcher who in 1985 proved to a number of banks that it was possible to read information from their cathode ray tubes (CRTs) at distances of almost a mile away, using relatively simple technology.⁸ Because many types of electronic equipment emit radio-frequency signals, receivers that capture these signals can be used to reconstruct keystrokes, video displays, and print streams. Using simple, inexpensive wide-band receivers, criminals can detect and use such emissions at distances of tens or hundreds of meters (yards).

Since radio-frequency signals leak easily through single-pane windows, PCs should never be placed in full view of ground-floor windows (and certainly not facing the windows!). Attenuators that tap the window at irregular intervals can be installed to defeat such leakage. A special double-pane window with inert gas between the panes also can lessen the amount of signals leakage.

Other countermeasures include special cladding of hardware, such as computers and printers, to attenuate broadcast signals. This protection often is referred to by the name of the classified government standard for protection of sensitive military systems, TEMPEST. Although TEMPEST was allegedly a classified code word to begin with, it is now sometimes expanded as *Transient ElectroMagnetic Pulse Emission Standard* or *Telecommunications Electronics Material Protected from Emanating Spurious Transmissions*.

15 · 14 PENETRATING COMPUTER SYSTEMS AND NETWORKS

TEMPEST-certified equipment costs many times more than the same equipment without TEMPEST cladding.⁹ A less expensive alternative is to use a special device that emits electromagnetic noise that masks meaningful signals. Yet another approach to protection against this threat is to locate systems within buildings, or rooms within buildings, that have been constructed to TEMPEST standards. There are federal regulations concerning the methods of building sensitive compartmented information facilities (SCIFs), and the testing to obtain a TEMPEST rating is quite stringent. These measures include such things as cladding of all walls and ceilings, cladding of all electrical and network cabling, lead-lined doors, and the absence of any external windows.

15.3.2.16 Trapping Login Information. Criminals can capture identification and authentication codes by inserting Trojan horse programs into the login process on a server host and by using macro facilities to record keystrokes on a client node. More commonly today, however, specifically written malware is used to capture keystrokes and transmit them at intervals back to remote systems.

15.3.2.17 Host-Based Login Trojans. A Trojan horse is a program that looks useful but contains unauthorized, undocumented code for unauthorized functions. The name comes from Greek mythology, in which Odysseus (Ulysses in Latin), weary of the never-ending siege of Troy, sailed his ships out of sight as if he and his warriors were giving up, but left a giant wooden horse at the city gates. Entranced by this magnificent peace offering, the Trojans dragged the great horse into the city. During the Trojans' wild celebrations that night, the soldiers Odysseus had secreted in the belly of the hollow horse let themselves out and opened the gates to their army. The Greeks slaughtered all the inhabitants of the city, and the Trojan War was over.

In February 1994, the Computer Emergency Response Team Coordination Center (CERT-CC) at Carnegie Mellon University in Pittsburgh issued a warning that criminal hackers had inserted Trojan horse login programs in hundreds of UNIX systems on the Internet. The Trojan captured the first 128 bytes of every login and wrote them to a log file that was later read by the criminals. This trick compromised about 10,000 login IDs.

Trojan code might be installed on a computer or terminal used by several people (e.g., on a mainframe terminal in the 1970s or in an Internet café today) so that when someone enters a user ID and password to logon, the system—controlled by the Trojan—displays a message such as “Invalid password, try again,” and the user does so. This time the login is accepted. The victim continues working, unaware that there is anything unusual going on. The Trojan, installed earlier, simulated the normal login procedure, displaying a semblance of the expected screen and dialog. Once the victim entered a password, the Trojan writes the authentication data to a file and then shows a misleading error message. The spoof program then terminates and the regular program is ready for login.

Such a case occurred in April 1993 in a suburb of Hartford, Connecticut. Shoppers noticed a new automated teller machine (ATM) in their mall. At first, the device seemed to work correctly, disbursing a few hundred dollars to bank card users on demand. It quickly changed to a more sinister mode. Users would insert their bank cards and respond as usual to the demand for their personal identification numbers (PIN). At this point, the new ATM would flash a message showing a malfunction and suggesting that the user try an adjacent bank machine. Most people thought nothing of it, but eventually someone realized that the ATM was not posting the usual “Out of Order”

indicator after these supposed errors. In addition, banks began receiving complaints of a rash of bank card frauds in the immediate area. Investigators discovered that the ATM had no connection to any known bank—that it had been purchased used, along with equipment for manufacturing bank cards. The ATM was a spoof; it was merely collecting the user ID and PIN of every victim for later pickup by the criminals who had installed it without permission in the mall. The criminals were caught after having stolen about \$100,000 over a four-week period using fraudulent bank cards.

Chapter 20 in this *Handbook* includes more details about Trojans and other low-tech attacks.

15.3.2.18 Keystroke Logging. Another threat to identification and authentication codes is the ability to record keystrokes for later playback or editing. Most word processing programs provide macro facilities, so named because of their ability to store and output multiple keystrokes, such as the typing of boilerplate text, with one keystroke. More sophisticated terminate-and-stay-resident (TSR) programs can record sequences of commands, and are sometimes used to demonstrate software or to automate quality assurance tests. This technology can also be used to lay in wait on a workstation and record everything the user does with the mouse and types with the keyboard; such programs are sometimes called *keystroke loggers*. Later, the criminal can harvest the records and pick out the login codes and other valuable information.

There are also hardware implementations of keystroke logging. One is a small device inserted between the keyboard and the computer, capturing what is typed and holding it in nonvolatile memory until it can be retrieved. At the time of this writing in May 2013, such devices were widely available through Internet sales for about US\$40.

By far the most common form of keystroke logging is done by *hooking* the operating system mechanisms for providing keyboard functionality. This is done in software. There are numerous specific technical techniques to accomplish the hooking process depending on the operating system and hardware. Sometimes the software used to accomplish the keystroke logging is stand-alone, but often it is part of a larger piece of software that also provides C2 (command and control) capabilities. It is also quite common for the keystroke logging functionality to be part of a rootkit in order to avoid detection.

It is possible to defeat the attempted reuse and abuse of login credentials captured by any of these methods by switching to one-time passwords generated by microprocessors. One-time passwords are discussed in Chapter 28 of this *Handbook*. However, both key loggers and Trojans can be deployed to gain unauthorized access to data without resorting to the reuse of passwords.

15.3.3 Breaching Access Controls. Criminals and spies use two broad categories of technical attacks to deduce access phone numbers, user IDs, and passwords: brute-force attacks and intelligent guesswork. In addition, there are ways to manipulate people into revealing their access codes; these techniques are discussed in the section on social engineering.

15.3.3.1 Brute-Force Attacks. Brute-force attacks consist of using powerful computers to try all possible codes to locate the correct ones. Brute force is applied to locating modems, network access points, vulnerable Internet servers, user IDs, and passwords.

15.3.3.2 Demon (War) Dialing. Despite the wholesale shift of data communications to TCP/IP networks and the Internet, modems on dial-up phone lines remain a common, and sometimes forgotten, means of external access to a system. The telephone numbers of any modems connected to hosts or servers or intelligent network peripherals, such as high-end laser printers, are sensitive and should not be posted or broadcast.

Demon dialers are programs that can try every phone number in a numerical range and record whether there is a voice response, a fax line, a modem carrier, or no answer. When phones ring all over an office in numerical order, one at a time, and when there is no one on the line if a phone is picked up, it is undoubtedly the work of someone using a demon dialer. Of course, good demon dialing software accesses the numbers in the target range nonsequentially.

During the heyday of fax machines, some youngsters were reported to have “farmed” entire telephone exchanges during the night, then to have sold the fax numbers for \$1 dollar per number to unscrupulous junk-fax services that sold advertisers access to them.

15.3.3.3 Exhaustive Search. The same approach as demon dialing can find user IDs and passwords after a connection has been made. The attacker uses a program that cycles systematically through all possible user IDs and passwords and records successful attempts. The time required for this attack depends on two factors:

1. The keyspace for the login codes
2. The maximum allowable speed for trying logins

In today’s technical environment, any inexpensive computer can generate login codes far faster than hosts permit login attempts. Processor speed is no longer a rate-limiting factor. Note that this type of attempt to “guess” passwords is different from password cracking, described elsewhere, which operates on captured or stolen copies of encrypted password files.

15.3.3.4 Keyspace. As discussed in Chapter 7 in this *Handbook*, the keyspace for a code is the maximum number of possible strings that meet the rules of the login restrictions. For example, if user passwords consist of exactly six uppercase or lowercase letters or numbers and the passwords are case-sensitive (i.e., uppercase letters are distinguished from lowercase letters), the total number of possible combinations for such passwords is calculated in this way:

- There are 10 digits and 52 upper- or lowercase letters (in the English alphabet) = 62 possible codes for any of six positions.
- If there are no restrictions on repetition, a string of n characters to be taken from a list of r possibilities for each position will generate r^n possible combinations.
- Thus, in our example, there are 62^6 possible sequences of 62 codes taken in groups of six = 56,800,235,584 (more than 56 billion) possible login codes.

If there are restrictions, the keyspace will be reduced accordingly. For example, if the first character of a password of length six must be an uppercase letter instead of being any letter or number, there are only 26 possibilities for that position instead 62,

thus reducing the total keyspace to $26 \times 62^5 = 23,819,453,632$ (more than 23 billion) possibilities.

15.3.3.5 Rainbow Tables. Cryptanalysts (including criminal cryptanalysts) can generate all possible one-way hashes for the keyspace of any given password rule; brute-force cracking using the tables can thus be accelerated. There are even Websites distributing such tables freely.¹⁰

15.3.3.6 Login Speed. Generating login codes is not hard. The greatest barrier to brute-force login attacks is interruption in the login whenever the host detects an error. Most operating systems and security monitors allow the administrator to define two types of login delays following errors:

1. A usually brief delay after each failed attempt to enter a correct password
2. A usually long delay after several failed login attempts

Suppose each wrong password entered causes a 1/10th-second delay before the next password can be entered; then for our example involving six repeatable uppercase or lowercase letters or numbers, it would take 5,680,023,558 seconds = 1,577,784 hours \approx 180 years to try every possibility.

Suppose, in addition, that after every fifth failed login attempt, the system were to inactivate the user ID or the modem port for three minutes. Such interference would stretch the theoretical time for a brute-force exhaustive attack to around 650 years.

Should the security manager completely inactivate the ID if it is under attack? If the ID is inactivated until the user calls in for help, user IDs become vulnerable to inactivation by malicious hackers. Attackers need merely provide a bad password several times in a row and the unsuspecting *legitimate* user will be locked out of the system until further notice. A widespread attack on multiple user IDs could make the system unavailable to most users. Such a result would be a denial-of-service attack (see Chapter 18 in this *Handbook*).

Should the port be inactivated? If there are only a few ports, shutting them down will make the system unavailable to legitimate users. This drastic response may be inappropriate—indeed, it may satisfy the intentions of criminal hackers. A short delay, perhaps a few minutes, would likely be sufficient to discourage brute-force attacks.

In all of these examples, the illustrations have been based on exhaustive attacks (i.e., trying every possibility). However, if passwords or other codes are chosen randomly, the valid codes will be uniformly distributed throughout the keyspace. On average, then, according to a principle of statistics called the *Central Limit Theorem*, brute-force searches will have to search half the keyspace. For large keyspace, the difference between a very long time and half of a very long time will be negligible in practice (e.g., 325 years is not significantly different from 650 years if everyone interested will be dead before the code is cracked).

15.3.3.7 Scavenging Random Access Memory. Not all attacks come from outside agents. Criminals with physical access to workstations, malicious software, or authorized users who can use privileged utilities to read main memory, can scavenge memory areas for confidential information such as login IDs and passwords.

On a workstation using a terminal emulator to work with a host, ending a session does not necessarily unload the emulator. Many emulators have a configurable screen

15 · 18 PENETRATING COMPUTER SYSTEMS AND NETWORKS

display buffer, sometimes thousands of lines long. After an authorized user logs off and leaves a terminal, a scavenger can read back many pages of activity, sometimes including confidential information or even login codes. Passwords, however, usually are invisible and therefore not at risk.

If a workstation is part of a client/server system, an application program controlling access may leave residues in random access memory (RAM). A RAM editor, easily available as part of utility packages, can capture and decode such areas as file buffers or input/output (I/O) buffers for communications ports. However, rebooting the workstation after communication is over prevents RAM scavenging by reinitializing memory.

15.3.3.8 Scavenging Cache Files. The same principle can be applied to the various cache and swap files created by the operating system. Cache files are used to keep frequently used data readily available to applications. Swap files store data and code that is moved out of memory onto disk when memory is full. Some operating systems also create hibernation files, writing memory to disk just prior to powering down, and thus enabling a quick resumption of work when the system is powered up. Operating systems may also provide auto-saved recovery files that allow restoration of data after a system error. All of these can be mined for system credentials as well as other valuable data.

15.3.3.9 Scavenging Web History Files. A more recent variation on this scavenging approach is to examine files created by Web browsers. These sometimes contain not only the pages viewed by a user but also the credentials entered to access those pages.

15.3.3.10 Recovering Stored Passwords. Many applications store user passwords locally. Most applications attempt to secure these passwords, unfortunately they are seldom stored with proper encryption methods. It has become common for malicious software to recover these stored passwords and transmit them to remote servers for collection by attackers.

15.3.3.11 Intelligent Guesswork. Users rarely choose random passwords. Much more frequently, passwords are chosen from a subset of all possible strings. Instead of blindly batting at all possible sequences in a keyspace, an attacker can try to reduce the effective keyspace by guessing at more likely selections. Likely selections include canonical passwords, bad passwords, and words selected from a dictionary.

Hardware and software often come from the factory, or out of the box, with user IDs and passwords that are the same for all systems and users.

For example, wireless access points and routers have default user IDs when they ship from the factory. Naturally, these user IDs are set up with the same password. (For example, “admin” on Linksys wireless router devices.) Such systems always include instructions to change the passwords, but, too often, administrators and users neglect to do so. Criminals are familiar with factory presets—most of which are readily discoverable via Google—and exploit them to penetrate systems. The simple routine of changing all canonical passwords prevents hackers from gaining easy access to systems and software.

15.3.3.12 Stealing. Any element of a computer system has potential value to a thief. Therefore every element including hardware, software, media, files, documentation, and printouts must be safeguarded.

15.3.3.13 Data Scavenging. Criminal hackers have few scruples about using other people's property when they enter computer systems; they have none at all concerning using other people's trash. The term *data scavenging* describes the process that acquires information from throw-away sources. Perhaps the most widely known is Dumpster[®] diving, sorting through whatever an organization discards. Hard-copy printouts, CD-ROMs, tapes, and other assorted data-bearing media often end up in trash containers where they are easily accessible to Dumpster[®] divers after hours. In some areas, if one visits an office or industrial park at night, one can see half a dozen people rummaging about, sometimes headfirst in Dumpsters[®]. Criminal hackers use the information thoughtlessly discarded by naïve office workers as a source of procedures, vocabulary, and proper names that can help them impersonate employees over the phone or even in person. The classic example is a discarded internal phone directory, which can provide a social engineer with valuable data to use when making calls to employees. An employee who hesitates to comply with an attacker's bogus request for information over the phone may well be persuaded if the attacker says something like "I understand your hesitation; if it makes you feel more comfortable you can call me back at extension 2645." If 2645 is a legitimate internal extension, the caller gains considerable credence. Of course, the properly trained employee will hang up and make the call to 2645 rather than take the easy option and say, "I guess that's okay then, here is the information you wanted."

Some printouts contain confidential information that can lead to extortion or system penetration. For example, a thief who steals a list of personally identifiable information about patients with HIV infection could torment the victims and extort money. Every piece of paper, or other media to be discarded, should be evaluated for confidentiality. Unless the information is worthless to everyone, employees should shred paper before disposal or arrange to send paper to a bonded service for destruction. The same applies to CD-ROMs and other media.

15.3.3.14 Discarded Magnetic and Optical Media. Discarded paper poses a threat; discarded magnetic and optical media are a disaster. Many organizations fail to teach employees that the normal commands used to delete files do not remove all trace of them. Either through the use of utility programs or the operating system itself, the original file clusters can be located and any part of the original file that has not yet been overwritten can be regenerated.

Backup tapes, CDs, and DVDs may contain valuable information about the system security structure. For example, in the 1970s and 1980s, system backups on one brand of minicomputer contained the entire directory, complete with every user ID and password *in the clear* on the first tape. Using a simple file copy utility, any user could read these data.

To destroy information on magnetic media, users either must overwrite the medium several times with random data or physically destroy the medium. Degaussers are inadequate unless they meet military specifications, but such units typically cost thousands of dollars.

The problem of readable data is especially troublesome on discarded disk drives or on broken hard disk drives that have been repaired or that are subject to specialized forensic data recovery. Users have received operational, data-laden disk drives as

15 · 20 PENETRATING COMPUTER SYSTEMS AND NETWORKS

replacements for their own broken units. Sometimes the replacement disks have not even been reformatted; they contain entire directories of correspondence, customer databases, and proprietary software. Because it is by definition impossible to overwrite data on a defective disk drive, military security specialists routinely destroy defective hard disks using oxyacetylene torches or purpose-built grinders that reduce hard drives into small chunks.

For more information about secure disposal of magnetic and optical data storage media, see Chapter 57 in this *Handbook*.

15.3.4 Spying. Some techniques used by criminal hackers seem to have been lifted directly from spy novels. For example, laser interferometry can reconstitute vibration patterns from reflected infrared laser beams bounced off windows. Users of such equipment can hear and record conversations in rooms that have external windows that vibrate according to the sounds in the room. For more antispy measures related to physical and facilities security, see Chapters 22 and 23 in this *Handbook*.

Hackers surreptitiously steal people's access codes by watching their fingers as they punch in secret sequences. When pay phones were prevalent, *shoulder surfers* would capture telephone calling-card codes, which they sell to organized crime rings. Codes can be stolen by peering over the shoulders of neighboring callers, or by using binoculars, telescopes, and video cameras to track the buttons pressed by their victims.

Shoulder surfing can occur within installations as well. For example, most users of punch-key locks pay no attention to the visibility of their fingers. Whenever punching in a code, users should guard against observation by unauthorized people. In public places, users should stand up close to the keypad. In fixed installations, facilities managers should cover keypads with opaque sleeves allowing unimpeded access but concealing details of the access codes.

Criminals are adept at surfing both wired and wireless network connections, either by cruising around town with a war-driving setup or hanging out in a target-rich environment such as an airport, train station, coffee shop, or hotel lobby. There is more about wireless hacking in Chapter 33 in this *Handbook*.

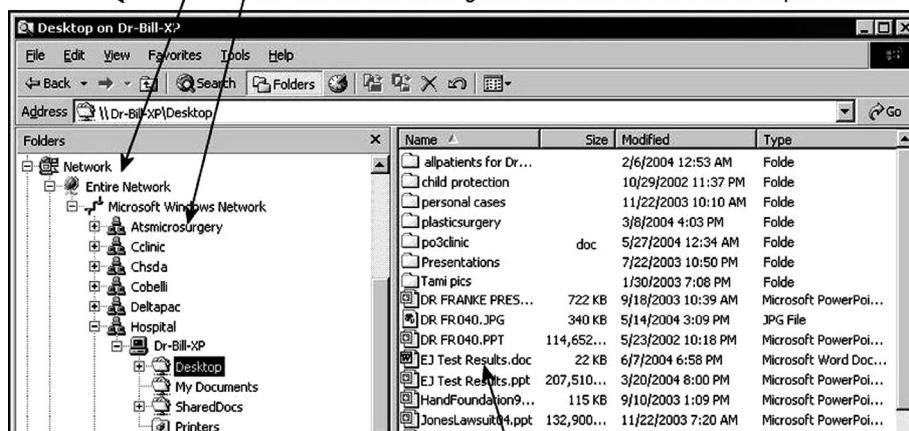

One particular type of wired connection that should be used with care is the broadband guest-room connection offered by many hotels. Too often, these are set up without proper security measures, enabling a curious or criminally inclined guest to locate machines belonging to other guests (sometimes by merely clicking the Network Neighborhood icon in Windows Explorer). Employees should be instructed not to plug their company laptops into such connections unless they have a properly configured firewall in place and turned on and are using a virtual private network (VPN) to access corporate systems (see Chapter 32 in this *Handbook*). Even some of the most expensive upscale hotels have been found to suffer from this problem, as illustrated in Exhibit 15.1.

15.3.5 Penetration Testing, Toolkits, and Techniques. Verifying and improving the security of systems by attempting to penetrate them is a well-established practice among security professionals and system administrators. However, although some were practicing this technique earlier, it was not openly discussed prior to 1993. That year, Dan Farmer and Wietse Venema released the pioneering paper entitled "Improving the Security of Your Site by Breaking into It."¹¹ This paper advanced the notion of assessing system security by examining a system through the eyes of a potential intruder. Farmer and Venema showed that scanning for seemingly benign network services can reveal serious weaknesses in any system. Prior to the publication of this important paper, many system administrators were unaware of the extent of vulnerabilities affecting their systems.

Dr. Bill checks into hotel for medical conference, plugs his laptop into the broadband in his room.

In another room, a different guest also plugs into the hotel broadband. She opens Windows Explorer and double-clicks on the Network icon.

Due to the poor configuration of the hotel network, this guest can see all the other guest machines and is free to explore them.

Dr. Bill has no firewall on his laptop and so all his files are exposed.

This is an actual screenshot taken at a five-star hotel in Boston. To protect privacy, we changed the names of computers, folders, and files. Note that no hacking tools were required to see or to access Dr. Bill's files.

EXHIBIT 15.1 Poorly Configured Hotel Room Internet Connectivity

Farmer and Venema then released a network-testing program called SATAN (Security Analysis Tool for Auditing Networks). Security professionals and system administrators both lauded and were angered by the program. Some system administrators cheered the availability of an all-in-one tool that revealed security holes but did not exploit them. Others questioned the authors' motives in releasing a free and readily available tool that hackers could use to attack networks. While the debate raged on, system administrators and hackers alike began using SATAN to interrogate networks.

15.3.5.1 Common Tools. Since that time, hundreds of penetration toolkits have appeared; they are commonly referred to as *scanners*. Today one can find innumerable freeware tools or invest in one of the commercial tools. Scanners vary in complexity and reliability. However, a majority of the tools employ the same basic functions to test a network: query ports on the target machines and record the response or lack of response.

Used in the proper manner, these tools can be effective in discovering and recording vast amounts of data about a network of computer systems and revealing security holes in the network. Many scanner packages also include packet-sniffing applications, described earlier. Administrators can use this information to reduce the number of systems that can be compromised.

A wide variety of basic network tools may be used in any penetration test. These tools may include mundane programs, such as PING, FINGER, TRACEROUTE, and NSLOOKUP. However, most serious penetration tools make use of an automated vulnerability analysis tool consisting of a series of port queries and a database of known vulnerabilities. Some tools also attempt to exploit identified vulnerabilities in order to eliminate false positives. Once the vulnerabilities have been found, it is

remarkably easy to obtain “exploits” or programs with which to launch an attack against the susceptible machines. All the tools make use of the basic operations of the TCP suite of protocols. Although these protocols will operate on different port numbers, they all share a common structure of a three-way handshake. All TCP protocols look for a connection attempt (connect), a synchronization and acknowledgment exchange (SYN/ACK), various conditions (FLAGS), and a close port request (FIN). Therefore, the operation of port scanners is quite similar. They attempt to find open, or listening, ports on a machine, ask for a connection, and then log the results to a file to be compared to the internal database. The scanner will display the results of the scans by listing the open ports and the services that appear to be running. At this point the various programs differ. Some attempt an in-depth analysis of the possible security holes associated with the ports and services, along with the appropriate security measures to secure them. The more malicious scanners also include automated scripts for exploitation of the vulnerabilities thus revealed.

Of the freeware tools, Nessus, Netcat, and nmap are probably the best known, although there always seems to be a new flavor of the month among both hackers and system administrators. SATAN is still available, as are its spin-offs, SAINT and SARA. A fair amount of skill is required to use these tools as they are fairly sophisticated, and some of the scans can overload a system and cause it to hang or crash.

15.3.5.2 Common Scans. As previously mentioned, most of the scanners/sniffers available will run through the same basic routines in order to develop a picture of a machine as a whole. The purpose is to determine what is running on the machine and what its role is in the network. The next sections describe most basic scans and their results.

15.3.5.2.1 TCP Connect. This is the most basic form of TCP scanning. This system call is provided by the operating system. If the port is listening, the attempt at a connection will proceed. This scan does not require root or supervisor privileges. However, this scan is easily detectable, as many connection and termination requests will be shown in the host’s system logs.

15.3.5.2.2 TCP SYN. This scan does not open a full connection and is sometimes referred to as a *half-open scan* because a full handshake never completes. A SYN scan starts by sending a SYN packet. Any open ports should respond with a SYN/ACK. However, the scanner sends an RST (reset) instead of an ACK, which terminates the connection. Fewer systems log this type of scan. Ports that are closed will respond to the initial SYN with an RST instead of an ACK, which reveals that the port is closed.

15.3.5.2.3 Stealth Scans. Also referred to as Stealth FIN, Xmas Tree, or Null scans, the stealth scan is used because some firewalls and intrusion detection systems watch for SYNs to restricted ports. The stealth scan attempts to bypass these systems without creating a log of the attempt. The scan is based on the fact that closed ports should respond to a request with an RST and open ports should just drop the packet without logging the attempt.

15.3.5.2.4 UDP Scans. There are many popular User Datagram Protocol (UDP) holes to exploit, such as an rpcbind hole or a Trojan program, such as cDc Back Orifice, which installs itself on a UDP port. The scanner will send a 0-byte UDP packet to each port. If the host returns a “port unreachable” message, that port is considered closed.

This method can be time consuming because most UNIX hosts limit the rate of Internet Control Message Protocol (ICMP) errors. Some scanners detect the allowable rate on UNIX systems and slow the scan down, so as not to flood the target with messages.

15.3.5.2.5 IP Protocol Scans. This method is used to determine which Internet protocols are supported on a host. Raw IP packets without any protocol header are sent to each specified protocol on the target machine. If an ICMP unreachable message is received, then the protocol is not in use. Otherwise, it is assumed to be open. Some hosts (AIX, HP-UX, Digital UNIX) and firewalls may not send protocol unreachable message, so all protocols appear to be open.

15.3.5.2.6 ACK Scan. This advanced method usually is used to map out firewall rule-sets. In particular, it can help determine whether a firewall is stateful or just a simple packet filter that blocks incoming SYN packets. This scan type sends an ACK packet with random-looking acknowledgment/sequence numbers to the ports specified. If an RST comes back, the port is classified as “unfiltered.” If nothing comes back, or if an ICMP unreachable is returned, the port is classified as “filtered.”

15.3.5.2.7 RPC Scan. This method takes all the TCP/UDP ports found open and then floods them with SunRPC program NULL commands in an attempt to determine whether they are RPC ports and, if so, what program and version number they return.

15.3.5.2.8 FTP Bounce. This scan looks like it is an FTP proxy server within the network (or trusted domain). It could eventually connect to an FTP server behind a firewall. Once the FTP server has been found, scanning of ports normally blocked from the outside can be made from the internal FTP server. Of course, reading and writing to directories can be checked from this server as well.

15.3.5.2.9 Ping Sweeps. This scan uses Ping (ICMP echo request) to find hosts that are up. It can also look for subnet-directed broadcast addresses on the network. These are IP addresses that can be reached externally. Ping sweeps often are used to try to “map” the network as a whole.

15.3.5.2.10 Operating System Fingerprinting. As many security holes are dependent on the operating system of the host, this scan attempts to identify which operating system is running, based on a number of suppositions. It uses various techniques to detect subtleties in the underlying operating system (OS) network stack of the computers being scanned. The data gathered are used to create a “fingerprint” that is compared to the scanner’s database of known fingerprints. If an unknown fingerprint is found, attackers can check Websites and newsgroups where information about fingerprints is freely traded, to discover what a particular OS might be. Once the OS has been identified, it is quite easy to find exploits by simply using a search engine on the Web. OS fingerprinting is unnecessary if the OS can be discovered by reading the banners. For example, if one was to telnet to a machine, the response could be:

```
badgny~> telnet abcd.efg.com
Trying 163.143.103.12 ...
Connected to abcd.efg.com
Escape character is '^]'.
HP-UX hpux B.10.01 A 9000/715 (ttyp2)
login:
```

15 · 24 PENETRATING COMPUTER SYSTEMS AND NETWORKS

The banner, which was included in the default configuration, simply indicates that the OS is HP-UX. A good system administrator will turn off the banners on all services that have them.

15.3.5.2.11 Reverse Ident Scanning. This scan usually is used to see if a Web server on the network is running as root. If the *identd* daemon is running on the target machine, then a TCP Ident request will cause the daemon to return the username that “owns” the process. Therefore, if this request is sent to port 80 (hex), and the return user is root, then that server can be used for an attack on the system. This scan requires a full TCP connection to the port in question before it will return the username.

15.3.5.2.12 Scanning One’s Own Port Configuration. Steve Gibson of Gibson Research Corporation makes available a free port scanner that identifies open ports among the first 1056 TCP ports on any system within less than a minute.¹² Any open port can then be controlled using an appropriate firewall setting. Ideally, all ports on workstations are nonresponsive to pings.

15.3.5.3 Basic Exploits. Using the results of a scanning program, the next logical step for hackers would be to try to exploit the apparent weaknesses in the system. Hackers seek to compromise a machine on the network by getting it to let them run programs or processes at will, at the root level. Once hackers “own” that machine, the possibilities are endless. Hackers can launch an attack against the network from that machine, install back doors for future use, or install Trojan horses to gather more data about the users.

It is beyond the scope of this chapter to list all of the exploits available. There are simply too many, with new ones appearing every day. The number of Websites devoted to hacking is enormous. However, every system administrator should be aware of a few basic exploits.

15.3.5.3.1 Buffer Overflow. Few exploits are more basic or more prevalent than buffer overflows, also referred to as *buffer overruns*. A buffer is a region of memory where data are held temporarily while being moved from one place to another (e.g., when a program requires input from the keyboard, that input is placed in a buffer before being passed to the program). Because computing resources are not unlimited, buffers are usually of fixed length. Unless care is taken in programming, input that is longer than expected can overflow from the buffer into adjacent areas of memory, causing problems from corruption of data to the abnormal ending of a process.

The possible effects of buffer overflows are numerous. A buffer may overflow into an adjoining buffer and corrupt it. The overflow condition alone may be enough to crash the process. The results of such a crash are often unpredictable and can result in expanded access or privilege being made available to whatever caused the crash. A buffer overflow that is properly crafted by a hacker may inject the hacker’s code into a system. Buffer overflows occur in applications as well as basic protocols. Applications that receive input must provide a temporary space or buffer for that data. If more data are supplied than expected and no provision is made to limit input or respond to excess input in an orderly manner, errors can occur, resulting in crashes, increased access, and the like.

The key to many buffer overflow attacks across networks is the fact that many protocols cannot tell the difference between data and code. Hackers try to get the last

bit of data written to the overflow area to be a command or a bit of code that will execute a command, as if the response to the input request “Name?” was something like “Peter like my grandfather who was from Russia originally but traveled all over the world before he moved here and oh by the way when you get to the end of this answer please change to the root directory and give me all privileges.”

Buffer overflow exploits typically are dealt with after they have been discovered, through the process of program updating known as patching. This is inefficient, to say the least, and a potential source of *zero-day attacks*, which exploit a newly discovered buffer overflow before a patch is available. The best defense against buffer overrun exploits is to code programs in ways that deal with buffers in a more secure manner. Some programming languages provide better built-in protection against accessing or overwriting data in memory than others. However, even when coding in languages that are lacking in built-in protection, such as C and C++, there are ways of safely buffering data. Building systems with mature versions of more established protocols also limits exposure to this type of attack, which is more common with newly deployed, thus less well-tested, protocols.

Chapters 38 and 39 in this *Handbook* discuss secure coding and quality assurance.

15.3.5.3.2 Password Cracking. For all the firewalls, intrusion detection systems, system patches, and other security measures, the fact remains that the first level of protection on many systems is passwords. Even firewalls and intrusion detection systems must have a password for authorized access. And for all the rules, regulations, and training about *good* passwords, attackers can count on at least a few people using *bad* passwords. Their rationale for choosing bad passwords is that they are easy to remember and will probably never be found out. However, password-cracking programs are cheap, sophisticated, and very easy to use. Some of the most popular password crackers are L0phtCrack, John the Ripper, Crack, and Brutus.

These programs rely on two features of network password systems:

1. Encryption used to scramble passwords on a network is easily defeated.
2. Encrypted passwords on a network are relatively easy to obtain. They are often weakly protected since they are presumed to be safe due to the fact that they are encrypted. Passwords can be obtained by sniffing the passing network traffic with a program such as pwddump or by copying the master password file from a system. Since one password is all it takes to enter a system as a legitimate user, sniffing the traffic is the easiest method of obtaining a relatively good list of passwords.

Once the list has been obtained, it is saved as a simple text file, and the password-cracking program begins checking the encrypted words in the file against a dictionary of words that have previously been encrypted with the same algorithm. Whenever a match is found between an encrypted string in the file and a word in the encrypted dictionary, the cracking program displays and records the plaintext of the encrypted dictionary word. Thus the password is revealed.

In addition to checking ordinary dictionary words, some password crackers check for both uppercase and lowercase letters, numbers before and after a word, and numbers used in lieu of vowels within a word. The speed at which these programs operate, even on a basic desktop or laptop computer, is impressive, and it is entirely

possible to obtain cracked passwords within seconds. Indeed, a useful security awareness exercise is to demonstrate such a program to employees: The first passwords to be cracked will be the weakest ones, and that can serve as a warning to users who choose such words.

A good security officer will ensure that passwords on a network are checked regularly with a password cracker or by implementing one of the many strong-password enforcers. Password enforcers augment the password program by comparing the passwords chosen by the user to the rules set by the enforcer.

A simple online tool from Steve Gibson's GRC allows one to calculate the keyspace and estimate cracking time for sample passwords.¹³ Users should not enter their actual password but only one using the same rules; for example, if one's actual password were *Dk3*(4n\$2*, one could enter *Eh5&%9g#t8* to arrive at exactly the same analysis. In the example presented here, the calculations result in a keyspace of 6.05×10^{19} with a cracking time of 1 week if a massively parallel array of processors supported 10^{15} guesses per second. The password *evanescent porridge* would take the same processors 14.32 billion centuries to include by brute-force cracking of the 4.50×10^{33} keyspace.

15.3.5.3.3 Rootkits. Rootkits are one of the many tools available to hackers to disguise the fact that a machine has been "rooted." A rootkit is not used to crack into a system but rather to ensure that a cracked system remains available to the intruder. Rootkits are comprised of a suite of utilities that are installed on the victim machine. The utilities start by modifying the most basic and commonly used programs so that suspicious activity is cloaked. For example, a rootkit often changes simple commands such as "ls" (list files). A modified "ls" from a rootkit will not display files or directories that the intruder wants to keep hidden.

Rootkits are extremely difficult to discover since the commands and programs appear to work as before. Often a rootkit is found because something did not "feel right" to the system administrator. Since rootkits vary greatly in the programs they change, one cannot tell which programs have been changed and which have not. Without a cryptographically secure signature of every system binary, an administrator cannot be certain to have found the entire rootkit.

Some of the common utilities included in a rootkit are:

- Trojan horse utilities
- Back doors that allow the hacker to enter the system at will
- Log-wiping utilities that erase the attacker's access record from system log files
- Packet sniffers that capture network traffic for the attacker

15.3.5.3.4 Trojan Code. As described earlier in the context of compromised login procedures, Trojan code is something other than it appears to be. In this case, the Trojans are the changed programs in a rootkit that allow an intruder's tracks to be hidden or allow the program to gather more information as it sits silently in the background. Local programs that are Trojaned often include "chfn," "chsh," "login," and "passwd." In each case, if the rootkit password is entered in the appropriate place, a root shell is spawned.

15.3.5.3.5 Back Doors. Back door utilities often are tied to programs that have been Trojaned. They are used to gain entry to a system when other methods fail. Even if

a system administrator has discovered an intrusion and has changed all the usernames and passwords, there is a good chance that he or she does not know that the back doors exist. To use the back door, the hacker needs only to know the correct port to connect to the compromised machine and to enter a password or command where one is not usually entered.

For example, `inetd`, the network super daemon, is often Trojaned. The daemon will listen on an unusual port (`rfe`, port 5002 by default in Rootkit IV for Linux). If the correct password is given after connection, a root shell is spawned and bound to the port.

The function `rshd` can be similarly Trojaned so that a root shell is spawned when the rootkit password is given as the username and thus `rsh [hostname] -l [rootkit password]` will obtain access to the compromised machine.

15.3.6 Penetration via Websites. A vast new network territory opened up in the final decade of the twentieth century, partially devoted to commerce and largely driven by attempts to make money from a technology that originally had been developed for military and academic purposes. The relentless growth of this network surpassed 145 million registered domains at the time of writing in May 2013 as reported by the Whois Source (www.whois.sc/internet-statistics), one of the most reliable sources of statistics about the Internet.

Worldwide Internet penetration, measured as the number of Internet users as a percentage of total population, was over one third by June 2012, with North America, surpassing 75 percent.¹⁴ Asia had almost 4 billion users at that time. Not surprisingly, with so many machines in one network and over 2.4 billion users (twice what was reported in the 2009 Fifth Edition of this *Handbook*), this new territory is the primary playground for hackers, from the merely curious to the seriously criminal. The Web presents a target-rich environment for people seeking unauthorized access to other people's information systems. There are several reasons for this; chief among them is the fact that many organizations, both commercial and governmental—including the military—have external, public Websites that are connected, in some way, to internal, private networks. This connection provides a system penetration path that can be exploited in many different ways, as outlined in this section.

For more detailed analysis of Website security, see Chapter 21 in this *Handbook*.

15.3.6.1 Web System Architecture. Standard practice when placing a commercial Website on the Internet is to screen it from hostile activity, typically using a router with access-control lists (ACLs) or a firewall, or both. However, unless the Web site is of the basic, “brochure-ware” kind, which simply exists to provide information on a read-only basis, the site has to allow for user input of data. Input is required for something as simple as a guest book entry or an information request form; more complex applications such as online shopping have more complex input requirements.

A typical method of processing input is the Common Gateway Interface (CGI). This is a standard way for a Web server to pass user input to an application program and to receive a response, which can then be forwarded to the user. For example, when a user fills out a form on a Web page and submits it, the Web server typically passes the form information to a small application. This application processes the data and may send back a confirmation message. This method is named *CGI*, and it forms part of the Hypertext Transfer Protocol (HTTP). Because it is a consistent method, applications written to employ it can be used regardless of the operating system of the server on which it is deployed. Further adding to the popularity of CGI is the fact that it works

with a number of different languages including C, C++, Java, and PERL. The term “CGI” is used generically for Web server code written in any of these languages.

Any system that receives input must provide a path within the system through which that input can flow. This is referred to as an “allowed path.” The necessity of allowed paths, combined with the ability to exploit them for penetration attacks, led the system security expert David Brussin (author of Chapter 26 in this *Handbook*) to coin the term “allowed path vulnerabilities” for this class of vulnerability. The two leading categories of exploits that employ allowed paths are input validation exploits, which are akin to buffer overflow exploits and often employed to abuse CGIs, and file system exploits, which abuse the Web server operating system and services running on the server.

Of course, there are other ways to abuse Websites as well. Denial-of-service attacks can be used to inhibit legitimate access and thus compromise availability. (Chapter 18 in this *Handbook* covers DoS attacks.) Not every attack is aimed at further penetration of systems; the Web pages themselves may be the target of attack, as in a defacement, an unauthorized change to Web pages. Defacement often is committed to embarrass the Website owner, publicize a protest message, or enhance the reputation of the criminal hacker who is performing the defacement. But in terms of penetration, the primary goal of attacks on Websites is to compromise internal networks that might be connected to the Web server. Exploitation of allowed path vulnerabilities is probably the most common form of such attacks.

15.3.6.2 Input Validation Exploits. Whenever an allowed path is created to accommodate user input, the possibility exists that it will be abused. Such abuse can lead to unauthorized access to the system. This section describes a range of penetration methods using this approach, all of which somehow employ invalid input, or input that is:

Not expected by the receiving application on the server.

Not “allowed” according to the rules by which the receiving application is operating.

15.3.6.3 Unexpected Input Attacks. How is it possible to submit unexpected input to a server? The answer lies in the architecture of the Internet and the paradoxical nature of the client system that is accessing the server. The typical Web client is a client in name only. It is often a powerful machine, capable of being a server in its own right, and very difficult for any other server to control, due to the inherent peer-to-peer nature of the huge network that is the Internet. All nodes of the Internet are considered hosts. And, of course, many of these hosts are outside the physical control of the organizations hosting those machines that are acting as servers. This fact has serious implications for security.

Unless the server can install tightly controlled application code on the client, and restrict user input to that code, the server must rely on the coding most commonly used to implement Web client-server interaction, Hypertext Markup Language (HTML) and Hypertext Transfer Protocol Daemon (HTTPD). Both are complex and relatively immature. For example, they do not automatically identify the source of the input. Consider an HTML form on a Web page, designed to be presented to a visitor to the Website who fills in the fields and then clicks a button to submit the form. There is nothing on the client side to control the user’s input. So instead of entering a first name in the First Name field, a user might enter a long string of random characters. Unless the application processing this data field performs extensive input validation, the effects of

such action can be unpredictable, even more so if the user includes control characters. Similarly, if the Web server itself is not designed to validate page requests, a user might cause problems by submitting a bogus Universal Resource Locator (URL).

The problem is even more severe than this. Unless the Web server application is specifically written to defeat the following abuse, it can be used to cause all sorts of problems that potentially lead to successful penetration. Suppose that, instead of simply filling out a form, the user creates a local copy of the page containing the form, then alters the source code of the form, saves the file, and submits it to the Website instead of the original page. This does not violate the basic protocols of the Web but clearly provides considerable penetration potential. Many Websites are still vulnerable to attacks of this type.

15.3.6.4 Overflow Attacks. As described earlier in the context of hidden form fields, it is possible to gain access to Web servers by supplying more input than expected. Such an attack is possible with any field on a user-submitted form, not just a hidden field. The defense is to build extensive error checking into the application that processes the form.

Overflow attacks, which were described in general terms earlier, also can be directed at applications or services running on the Web server. For example, in June 2001, CERT announced a remotely exploitable buffer overflow in one of the Internet Server Application Programming Interface (ISAPI) extensions installed with most versions of Microsoft Internet Information Server 4.0 and 5.0, specifically the Internet/Indexing Service Application Programming Interface extension, IDQ.DLL. An intruder exploiting this vulnerability may be able to execute arbitrary code in the local system security context, giving the attacker complete control of the victim's system.

15.3.6.5 File-System Exploits. Another category of attack against Websites exploits problems with the file system of the Web server itself. Ever since Web servers started appearing on the Internet, there has been a constant procession of vulnerability announcements arising from file system issues. The main ones are presented here, but the possibility of others appearing is high due to a lack of what David Brussin has called *vulnerability class analysis*. A vulnerability class is a type of problem, such as buffer overflow or file system access control. Developers of Web servers, and many other applications, are often averse to, or resource-constrained from, the elimination of vulnerabilities as a class, being focused instead on the hole-by-hole fixing of specific instances of the vulnerability as they arise. This phenomenon is largely a result of the rapid pace at which the Web has been developed and deployed, driven by powerful commercial forces.

15.3.6.6 Dot Dot, Slash, and Other Characters. Persons responsible for the security of information systems that employ Web servers must be alert for new vulnerabilities. Web server software has proven particularly susceptible to certain categories of vulnerability that tend to recur in new versions. Whenever these vulnerabilities are discovered, attackers quickly exploit them. Typically, software vendors issue patches to solve the problem, but systems remain susceptible until patched, and attackers use automated tools to scan the Internet for servers that are still susceptible. For example, in April 2001, a flaw was discovered in versions of Microsoft Internet Information Server (IIS) in use at that time. This flaw made it possible for remote users to list directory contents, view files, delete files, and execute arbitrary commands.

In other words, if a Web server running IIS was connected to the Internet, anybody using the Internet could potentially copy, move, or delete files on the Web server. With this level of access, it was possible to use the Web server to gain access to connected networks unless strong internetwork access controls were in place. In alerts that were issued to warn users of this software, exploitation of this vulnerability was described as “trivial.” In fact, a large number of sites were penetrated because of it, and many suffered defacement (i.e., unauthorized changes to the appearance of their Websites). In other cases, attackers downloaded sensitive customer data and uploaded and installed back door software.

Particularly worrying about this vulnerability was the fact that it was essentially a recurrence of the so-called dot dot directory traversal attack, which was possible on a lot of early Web servers. These servers would, upon request, read “..” directories in URLs, which are unpublished parent directories of the published directory. Thus, attackers were able to back out to the Web root directory and then to other parts of the server’s directory structure. This technique basically allowed attackers to navigate the file system at will. Many Web servers, including IIS, began to incorporate security measures to prevent the “dot dot” attack, denying all queries to URLs that contain too many leading slashes or “..” characters.

The vulnerability published in April 2001 involved bypassing these restrictions by simply substituting a Unicode translation of a “/” or “:.” Attackers found that, by appending the “..” and a Unicode slash or backslash after a virtual directory with execute permissions, it was possible to execute arbitrary commands. Attackers could execute any command via a specially crafted HTTP query. The frequency with which “old” vulnerabilities reappear in new software should serve as a warning to information security professionals not to assume that “new” is the same as “improved.” Indeed, all software needs to be treated with a healthy degree of skepticism and a fair amount of heavy testing prior to deployment.

15.3.6.7 Metacharacters. Dots and slashes used in field system references are closely related to metacharacters, which also can be used to attack Web systems. A metacharacter is a special character in a program or data field that provides information about other characters, for example, how to process the characters that follow the metacharacter. Users of DOS or UNIX are probably familiar with the wildcard character, a metacharacter that can represent either any one character or any string of characters. If used inappropriately, for example, in user-supplied data, metacharacters can cause errors that result in unintended consequences, including privileged access.

15.3.6.8 Server-Side Includes. Server-side includes (SSIs) are special commands in HTML that the Web server executes as it parses an HTML file. SSIs were developed originally to make it easier to include a common file, called an *include file*, inside many different files; examples include files containing a logo or text files consisting of the page, date, author, and so on. This capability was expanded to enable server information, such as the date and time, to be included automatically in a file. Eventually, several different types of include commands were provided on Web servers: *config*, *include*, *echo*, *fsize*, *flastmod*, *exec*. The last of these, *exec*, is quite powerful, but it is also a security risk, as it gives to the user of the Web client permission to execute code. A number of attacks are possible when *exec* is permitted within an inadequately protected directory.

Analogous to SSIs are ASPs (Active Server Pages) and JavaServer Pages, as well as Hypertext Processors (PHP). All are technologies that facilitate dynamic page building

and allow execution of codelike instructions within an HTML page. All should be employed with special attention to security implications and strict adherence to secure Web application programming methods. Security professionals will note that many of the weaknesses in these newer technologies are simply old exploits reborn. Anything that offers “greater interactive functionality” may increase the likelihood of new vulnerabilities simply because, in the absence of rigorous software quality assurance, changes are so often associated with new bugs.

15.3.7 Role of Malware and Botnets. Several new twists on system penetration via Websites and Internet email have emerged in recent years, starting with the evolution of computer viruses and worms. Some worms and viruses are designed to install Trojan code. The term “malware,” derived from “malicious” and “software,” is now widely used to refer to the entire category of software coded with malicious intent, including viruses, worms, and Trojans. In fact, viruses and worms, which are dealt with in more detail in Chapter 16 in this *Handbook*, are themselves a form of system penetration; after all, the creators of virus and worm code are getting their code onto systems that they are not authorized to use, so one may consider those machines to have been penetrated. Some criminal hackers have combined different elements of malware to penetrate computers used to surf the Web. Those compromised machines are then used, in turn, to spread malware and compromise additional machines. The goal may be gathering of user names and passwords (helpful for yet more system penetrations) or financial data used to perpetrate fraud and identity theft.

The two main components of this penetration strategy are drive-by downloads and botnets. A drive-by download attempts to compromise machines used to visit a malicious Website, taking advantage of either user gullibility or vulnerabilities in their Web browsers to install, without explicit permission, unsolicited code, typically a Trojan of some sort. A botnet is a collection of bots, host computers that can be controlled remotely (i.e., robotically) through Trojan code installed on those machines, either via a drive-by download or other means, such as a virus or worm. Here is how researchers at Google described the phenomenon in a landmark 2007 report:

[C]omputer users have become the target of an underground economy that infects hosts with malware or adware for financial gain. Unfortunately, even a single visit to an infected Website enables the attacker to detect vulnerabilities in the user’s applications and force the download of a multitude of malware binaries. Frequently, this malware allows the adversary to gain full control of the compromised systems leading to the ex-filtration of sensitive information or installation of utilities that facilitate remote control of the host.¹⁵

What makes the Google report a landmark is not the existence of drive-by exploits, which have been on the rise for several years, but their prevalence. Because Google maintains a massive repository of Web pages in order to operate its search engine, it is in a fairly unique position when it comes to analyzing the content of the Web as a whole. The solidly researched finding that at least 1 in 10 of all Web pages contained some form of malware should be a wakeup call to IT departments everywhere. Are your users surfing to Facebook pages? Are they aware that something as seemingly harmless as visiting their favorite singer’s page on the Web might cause malicious code to be downloaded onto their computer from a server in China?

That sort of attack started to become commonplace in 2007, as documented by Roger Thompson of Exploit Prevention Labs, with Alicia Keys being one of a number of artists targeted by criminal hackers. One exploit used in these attacks installed a

proxy network bot, known as a *flux bot*. The goal of a flux bot is to obscure the location of phishing sites by using constantly changing proxy servers, thus making it harder for banks and other institutions targeted by the phishing scam to shut it down. (There is more about phishing scams in Chapter 20 in this *Handbook*.)

According to the Google report, there are four main methods by which Web pages are turned into malware infection vectors: advertising, third-party widgets, user-contributed content, and Web server security. This implies that company Websites not only need to be firmly secured, but that all advertising and user-supplied content should be validated, as should any widgets that are employed or distributed by the site.

15.3.8 Sophisticated Attackers. In recent years several groups of attackers have been very successful using a very different approach to compromise security systems than has been used historically. These groups have been termed “Advanced Persistent Threats” by the United States Air Force in 2006. While many of these groups are nation state–sponsored these same techniques are being employed by groups with purely financial gain as well.

It is important to understand up front that these attacks, regardless of specific source group, are targeted. In the case of the nation state–sponsored groups, the goal is information theft. This information theft often takes the form of email, but also can range much deeper to research and development information or other intellectual property. The financially motivated groups focus on financial institutions for the purposes of financial gain.

As of this writing, there are many known groups active in the world. Each of these groups uses a little different specific components in their overall process, but the overall process is the same and can be broken down into some distinct stages.

The first stage is reconnaissance, planning, and preparation. This is where they select specific individuals within the target organization. They also plan out their attack based on the results of the reconnaissance. Finally they set up specific command and control servers to be used against the target and build the malicious software to be used as part of the attack.

The second stage is obtaining foothold and persistence. In this stage their goal is to get onto the target network. This is the point they deploy their attack (most often through spear-phishes) and gain remote access to the target network. Since gaining a foothold is one of the more challenging parts, they also seek to ensure they can maintain that foothold on the network.

The third stage is mapping the internal network and locating the desired data. At this point, they seek to understand the target environment and find their ultimate target of either specific data or systems on which they can perpetrate their financial impact.

The fourth and final stage is exfiltration or exploitation. This is the point at which they transmit the collected information outside of the target environment (typically nation-state actor goal) or execute their financial attack (in the case of the cybercrime actors).

15.3.8.1 Stage One—Reconnaissance, Planning, and Preparation.

The attackers often begin with selecting a handful of individuals at the target organization. They employ open source intelligence sources like the company Website, Facebook, and LinkedIn to gather information and identify recipients at the target organization. Other sources, such as press releases from companies and news articles about those companies, provide a rich resource for attackers to zero in on individuals close to the ultimate target of the attackers.

Once individuals have been identified an appropriate delivery can be created. The most common delivery means is through spear-phishes. A spear-phish is a targeted phish (as compared to a normal phish that is sent to thousands or millions of recipients). These spear-phishes are often simple and straightforward but can be quite sophisticated.

While spear-phishing is the most common means of delivery attackers will also compromise Websites commonly used by their targets as a means of delivery. This method of delivery is referred to as watering hole attacks. The term *watering hole* refers to the hunting method whereby a hunter waits for their prey at a watering hole, knowing that eventually the target will come for a drink. Watering hole attacks work by modifying a compromised Website's code so that when users view the Website an exploit is delivered to the victim browser. This exploit is in turn used to install malicious code on the system.

Least commonly, the sophisticated attackers have been found to use malicious code placed on USB keys. These are either left where target users will find them or even mailed directly to the targets. Exploit code is used on the USB device so that when users access the device the exploit code will install malicious code onto the user system.

Also as part of stage one the attackers will configure C2 (command and control) servers to be used over the course of the attack. These C2 servers are often compromised hosts at legitimate organizations but can also be hosting servers obtained legitimately. In particular, attackers prefer servers at places such as large universities, as these are unlikely to be blocked by common prevention mechanisms like Web proxy filters commonly employed by organizations today.

The final major aspect of the preparation is the creation of the backdoors to be employed against the target organization. The attackers generally have several variants of their backdoor with slightly different characteristics. Some groups will even use commonly available RATs (Remote Access Trojans) such as Poison Ivy and configure them to use the appropriate C2s. Many of the attackers have tools that will weaponize legitimate PDF or office documents. Weaponization is the process of turning a legitimate file into a malicious one. If, for instance, the individuals share a particular industry in common, the attackers might find a relevant industry conference in the near future and download an actual agenda PDF file from the conference Website. They might then weaponize that PDF or simply use information from the file to add to their spear-phish to add realism and improve their chances for the targeted users to fall for the spear-phish.

15.3.8.2 Stage Two—Foothold and Persistence. The end result of stage one is an RAT being installed on one or more target systems. This Trojan provides covert backdoor access to the victim systems. Now that the attacker has a foothold on the target network, they want to maintain that access. Attackers want access from more than a single system, since a single host might not be running when they want access. The attackers also understand that eventually the RAT will be found or removed. The attackers also want to increase their access to ensure they can get to whatever their final objective is.

To accomplish all of this, the attackers will usually follow a consistent process. They start with dumping the password hashes from the local host cache. By default, Microsoft Windows (the predominant operating system in use by users at most organizations) keeps a cache of the last 10 user IDs and passwords used to log into a computer. This is done so that if the computer is not connected to the corporate environment and thus can't access the domain controllers, the user will still have the ability to log into the system locally. Tools like pwdump, Windows credential editor, and fgdump

will display the user IDs and passwords in the local system cache. These can then be cracked using rainbow tables or cracking software back at the attacker's location.

The second step is to look at the host network connections to determine what computers the host is communicating with. The logic behind this is simple—any credentials in the local computer will very likely work on other hosts the system is interacting with. Remember that the purpose of user IDs is to provide authentication to other systems for the purpose of using them. Using the cracked password for the locally cached user IDs, the attacker connects to the subsequent systems and proceeds to extract the user IDs and password hashes from that host. The process of moving from host to host like this is termed *lateral movement*. It is especially important to note that the attackers are not using malware to accomplish this access. They are using legitimate user IDs and passwords. Ultimately, the attacker will continue this process until they find a system with an administrative account that will give them access across the entire environment. It is rare for them to have to traverse more than six to ten systems in order to find one with a network or domain administrator account cached. Once they have an administrative account they are free to use it to move throughout the network.

In addition to obtaining local user IDs and passwords from system caches, the attackers also map the target environment at this stage. Mapping the network is done through simple querying of Active Directory. The simplest way for the attackers to gain information about the environment is with a series of simple commands:

```
net group "domain computers" /domain
net group "domain users" /domain
net group "domain controllers" /domain
net group "domain admins" /domain
```

If you aren't familiar with those commands, you should try them. The only requirement is to do them from a computer that is a member of the local domain. No administrative credentials are necessary. The result is a list of all computers, users, domain controllers, and domain admin accounts in the environment. This information is returned immediately and is far more useful for attackers' purposes than running a tool like nmap. A further benefit is that the use of these commands is very, very difficult to detect as compared to nmap or similar tools that are very noisy. When the attackers want to gain more thorough information about an environment they will typically use dsquery and dsget. These are two command line tools provided by Microsoft to query active directory. Here are the contents of a batch script that was recovered from a recent incursion showing the use of these tools.

```
dsquery user -limit 0 | dsget user -samid -display -title
    -email -dept -office -company -c >1
dsquery user -limit 0 | dsget user -samid -pwdneverexpires
    -acctexpires -loscr -profile -hmdir -hmdrv -c >2
dsquery user -limit 0 | dsget user -c > 3
dsquery group -limit 0 | dsget group -c >g
dsquery subnet -limit 0 | dsget subnet -c >sn
dsquery site -limit 0 | dsget site -c >s
dsquery computer -limit 0 | dsget computer -c>c
dsquery ou -limit 0 | dsget ou -c>o
```

Attackers understand that users leave organizations and change roles. To ensure they have plenty of user IDs at their disposal it is a high priority for them to dump the entire domain credentials. This usually occurs within minutes of them achieving an administrative account with sufficient credentials. Their tool of choice for this is the

well-known pwdump. They simply run pwdump against one of the domain controllers using a recovered domain administrator account. Once the hashes are obtained, they can crack them at their leisure back at their location.

Another priority of the attackers is to install additional mechanisms for gaining access to the environment. To accomplish this they will use a variety of methods. If a company employs a single-factor VPN, then the attackers have unlimited access to the environment using the stolen user credentials. They will also install several additional backdoors. These are distributed throughout the environment to make it difficult for security personnel to find them all. The attackers understand that malware is the easiest thing to spot in an environment, however, and so they will only install copies on a handful of the overall hosts they compromise. As a further precaution to detection, they will usually configure the extra backdoors to sleep for extended periods of time. This tactic results in it being very challenging for security staff to find and eliminate all copies of their backdoors. Finally, in the last couple years, they have been observed also deploying Web shells in corporate DMZs as a further level of backup access to an environment. Web shells were very popular with attackers in the late 1990s and early 2000s but have been rare for the last several years, and thus are not commonly looked for. The Web shells being employed by the attackers are very small and do nothing until remotely accessed, making them very difficult to uncover as well.

As if the use of so many techniques in order to maintain access to a company was not enough, most groups will also monitor their installed backdoors in real time. If they observe an organization actively removing them they will quickly jump onto compromised hosts and install entirely different backdoor versions with very different characteristics so as to maintain access and remain undetected. It is important to realize that the majority of the backdoors are proprietary, not commodity, and very rarely found with standard antivirus. The net result for the attackers is a long-time presence on an environment, during which they can move around and access whatever they desire.

15.3.8.3 Stage Three—Information Theft. The final stage and aspect of the advanced attackers is where they find and exfiltrate the information they see or execute the financial transfers in the case of the cybercrime-motivated actors. All of the efforts of the attackers are for the ultimate purpose of stealing something.

After establishing long-term persistence in an environment, the attackers begin moving from host to host looking for the information they seek. Mostly this is done by command line, but some groups will also tunnel RDP protocol through their C2 infrastructure. If an organization has some other form of remote control, such as VNC, the attackers will gladly utilize that as well with the legitimate credentials they compromised. Through the simple expedient of the Windows ‘dir’ command, they look in the documents of each host, seeking the data they desire. This is facilitated by the deep organizational knowledge they acquired in earlier stages.

Often the majority of their theft is simply e-mail. When you consider the amount of business activity details that are conducted with e-mail, you realize an attacker can gain incredible competitive advantage from information contained in e-mail.

When the attackers find the data they seek, they will compress and encrypt it, then transmit it back to the C2 infrastructure. This process is known as *exfiltration*. Since sophisticated attackers understand organizations have logging measures in place, the transfer is done to intermediary systems, rather than directly to their location. Subsequently they can move it from the intermediary systems to the final destination without risk of the compromised organization being able to trace it.

Most often RAR is used to package the data for exfiltration. RAR is particularly useful for attackers because of its unique characteristic among compression formats: Data in an RAR file can be recovered even if the RAR is incomplete. If exfiltration is interrupted midtransmission, the attackers will still be able to extract whatever portion of the data made it out. Encryption is used to make it more difficult for a compromised company to figure out what data was stolen. Most groups also prefer to use a media file extension for their RAR files as a further means of obfuscation. The renamed files may have a .mpg or .avi extension but they are simply normal encrypted RAR files.

For transmission of the data the attackers typically use Secure Sockets Layer (SSL). This tool, combined with the compressed and encrypted contents, makes it very difficult for companies to detect that anything malicious is occurring. The sophisticated attackers are so successful overall because the majority of their activities are done by hiding in the large volume and noise of legitimate activity. Consequently, they've all been observed using services like dropbox, box.net, and other cloud providers for exfiltration as well, given the significant adoption rate of these types of services legitimately by our users. Detecting malicious activity to a cloud provider from legitimate activity is very difficult indeed.

15.4 POLITICAL AND LEGAL ISSUES. Thanks to the World Wide Web, the Internet has become a self-documenting phenomenon. One can use the Internet to find out everything one wants to know about the Internet, including how to penetrate information systems that employ Internet technology. However, the penetration information available on the Internet is not restricted to Internet systems, and the Internet is not the only source of penetration information. Furthermore, the very availability of penetration information is fraught with political and legal issues. These are discussed briefly in this final section of the chapter.

15.4.1 Exchange of System Penetration Information. The sharing of system penetration information—that is, information that could facilitate illegal penetration of an information system—is the subject of a long, heated, and ongoing debate. This debate encompasses both practical and ethical aspects of the issue. Although complete coverage is not possible within the confines of this chapter, we do review the question of full disclosure, along with some of the sources for penetration information.

15.4.2 Full Disclosure. How should we handle known vulnerabilities and potentially damaging computer viruses? Should we publish full details, conceal some details, or suppress any publication that would allow exploitation until patches or updates are available from manufacturers? Is there a case for handling some viruses and exploits differently from others?

Over the last two decades, formal venues for full disclosure of system or network vulnerabilities and exploits have evolved (e.g., BugTraq). Support for full disclosure of such details, down to the source code or script level, from professional, honest security experts (the Good Guys) is based on subsets of several key beliefs:

- The Bad Guys know about the vulnerabilities anyway.
- If they do not know about it already, they will soon with or without the posted details.
- Knowing the details helps the Good Guys more than the Bad Guys.

- Effective security cannot be based on obscurity.
- Making vulnerabilities public may force vendors to improve the security of their products.

Since those who would use vulnerabilities and exploits for gain or harm often learn of them before system administrators and security experts, it makes sense—so the argument goes—for the Good Guys to spread the knowledge where it can do some good. One might also argue that, because cryptographic techniques are routinely exposed to public scrutiny by experts to detect vulnerabilities and to avoid future failures, other aspects of security should also be made public.

As for putting pressure on manufacturers, one colleague describes an incident that illustrates the frustrations that sometimes underlie full disclosure. He informed an important software supplier of a major security vulnerability. The product manager ignored him for a month. At that point, patience gone, the colleague informed the product manager that he had exactly one more day in which to produce a patch; otherwise, he said, he would publish the hole in full in the appropriate Usenet group. A patch was forthcoming within one hour.

Why would anyone object to full disclosure of detailed viral code and exploits? The arguments are that:

- Nobody except researchers needs to know the details of viruses or even of specific exploits.
- Publishing in full gives credibility to ill-intentioned Bad Guys who do the same.
- Full disclosure makes impressionable youths more susceptible to the view that illegal computer abuse is acceptable.

How, exactly, does publishing the details of a new virus help system administrators? In one view, such details should be exchanged only among colleagues who have developed trust in each other's integrity and who have the technical competence to provide fixes. For example, a "zoo" of computer viruses serves this function, with access limited to legitimate virus researchers who sign a code of ethics that forbids casually distributing viruses to anyone who wants samples. Opponents of this stance see the attitude as arrogant and elitist. Furthermore, some virus and worm code is written in a form that is easily read by anyone who receives a copy (a large population, considering that in 1999, the Melissa virus is thought to have infected over a million computers within a matter of days).

There is a danger in publishing exploits where any person with access to the Web can use them for automated attacks on Websites. This gives naïve people the impression that it is okay to publish any attack code, regardless of consequences. (Note that the consequences are often relatively minor—the author of the Melissa virus, which is estimated to have caused at least \$80 million in damages, served only 20 months in a federal prison and paid a fine of only \$5,000.) What is the difference, then, between publishing vulnerabilities or exploits and actually creating attack tools? Was creating and publishing BackOrifice a morally neutral or even a useful act? BackOrifice is a tool that is explicitly designed to install itself surreptitiously on systems and then hide in memory, using stealth techniques modeled on what some viruses use. Is this a contribution to security?

There are no simple or uncontested answers to these questions, but in some cases technology has answered them for us. Before 1995, when macro viruses first appeared

“in the wild,” most viruses were written in assembly language or machine code. This limited the number of people who could read them or understand them to persons familiar with assembly language and machine code. However, anyone who receives a macro virus has the text editor tools needed to read its code. The tools required to develop and test macro viruses are provided in mainstream applications such as Microsoft Word, which has tens of millions of users worldwide, a significant percentage of whom have, or can easily acquire, the rudimentary programming skills required to develop their own viruses. The rapid spread of the original Word Concept virus in the summer of 1995 pretty much ensured that anyone who wanted a copy of it could get one (and many of those who did not want a copy got one anyway). The idea of keeping the content of the virus secret was a nonstarter.

Faced with vendor inability or unwillingness to fix security vulnerabilities in a timely manner, some users and experts can be expected to turn to full disclosure of security information, even though many of them may deplore using such tactics. However, they will always run the risk of making the wrong call when it comes to the effect of such disclosures, which are inherently unpredictable. Indeed, the release of the Word Concept virus may have been motivated by a desire to make Microsoft change the way its office applications handle macros. Other office applications, such as Word Perfect and Lotus 1-2-3, were designed to keep macro code separate from document content, making a malicious document much harder to create.

15.4.3 Sources. There are many sources for information about how to penetrate systems. The motives behind these sources range from highly ethical to downright criminal. Chapter 74 in this *Handbook* discusses training and certification in penetration testing for legitimate, authorized purposes.

15.4.3.1 Online Sources. There is no small irony in the fact that much of what a person needs to know about how to penetrate information systems is made available by information systems. Fortunately, the inverse is also true, as one of this chapter’s authors has observed: “The best weapon with which to protect information is information.”¹⁶ For this reason, security professionals need to know what sources of penetration information are available.

Today there are thousands of Websites that

- Document security holes in different versions of operating systems
- Distribute hacking tools and discuss how to use them
- Catalog default credentials for network hardware
- Teach malicious code writing, including how to make viruses and worms
- List license codes to enable activation of pirated software
- Buy, sell, and trade system access codes, stolen credit cards, stolen identity data, and networks of compromised hosts (botnets)
- Provide a forum and meeting place for those seeking to penetrate systems

These sites have assumed the mantle of earlier online communication channels, such as bulletin boards and Usenet groups, where legitimate sharing of information occurred alongside the exchange of illegal information, pirated code, and so on. Some Websites are moderated and so maintain certain ethical standards. Others follow the Internet tradition of “anything goes.” System administrators and employees should

never participate in discussions on these Websites with company email addresses. In a popular strategy, hackers wait for platform-specific vulnerabilities to be announced, then search the Internet for messages from people using that platform, look at their email addresses to see where they work, and attack systems at those companies in the hope that patches are not yet installed.

15.4.3.2 Publications. Over the years many publications have specialized in hacking. Often these provided information on how to penetrate systems. Some publications were primarily electronic, such as *Phrack*, while others have been print based, such as *2600*, which is now widely distributed through conventional magazine channels as well as through paid subscriptions.

15.4.3.3 Hacker Support Groups. Numerous groups of people exist to share hacking information, ranging from relatively stable entities with their own publications (e.g., *2600* and *cDc*) to annual conventions with thousands of participants (e.g., DefCon). Although some members of these groups may have committed criminal acts, and some participants at hacker conventions actually have been convicted of such and served time, there is usually a diverse mix of elements with different motivations in these groups and meetings. DefCon, for example, draws not only people who openly advocate unauthorized security testing of other people's systems and networks, but also law enforcement personnel and legitimate security experts. Some participants go to DefCon specifically to convince young people not to break laws while trying to learn about security.

Many security professionals would prefer that the line between white-hat hacking and black-hat hacking be clearer and more sharply enforced; however, some companies overlook past transgressions in order to gain the perceived value of the hackers' technical security expertise. Indeed, in recent years, investors have even cooperated with groups of hackers in founding security consulting companies, complete with some employees who continue to use hacker handles. The fact remains that some of the best technical training in the field is provided by people who gained their expertise in criminal (or quasi-criminal) hacking, but who now help defend against such activity.

15.4.4 Future of Penetration. Trends over the last 15 years strongly suggest that attempts to penetrate information systems will not decrease any time soon. These factors have been in play for some time:

- The declining cost of, and increased access to, penetration technology—from software and hardware used to crack passwords and encryption to eavesdropping and interception devices
- The continuing practice of fielding inadequately tested systems, built with immature technology and with insufficient attention to security
- The increased availability of automated hacking tools with easy-to-use interfaces
- The continuing allure, and portrayal in popular culture, of hacking as a “cool” activity, without adequate reflection on its legality or consideration of its morality

Additionally, these factors have emerged strongly in recent years:

- The very real opportunity to make money from penetrating systems, given a thriving market in purloined personal data, compromised hosts (bots), and exploits

15 · 40 **PENETRATING COMPUTER SYSTEMS AND NETWORKS**

- The increased interest and involvement of organized crime in system penetration
- The rise of transnational terrorist organizations that are increasingly computer-literate and may be inclined to penetrate systems belonging to entities or countries to which they are opposed¹⁷

Although some companies and government agencies are actively pursuing improved responses to these threats, others are not. Through lack of concern, resources, or time to address these trends, many entities are at increasing risk. Each new technology brings new threats, but new threats typically are discounted as scaremongering by vendors who offer defenses against them. For many companies and government agencies, the enthusiasm to reap the benefits of new technology overrules the warnings about risks inherent in its deployment. When those risks finally manifest themselves in ways that threaten the organization, the reaction is usually to buy a technical fix, while the root causes of vulnerability, namely human behavior and employee awareness of security issues, fail to receive the attention and resources they deserve.

New applications of computer technology, such as implanted medical devices and control systems for automobiles and autonomous vehicles, are providing fertile ground for experimentation by research scientists and criminal hackers, who are finding many vulnerabilities.¹⁸

15.5 SUMMARY

- Penetration of information systems is possible by means of a wide range of methods, some of which are very hard to defend against.
- Those responsible for securing systems have to defend against this wide range of penetration methods.
- Making sure all defenses against all attacks are effective all of the times is a lot harder than finding a single point of failure within those defenses.
- Although all systems do not need to defend against all types of attack equally, the cost of even the more exotic attack strategies is constantly falling, expanding the range of possible attackers.
- The cheapest and most effective attacks are often nontechnical, exploiting human frailty rather than weaknesses in the technology.
- Experienced criminal hackers tend to favor the nontechnical attack over the technical; and the best defense, employee awareness, is also nontechnical.
- Systems can be attacked at the client, at the server, or at the connection between the two.
- Both wired and wireless systems are highly susceptible to eavesdropping and interception.
- Many systems today are built with immature and insecure technology, making them susceptible to a wide range of attacks.
- New attacks come to light with alarming but predictable regularity.
- Many of these new attacks are old attacks reborn, due to a lack of vulnerability class analysis. As a result of economic pressures, faulty reasoning, and insufficient desire for security, vulnerabilities are fixed one instance at a time rather than one class at a time.

- Allowed path attacks against Websites are consistently the most effective strategy for system penetration whenever a system is Web connected or Web enabled.
- Penetration testing, both by internal staff and by objective external experts, always should precede system deployment.
- Given the inevitability of penetration attempts and the high probability of their eventual success, systems should be designed to survive attacks, limiting the scope of compromise from any single point of failure.
- Penetration of systems will continue to fascinate the curious and tempt them to break the law by illegally accessing systems. The potential gains from system penetration, in terms of money, power, competitive advantage, and notoriety, will continue to motivate those to whom laws and morality are not effective deterrents.
- Penetration of systems will become increasingly automated and simplified, further widening the range of possible attackers.
- Human nature, not technology, is the key to defense against penetration attempts. Only by raising society's ethical standards and educating employees to understand the willingness of others to behave unethically can the occurrence of criminal hacking into information systems be significantly reduced.

16.4	DETECTION OF MALICIOUS CODE	16·11		

16.1 INTRODUCTION. Malicious logic (or code) is “hardware, software, or firmware that is intentionally included in a system for an unauthorized purpose.”¹ In this chapter, we enumerate the common types of malicious code, sources of malicious code, methods of malicious code replication, and methods of malicious code detection.

A 2011 study of 200 small and medium businesses (SMBs) with up to 249 employees reported that “... two in five SMBs know with certainty that they have suffered some sort of security breach as a result of employees navigating to Web sites that host malware, infected downloads or have been corrupted by malicious code.”²

16.2 MALICIOUS CODE

Common types of malicious code include viruses, worms, Trojan horses, spyware, rootkits, and bots. Emerging malicious code threats include kleptographic code, cryptoviruses, and hardware-based rootkits. Present-day malicious code threats do not always fit into neat categories, resulting in confusion when discussing the topic. It is not possible to classify all code as being *good* code or *malicious* code. Absent the *mens rea*, or criminal intent of the author or user, code is neither good nor bad. Authors develop code to achieve some goal or fulfill some purpose just as users run code to achieve some goal or purpose. It is therefore the context of use and the intent of the wielder that determines whether code is malicious.

16.2 MALICIOUS CODE THREAT MODEL. In a threat model or profile, an *actor* uses *access* to target an *asset*, with an *action*, to yield an *outcome*.³ To understand the scope of the problem (and possible prevention), it is useful to study malicious code threats in this model. *Actors* may be structured or unstructured threats posed by individuals, organizations, or nation-states. *Access* is some allowed physical or logical path to the targeted *asset*. The execution of malicious code or logic is an action used to yield the desired *outcome*. This outcome could be intelligence (such as theft of trade secrets), surveillance, reconnaissance, disruption of operations, destruction of assets, publicity for some cause, or negative publicity for the victim.

16.2.1 Self-Replicating Code. Self-replicating code is not inherently malicious. A good deal of artificial intelligence research focuses on iterative self-replication. Hewlett-Packard and others⁴ have researched how techniques of self-replication could yield beneficial software such as code-patching worms. John Von Neumann proposed the basic concept of self-replicating code in his 1949 paper, “Theory of Self-Reproducing Automata.”⁵ In 1961 at Bell Labs, Douglas McIlroy, Victor Vyssotsky, and Robert H. Morris played a game called Darwin in which two opposing programs (memory worms) would enter a system and only one would leave. In an interview with one of the authors, Robert H. Morris the former Chief Scientist of the National Security Agency (NSA), stated:

We had this notion of putting two programs in a machine that would fight with each other and one would win and the other would die. Basically, the notion and the program were written by McIlroy and Vyssotsky and I was just on the side. But then, a few days later, I had a good idea and simply won the game and everyone else gave up ... just because I happened to hit upon a very good idea for writing it.⁶

Although it would be desirable to live in a world free of war, the ever-increasing integration of technology and warfare necessitates the development of offensive information warfare capabilities. Malicious code implants can serve useful intelligence, surveillance, and reconnaissance capabilities in national security and law enforcement operations. In addition, by researching and developing malicious code techniques, practitioners can better prepare for defense against developing threats.

16.2.2 Actors: Origin of Malicious Code Threats. Prior to discussing the specific types of malicious code, it is worth understanding the origin and source of malicious code attacks. Malicious code may originate from structured or unstructured threats. Structured threats include nation-states, corporate criminals, and organized crime. Unstructured threats include rogue actors such as individual intruders and so-called script kiddies.

16.2.3 Actors: Structured Threats. Structured threats are organized, well funded, and may operate with a long-term strategic view. Structured malicious code threats tend to have intelligence, surveillance, and reconnaissance capabilities among their primary functions. Structured threats may use these capabilities to engage in industrial espionage, adversarial information operations, or serious ongoing fraud and theft.

Organized crime is responsible for 90 percent of malicious code threats.⁷ Extortionists target the online gambling industry with threats of distributed denial of service (DDoS) attacks launched from compromised personal computers. Criminals use compromised systems to engage in pump-and-dump stock fraud with one media outlet reporting annual gains by such groups approaching \$1 billion a year.⁸ Malicious software-for-hire incidents are on the rise, indicating a maturing marketplace for malicious code. In 2006, an Israeli court sentenced a couple to prison time and ordered them to pay fines for authoring and placing malicious code used to spy on corporations and individuals by members of telecommunications and trading firms.⁹

Coordinated, systematic attacks originating from China routinely target defense and research and development facilities. In the 1999 text *Unrestricted Warfare*, two Chinese air force officers called for a transformation of warfare that would involve ongoing technological attacks on western assets.¹⁰ A Chinese military white paper released in 2006 called for a strategy whereby China could win an “informationized war”¹¹ against the West that is “high-paced, high-technology, and digitized.” Although Chinese officials publicly deny sponsoring such attacks, the lack of law enforcement action indicates, at the very least, toleration for electronic attacks on Western assets.

16.2.4 Actors: Unstructured Threats. Unstructured threats include rogue actors not acting in concert or coordination with larger entities. Although serious attacks may result from unstructured threats, they do not pose the same long-term challenges as structured threats. In testimony before the United States Congress, former NSA director Kenneth Minihan stated:

The unstructured threat is random and relatively limited. It consists of adversaries with limited funds and organization and short-term goals. While it poses a threat to system operations, national security is not targeted. This is the most obvious threat today. The structured threat is considerably more methodical and well-supported. While the unstructured threat is the most obvious threat today, for national security purposes we are concerned primarily with the structured threat, since that poses the most significant risk.¹²

16.2.5 Access versus Action: Vector versus Payload. Malicious code attacks involve a vector and a payload. In biology, a vector is an agent that transfers (potentially harmful) material (code) from one location to another. In computer attacks, a vector is an avenue of *access*, such as an allowed path via physical access or via the network. Physical access occurs via internal personnel or others with access to the premises. Access via the network may occur via an allowed path to a Web server, an allowed path from a malicious Web server to a Web client, to a user via an email attachment, or to some other software process through an accessible port. The payload is a function (*action*) placed on the system to achieve some end. Payloads may include additional malicious logic, remote access software (rootkits and the like), or remote control (robot or bot) software to achieve some objective (spamming, DDoS attacks, and so forth).

16.3 SURVEY OF MALICIOUS CODE

16.3.1 Viruses. In biology, a *virus* is “[a]n infectious organism that is usually submicroscopic, can multiply only inside certain living host cells, and is now understood to be a non-cellular structure lacking any intrinsic metabolism and usually comprising a DNA or RNA core inside a protein coat.”¹³ In computer terms, a virus is self-replicating code that requires a host executable or document and the aid of a human to replicate. Joe Dellinger created the first virus for the Apple disk operating system in 1982 while a student at Texas A&M.¹⁴ Fred Cohen created the first VAX computer virus in 1983 as a part of his doctoral research.¹⁵ Len Adleman, the A in RSA, first applied the biologic metaphor virus to describe the results.

Types of viruses include boot sector, file infector, macro virus, logic bomb, cross-site scripting viruses (really a form of worm), polymorphic viruses, and cryptoviruses. However, modern malicious code threats tend not to fall so neatly into categories.

16.3.1.1 Boot Sector Viruses. When users boot a computer from digital media, they allow code present in the boot sector of the media to run on the microprocessor with very little intermediation. Boot sector viruses in the 1980s and 1990s used this mechanism to spread via infected removable media such as (now extinct) floppy disks. If a user errantly booted from an infected floppy disk, compact disc (CD), DVD, or flash drive, the virus would copy itself to the boot sector of the hard drive. Thereafter, the malicious program code would copy itself to each medium inserted into the system. Although reportedly still in existence, boot sector viruses comprise very few modern malicious code threats. *Virus Bulletin* reports, “The last boot sector viruses fell off the WildList in early 2006, but various types continue to appear in our prevalence reports and a batch of laptops infected with ‘Stoned.Angelina’ was released in Germany and Denmark in mid-2007. More recently, [T]rojans have been observed using similar techniques to plant rootkits to hide their activities.”¹⁶

16.3.1.2 File Infector Viruses. File infector viruses inserted themselves into programs present on the host system. Whenever a user ran the host program (usually an .EXE or .COM file), the malicious code used the opportunity to insert itself into random access memory (RAM) and then replicate to other files on the system. Although probably still in existence, file infector viruses comprise relatively few modern malicious code threats.

16.3.1.3 Macro Viruses. Macro viruses spread via the macro definition languages used by some applications. The most widely abused is the Visual Basic for Applications (VBA) scripting language that Microsoft developed to allow the automation of functions inside the Office product suite. Any feature that allows for automation is a likely point of attack. Developers should carefully weigh security and ease of use when including such features in products. The first macro virus to target Microsoft Word¹⁷ appeared in the wild in 1995. Since that time, macro viruses have comprised a significant number of successful attacks.

16.3.1.4 Logic Bombs. A logic bomb is a form of malicious code function sometimes built into viruses that wait for some sequence of events to activate such as disappearance of an employee record from the human resources database or a particular

date and time. Kabay gave some examples of early logic bombs in a 2002 Network World article:

In 1985, a disgruntled computer security officer at an insurance brokerage firm in Texas set up a complex series of Job Control Language (JCL) and RPG (an old programming language) programs described later as “tripwires and time bombs.” For example, a routine data retrieval function was modified to cause the IBM System/38 midrange computer to power down. Another routine was programmed to erase random sections of main memory, change its own name, and reset itself to execute a month later.

In 1992, a computer programmer was fined \$5,000 for leaving a logic bomb at General Dynamics. His intention was to return after his program had erased critical data and get paid lots of money to fix the problem.

Time bombs are a subclass of logic bombs that “explode” at a certain time. Some of the first viruses, written in the 1980s, were time bombs. For example, the infamous “Friday the 13th” virus was a time bomb; it duplicated itself every Friday and on the 13th of the month, causing system slowdown. In addition, on every Friday the 13th it also corrupted all available disks. The Michelangelo virus from the early 1990s—one of the first viruses to make it into public consciousness because of news coverage—tried to damage hard disk directories on the 6th of March. The Win32.Kriz.3862 virus, discovered in 1999, detonates on Christmas day; its payload includes massive overwriting of data on all data storage units and also damage to the BIOS.

In 2000, a Stamford, Conn., man was indicted in New York State Supreme Court in Manhattan on charges of unauthorized modifications to a computer system and grand larceny. The defendant worked for Deutsche Morgan Grenfell starting in 1996 as a programmer. By the end of 1996, he became a securities trader. The indictment charged that he inserted a programmatic time bomb into a risk model on which he worked as a programmer; the trigger date was July 2000. The unauthorized code was discovered by other programmers, who apparently had to spend months repairing the program because of the unauthorized changes the defendant allegedly inserted.¹⁸

In 2002 an employee of UBS PaineWebber planted a logic bomb in his employer’s servers as part of an attempted stock manipulation scheme.¹⁹ The perpetrator, Roger Duronio, purchased numerous put option stock contracts allowing him to sell UBS stock at a fixed, high price. On March 4, 2002, at 9:30 A.M., the logic bomb began deleting files on over 1,000 computers, causing a reported \$3 million in damage. Duronio thought that the effects of the logic bomb would bring down the stock value of UBS, allowing him to make a large profit from his stock options. Duronio’s plot failed and his profit did not materialize. Federal authorities later charged him with securities and computer fraud. In 2006 a judge sentenced Duronio to 97 months in prison for the attack.²⁰

In March 2013, a logic bomb overwrote data on hard drives in South Korean banks and broadcasters. Kim Zetter of WIRED wrote,

The logic bomb dictated the date and time the malware would begin erasing data from machines to coordinate the destruction across multiple victims, according to Richard Henderson, a threat researcher for FortiGuard Labs based in Vancouver, the research division of the security firm Fortinet.

The attack, which struck machines on March 20, wiped the hard drives and master boot record of at least three banks and two media companies simultaneously. The attacks reportedly put some ATMs out of operation, preventing South Koreans from withdrawing cash from them.

The malware consisted of four files, including one called AgentBase.exe that triggered the wiping. Contained within that file was a hex string (4DAD4678) indicating the date and time the attack was to begin—March 20, 2013 at 2 pm local time (2013-3-20 14:00:00). As soon as the internal clock on the machine hit 14:00:01, the wiper was triggered to overwrite the hard drive and master boot record on Microsoft Windows machines and then reboot the system.²¹

16 · 6 MALICIOUS CODE

16.3.1.5 Cross-Site Scripting Viruses (or Worms). Cross-site scripting (XSS) viruses (or worms) replicate via flawed Web application servers and client code. A cross-site scripting exploit involving the social networking site MySpace and flaws in Microsoft Internet Explorer occurred in 2005 whereby a user named Samy amassed over 1 million friends overnight using a JavaScript insertion bug.²² The Los Angeles Superior Court sentenced the author, Samy Kamkar, to three years' probation and 90 days of community service for his actions.

In an excellent review of XSS, Sherif Koussa wrote,

Cross-site scripting is an attack that targets the application users. The simplicity of cross-site scripting is also why it is so powerful. If the application is vulnerable to cross-site scripting, the developer is not in charge of what runs on the user's browser anymore ... the attacker is. Cross-site scripting could be used in attacks like authentication hijacking and session hijacking. The power of cross-site scripting manifests itself even more when combined with cross-site request forgery. ...²³

He then cites the case of the Twitter attack below:

In 2009, Mikey Mooney, then 17 years old, claimed responsibility for attacking Twitter using XSS techniques: "... at least four separate variants of the original StalkDaily.com XSS worm hit the popular micro-blogging site Twitter, automatically hijacking accounts and advertising the author's web site by posting tweets on behalf of the account holders, by exploiting cross site scripting flaws at the site." Writer Dancho Danchev provided more details about the attack in his ZDNet article.²⁴

16.3.1.6 Polymorphic Viruses. Polymorphic code modifies itself to evade detection. The virus code may accomplish this by dynamically reassembling itself to modify the underlying structure while retaining overall functionality. In other methods, the virus is encrypted, encoded, or packed, and a stub loader decrypts, decodes, or unpacks the virus at run time. UPX, the Ultimate Packer for eXecutables, is currently the most widely used packer format.

In the SOPHOS Security Threat Report 2013, the authors write:

Polymorphism is not a new idea—malware authors have been using it for 20 years. Simply stated, polymorphic code changes its appearance in an attempt to avoid detection, without changing its behavior or goals. If a program looks different enough, attackers hope, antivirus software might miss it. Or the antivirus software might be forced to generate too many false positives, leading users to disable it.

In a polymorphic attack, code is typically encrypted to appear meaningless and paired with a decryptor that translates it back into a form that can be executed. Each time it's decrypted, a mutation engine changes its syntax, semantics, or both.

For instance, Windows malware authors have often used structured exception handling to obfuscate control flow and make it tougher to perform static analysis of programs before they run.

Traditional polymorphic viruses are self-contained and must contain the mutation engine in order to replicate. Sophos and other security companies have become adept at detecting these forms of malware. With access to the mutation engine, it's easier to analyze its behavior.

Today attackers are rapidly moving to web-distributed malware relying on server-side polymorphism (SSP). Now, the mutation engine and associated tools are hosted entirely on the server. Criminals can use these tools to create diverse file content on the fly. Recipients of this content (whether it is a Windows .exe, Adobe PDF, JavaScript, or anything else) see only one example of what the engine can create. They don't get to see the engine itself.²⁵

16.3.1.7 Cryptographic Viruses. Cryptoviruses use encryption to encrypt data, making it inaccessible to the user. Although some viruses use symmetric algorithms for self-encryption to evade detection, such algorithms are inappropriate for data encrypting viruses, as any copy of the virus is going to yield a copy of the symmetric key. For this reason, proper cryptoviruses use asymmetric techniques. The Gpcode virus encrypts files by extension (.xls, .doc, and the like) and leaves behind a text message prompting the user to email a given address to pay a ransom for access to their files. The next generation of cryptoviruses will likely use hybrid cryptosystems.

In a 2012 report on cryptoviruses, researchers developed proof-of-concept models of viruses using the public-key cryptosystem (PKC) to conceal themselves from scanners and then activate in response to an encrypted key or ticket. Their list of applications of cryptography in malware includes:

- Resist reverse engineering
- Improve anonymity of communications from controllers to the malware
- More effective data theft and denial-of-service attacks
- Remote-control back doors for extortion²⁶

16.3.2 Worms. The term *worm* refers to any form of self-replicating code that does not integrate into executable code. Common worm vectors include vulnerable services, email, instant messaging applications, and open file shares. Many worms use multiple vectors. For example, the Nimda worm spread via email, Web server vulnerabilities, hosted malicious Webpages, and open file shares.²⁷

The first large-scale Internet worm infection was the Morris (aka Internet) Worm released by Robert T. Morris on November 2, 1988, while he was a student at Cornell University. The worm exploited flaws in the Sendmail and finger services to replicate and infected nearly 10 percent of Internet hosts. Although he claimed that this was an experiment gone awry, Morris became the first person convicted under the Computer Fraud and Abuse Act.

In 2001, Nicholas Weaver coined the term “Warhol Worms”²⁸ for those worms that had the capability of propagating very quickly (taking a cue from Warhol’s famous quip that in the future everyone would have 15 minutes of fame). The SQL Slammer worm became the first such worm when it infected approximately 90 percent of vulnerable systems in 10 minutes.²⁹ The Slammer worm replicated due to a flaw in the Microsoft SQL database server. Because this was installed along with other components like Visual Studio, many people did not even know that they were running an SQL server. Slammer was exceedingly effective, because a Microsoft service pack downgraded a previously patched dynamic link library (dll) to an older, vulnerable version. Specifically, Microsoft issued four updates to *ssnetlib.dll* in 2002. Unfortunately, in October, hotfix Q317748 downgraded *ssnetlib.dll* to a vulnerable version, ironically making those who most faithfully applied patches and hotfixes the most vulnerable to Slammer.³⁰

The SQL Slammer worm is an interesting case study because it was a vector without a payload. The 376-byte worm ran in memory without touching the hard disk, leading some to believe that Slammer was an experiment in propagation techniques. Since it was based on the User Datagram Protocol (UDP) and traveled in a single packet, the overhead was minimal and the propagation rate was greater than any previous malicious code threat.³¹ The fact that the author(s) released it on a Saturday is also curious. It is unknown why a malicious attacker would deliberately release such a rabid

16 · 8 MALICIOUS CODE

virus on a day of the week that would lessen the overall business impact. If the author had released the worm on a peak business day such as a Tuesday, the damage caused would have been much more severe.

Worms are used to distribute other forms of malware such as Trojans, spyware, rootkits, and remote command and control channels called *bots*. An indication of the overall maturity of malicious code attacks is the Bagel worm, which has been in production at least since 2004. Bagel, like many other mail worms, arrives as an email with a malicious attachment. When the user runs the attachment, the payload is executed, which does a number of things depending on the variant. Later variants of Bagel install an open application framework that the remote attackers may update and extend. The harvested systems deliver spam (unsolicited commercial email), harvest additional addresses, and act as a staging point for other attacks. The author(s) appear to follow a sophisticated software development methodology and testing process.³² In 2007, attackers released 30,000 new variants in a six-week time span.³³ In April 2012, the Flashback worm “infected more than 650,000 Mac OS X systems using a vulnerability in Apple’s version of Java.”³⁴ Analysts with F-Secure wrote,

Flashback is the most advanced OS X malware we’ve ever seen. It boasts a series of firsts for its kind. It was both the first to be VMware-aware and the first to disable XProtect, OS X’s built-in malware protection program. Both these features were removed from later variants (the former presumably to avoid heuristic detections, and the latter presumably once the authors realized it was unnecessary, as XProtect was not designed to protect against non-quarantine files). Their removal indicates that Flashback is actively being reviewed and improved by its authors.

Another interesting first is Flashback’s exploitation of an unpatched vulnerability in the Java distribution of OS X, which allowed it to infect more than 650,000 Macs around the world. ... This made Flashback roughly as common for Macs as Conficker was for Windows. ... This means Flashback is not only the most advanced, but also the most successful OS X malware we’ve seen so far.

Flashback’s infection strategy is explicitly designed to select unprotected systems and will not infect a machine if certain security software or analysis tools are found. This implies that Flashback’s authors are targeting less security-conscious users, at the expense of the total number of potential targets. This turns out to be an effective strategy, as security researchers had difficulties getting sufficient samples from users. It took a mistake on the part of Flashback’s author to alert users to the presence of an infection and subsequently, to lead to the mass discovery of the malware.³⁵

16.3.3 Trojans. A Trojan horse application, like the horse of Greek mythology, carries both an overt function and a covert function. Although attackers may use worms as one possible propagation vector, Trojans require that a user run the malicious program in order to be effective. Trojans tend to use some form of social engineering or manipulation to persuade the user to run the program. Email worms may appear to originate from a known associate and thereby trick the user. Other Trojans may take the form of games, free offers, pictures of popular celebrities, or files on peer-to-peer file sharing services. One study of the *Limewire* peer-to-peer file sharing service found that “68% of all downloadable responses containing executable, archival, and Microsoft Office file extensions”³⁶ contained malware. Queries for movies were most likely to hold malicious code.

The covert function of Trojan horse application is typically some form of a remote access Trojan, keylogger, dialer, IRC bot, or rootkit. Remote access Trojans provide full remote access to the system. The developers of the Bo2 K Trojan bill it as “the

most powerful network administration tool available for the Microsoft environment” and insist upon the fact that it is functionally no different from other remote access solutions.³⁷ Keylogging Trojans record keystrokes and periodically upload the data to a remote user. Attackers carried out the Windows 2000 source code theft using credentials stolen by a QAZ Trojan installed on a remote workers computer. A dialer is a form of Trojan that silently dials remote toll numbers and runs up a large telephone bill for the victim. Internet relay chat (IRC) bots act as autonomous IRC clients. Early IRC bots provided technical support and channel monitoring features but are now widely used for malicious purposes such as command and control capabilities.

In 2013, Kaspersky Labs reported on “a Trojan build specifically for Android smartphones.”³⁸ sean Gallagher wrote,

On March 25, the e-mail account of a Tibetan activist was hacked and then used to distribute Android malware to the activist’s contact list. The e-mail’s lure was a statement on the recent conference organized by the World Uyghur Congress. ... If the targets opened the attachment ... they received malware packaged in an Android APK file.

When opened, the Trojan installs an app called “Conference” on the Android devices’ desktops. If the app is launched, it displays a fake message from the chairman of the WUC—while sending back a message to a command and control server to report its successful installation. The malware provides a backdoor to the device via SMS messages sent by the server. On command, it returns the phone’s contact lists, call logs, data about the smartphone, its geo-location data, and any SMS messages stored on it to a server via a Web POST upload.

The server itself is running on a Chinese-language configured Windows Server 2003 machine sitting in a data center in Los Angeles. In addition to providing an upload point for the data stolen from Android devices, it also hosts more Android malware in its home page and provides a public Web interface (in Chinese) that allows direct control over phones that have been infected with the malware. While the server itself is at an IP address registered to a company called Emagine Concept, a domain pointed at the machine is registered to Shanghai Meicheng Technology Information Development Co., Ltd., a Chinese company with a contact in Beijing.³⁹

This Trojan thus distributes spyware, the next topic.

16.3.4 Spyware. The term *spyware* refers to any software that collects user information without consent. Common varieties of spyware collect information on Web usage, serve advertising content (pop-ups), log keystrokes, engage in click fraud, or monitor program usage and licensing. Unauthorized access or exceeding authority on a computer system is a violation of the Computer Fraud and Abuse Act. Although some spyware may be illegal, some developers insist that they are engaged in a legitimate business activity. Such spyware provides an end user license agreement (EULA) allowing the user to opt out of installation. Since the user must grant permission for the software to install, it is almost certainly legal. However, whether this is ethical and conscionable is a different matter. Sony attracted significant negative publicity for their use of spyware technology to limit the ability of listeners to copy music compact discs. Due to this activity, Sony faced legal charges in multiple states and in 2005 settled a class-action lawsuit. Informed consent is the rule of thumb in any monitoring system. Organizations should endeavor to be forthright in these matters in order to maintain a positive public profile and to avoid legal challenges.

In May 2013, news surfaced about the use of spyware to monitor the communications of a Bahrain human-rights activist. In a court hearing, details arose describing

16 · 10 MALICIOUS CODE

how Dr Ala'a Shehabi was monitored through infection of her systems through a phishing attack:

According to her witness statement, a few weeks after her arrest Shehabi received a series of emails, the first purportedly from Kahil Marzou who was the deputy head of Bahrain's main opposition party, including one containing a virus. Other emails that claimed to be from an Al Jazeera journalist were also infected. Research found that the emails contained a product called FinSpy, distributed by a British company, Gamma International.

The witness statement claims that when a person's computer is infected with FinSpy, "it allows access to emails, social media messaging, and Skype calls, as well as copying the files saved on the hard disk. These products also enable whoever is doing the targeting to commandeer and remotely operate microphones and cameras on computers and mobile phones."⁴⁰

16.3.5 Rootkits. A rootkit consists of a set of tools for covertly compromising a system and maintaining administrative (root) access for the intruder. Present-day rootkits compromise a system at the application, library, kernel, hypervisor, or hardware level. Early application-level rootkits targeted UNIX-like systems and replaced standard system utilities (netstat, ps, and the like) with versions that omitted information on the intruder, such as open ports, running processes, open files, and other activity. API-level rootkits modify or patch the system call table to redirect system calls (like an API-level monkey-in-the-middle attack). Kernel-level rootkits run as device drivers and dynamically load into the kernel; compromising the integrity of the core of the operating system to filter information presented to users via application-level processes.

Nearly all modern operating systems make use of virtualization for memory and process management. An operating system normally runs in ring 0 of the microprocessor; the most privileged level. A hypervisor is a layer of code between the operating system and the hardware that fools the operating system into believing that it is running in ring 0. The hypervisor monitors and arbitrates exchanges between virtual machines and the real hardware. Hypervisor design is a key part of the trusted computing framework, and microprocessor designers like Intel and AMD are including enhanced hardware-based virtualization capabilities in their products. An emerging generation of rootkit technology uses this framework to create potentially undetectable code.^{41,42}

Other potential rootkit threats come from insiders, hardware designers, and manufacturers. An attacker with physical access could insert a peripheral component into a computer to create a logically undetectable rootkit. A hardware manufacturer or designer could include rootkit-like capabilities in a microcircuit. The 2005 sale of IBM's Personal Computer Division to Chinese manufacturer Lenovo caused enough concern in the United States to prompt a national security review of the transaction.⁴³ The review by the House Committee on Foreign Investment in the United States (CFIUS) eventually approved the sale despite concerns expressed by Reps. Henry Hyde and Don Manzullo of Illinois and Rep. Duncan Hunter of California.⁴⁴

16.3.6 IRC Bots. IRC bots are autonomous agents that make use of Internet Relay Chat (IRC) to offer interactive services like channel monitoring, support, information services, and games. Greg Lindhal wrote the first IRC bot GM (game master), which led users through the text-based role-playing game "Hunt the Wumpus." In 1999, the PrettyPark worm became the first worm to use IRC as a remote control channel. Infected systems would check into an IRC server and channel to download updates and upload stolen data. Attackers create malicious bots to carry out DDoS attacks (DDoS

bots), send unsolicited commercial email (SpamBots), and engage in exploitation, theft, or fraud.

Examples of current bot frameworks are GTbot, SDbot, Agobot, Goabot, Randex, Spybot, and Phatbot. The current generation of bot technologies includes keylogging, port scanning, exploitation, packet sniffing, process hiding, and adware fraud capabilities. A single network of these compromised systems may reach more than 100,000 bots. Researchers in 2004 estimated that there were over one million bots currently connected to the Internet.⁴⁵ Bot herders rent out these massive distributed networks systems to criminal organizations. In 2006, a California court sentenced one such bot herder, Jeanson Ancheta, to five years in prison for conspiring to violate the Computer Fraud and Abuse Act, conspiring to violate the CAN-SPAM Act, causing damage to computers used by the federal government in national defense, and accessing protected computers without authorization, in order to commit fraud.⁴⁶

16.3.7 Malicious Mobile Code. Web servers may host pages containing malicious mobile code. ActiveX controls, Java applets, JavaScript, Adobe Flash animations, and any other type of dynamic executing code can download to a user's system and run in their context with all associated privileges. Malicious Web servers are one method for dropping Trojans and bots onto computers. An attacker may use a spam or phishing attack to encourage users to click on a link embedded within an email. Another vector is to use a similar domain name to a legitimate organization. Yet another vector is for the site to offer information in some matter. Once indexed in the major search engines, this content will draw a number of users to the site. See Chapter 17 in this *Handbook* for further details on malicious mobile code.

16.4 DETECTION OF MALICIOUS CODE. Common methods of detecting malicious code include signature-based, network-based, and behavioral heuristic techniques. However, as far back as in the 1984 work *Computer Viruses—Theory and Experiments*, Fred Cohen demonstrated that the only way one could prevent all possible viral code would be through isolation.⁴⁷ While there are numerous methods of detecting malicious code, no one technique works on every variety or in every circumstance, and there is always some method for successfully evading detection.

16.4.1 Signature-Based Malicious Code Detection. Some of the oldest methods of malicious code detection are signature-based methods that utilize known strings or patterns in the code. Signature-based methods are easy to implement and impose very low overhead on the system but are just as easily evaded. Polymorphism and metamorphism⁴⁸ are two methods by which malware may change form over time and thereby evade signature-based detection. Detection systems can use hash functions to fingerprint a given binary program or code fragment. However, the hash will fail to match on any modified version, making this method reliable but not always useful. Overall, signature-based methods are not terribly reliable, although signatures are one useful metric in more complex heuristics.

16.4.2 Network-Based Malicious Code Detection. Network-based methods of malicious code detection look for network artifacts associated with malicious code, such as a connection to a server as in the case of a keylogging Trojan or Internet Relay Chat (IRC) bot. Network anomaly detection works well but is expensive and poorly understood by many security practitioners. A simple method for

16 · 12 MALICIOUS CODE

network-based detection is to analyze network flow (netflow) data in comparison with a statistical database of known good traffic. However, malicious code that acts normal can bypass such methods of detection. Predicting what is normal for a given environment may be difficult for an outsider, but analyzing certain activity like domain name system, email, and Web usage can produce generic models for evasion.

16.4.3 Behavioral Malicious Code Detection. Behavioral methods of detecting malicious code analyze the actions of running software to look for illegitimate activity. This could be opening a port, connecting to a remote host, or modifying the system call table or other memory areas. Behavioral methods of detection will fail if the malware acts normal or if the malicious code can target and exploit the detection system itself. A slow but effective method of detecting potentially malicious code is to use a virtual machine approach, whereby the system allows code to execute in a sandboxed virtual machine. This allows for a full functional analysis of the code, but the current throughput of such systems makes them not useful for today's high-speed production environments.

16.4.4 Heuristic Malicious Code Detection. Heuristics that are more complex may use both statistical and behavioral models to determine a relative score to a normal corpus (statistical database in this case) of legitimate behavior. Bayesian analysis is widely used in the detection of spam. However, this method can also detect new variants of existing malicious code with a high degree of accuracy. N-gram analysis is a form of frequency analysis borrowed from natural language processing that can model software and fingerprint data types. This method is useful for detecting executable code embedded within other data objects. In short, there is no single, monolithic way to detect all malicious code. Spinellis demonstrated that reliable detection of malicious code is NP-complete,⁴⁹ meaning that the dilemma is not solvable in polynomial time. However, the technologies discussed, used in concert, are relatively effective in detecting many common malicious code threats.

16.5 PREVENTION OF MALICIOUS CODE ATTACKS

16.5.1 Defense in Depth. As the problem of malicious code is demonstrably NP-complete (not solvable), a single antivirus program cannot protect against all malicious code threats. One strategy, called *defense in depth*, uses operational, human, and technical controls. Another strategy is to build networks and applications that only function one correct way. Such *orthogonal* networks and applications are a rarity as they are expensive and difficult to design, and many firms will resist imposing rigid limitations on the enterprise.

16.5.2 Operational Controls for Malicious Code. All organizations must create written policies and procedures regarding the introduction of program code into the operating environment. Policies should define what persons the firm allows to install programs, acceptable use for Internet access, acceptable use for email systems, and what to do if users suspect the compromise of a system or user. Organizations should subject all new employees to some level of background investigation. This should include, at a minimum, a criminal records search, verification of all references and credentials, and a credit report. Employers should ensure that the prospective employees are forthright and truthful on their application. If employees lie prior to employment, the odds are that they will lie later as well.

16.5.3 Human Controls for Malicious Code. All users (including executives) should receive training on the policies and procedures of the organization. Due to the evolving nature of the malicious code threat, the organization should update and refresh this training annually at the very least. The training sessions should introduce the prevalent types of threats, how to detect the threats, and proper response. Currently, this training should include identification of advance-fee fraud (also known as Nigerian 419 frauds), social engineering attempts, and detection of malicious attachments. Users should notify the help desk or other entity if they encounter any anomalous system or user behavior.

16.5.4 Technical Controls for Malicious Code. For more detailed information on antivirus technology, see Chapter 41 in this *Handbook*.

16.5.4.1 Implementing Antivirus Systems. Implement an antivirus (A/V) solution that suits the operational environment. This solution should include both network-based and host-based systems. Network-based systems function inline like a gateway, while host-based systems run on host end points. These systems should come from different vendors, as there is less benefit when using the same software on the network and hosts. A diverse detection and containment strategy will help firms avoid the pitfalls associated with active malcode exploitation of antivirus software, as occurred in 2004⁵⁰ and again in 2006.⁵¹ The last thing that organizations should permit when designing an A/V strategy is for antivirus software to serve as the vector for an active malcode attack.

The A/V solution should provide a mechanism for dynamically applying updates and should do so daily, at the least. Email systems may require a separate inline appliance to detect email-borne malicious code as well as spam, fraud, and phishing attacks. By using a diversity of detection approaches, organizations can attain higher rates of detection than by using a single stand-alone product.

16.5.4.2 Host Configuration Controls and Security. Host configuration can mitigate many malware threats prior to emergence. Implement a form of automatic updates (patches, etc.) that supports the operating environment. Many technical malicious-code threats (e.g., worms) target well-known and patched flaws. Eliminate all noncritical software and services. This will help minimize threats that target the ever-burgeoning code complexity that security professionals face. In one study, programmers trained in the capability maturity model for secure software development continued to make 4.5 errors per 1,000 lines of code.⁵² For an operating system like Microsoft Vista, which one estimate puts at 50 million lines of code,⁵³ extrapolating this statistic means that there are likely at least 225,000 code errors. Disabling or removing as much of this code as possible is a reasonable preventive control. If the environment permits, remove all Web browsers. If the environment does not allow this, lock down the browser configuration and use a secure Web proxy.

16.5.4.3 Network-Based Security Controls. A layered defense of routers, firewalls, proxies, and switched virtual local area networks (VLANs) can mitigate malicious code propagation. At the router, filter all inbound bogus network addresses (BOGONs), Request for Comment (RFC) 1918 addresses, and spoofed internal addresses per RFCs 2267⁵⁴ and 3704.⁵⁵ If the enterprise faces specific threats from certain nations, filter the network blocks allocated to those nations at the border router.

16 · 14 MALICIOUS CODE

Use the current best practices in firewall configuration. (These change rapidly.) Use a secure, authenticated Web proxy, and force all clients to use the proxy. (No user should be able to access the Web directly.) Disable all unused LAN access ports, or consider using 802.1x authentication to do so automatically. Segment the network into functional workgroups using VLANs or physically separate switch architecture. If possible, implement access control lists between VLANs or switched segments. The goal is to make the network as orthogonal as possible. If the network can function only one right way, the organization will avoid many automated malicious code threats entirely.

16.5.4.4 Network Monitoring. Prevention of malicious code threats is ideal, but detection is critical. Most malicious code attacks will have some artifact, whether host based or network based. To detect these artifacts, organizations should establish a security information management system that aggregates device logs, server logs, host logs, intrusion detection system alerts, and network flow data. Network flow data is a useful tool for detecting anomalous network activity. A network flow is a 5-tuple consisting of a source address, destination address, source port, destination port, and protocol with an associated time stamp. Any malicious network activity is going to have an associated flow. Stealthy malware, however, will attempt to act normal in order to evade detection. Detecting anomalous activity requires that operators understand what is normal for the environment. Without a historical statistical database or extensive experience, this can be difficult. Network anomaly detection (NAD) uses a statistical modeling methodology⁵⁶ to use this data to detect statistical outliers. This is extraordinarily effective for detecting new malicious code threats as well as other forms of anomalous behavior. However, a lack of understanding appears to limit the adoption of NAD. This is one area where many organizations could improve their practice of information security controls.

16.6 CONCLUSION. Malicious code threats are as numerous as the variety of nonmalicious code. Prevention of all malicious code is not possible as the problem is demonstrably NP-complete.⁵⁷ However, a strategy of defense in depth that uses operational, human, and technical controls can be relatively effective. Used properly, the current generation of technical controls available to organizations is effective in stopping a majority of malicious code threats. However, the trusted insider typically has the access needed to turn a threat into a reality of operational risk. Current trends in malicious code threats indicate a continued pattern of organized criminal involvement and international espionage that continues to target the weakest link in the security chain: the human being.

17.1 INTRODUCTION. Computing has been transformed in the last twenty years. In these past two decades, access to the World Wide Web has gone from a rare desktop novelty to the ubiquitous; now the majority of people carry mobile devices with full wireless Internet access. The online world has blossomed over the past two decades. The term mobile device is no longer an ironic oxymoron. Twenty years ago, today's dumb phone was the size of a suitcase; today, a far more powerful smart phone easily fits in a child's palm.

Today's portable devices are far more powerful than the mainframes of yesteryear. Their capabilities present a security and information assurance challenge. The consumer-friendly model of easy-to-add enhancements to these devices complicates the security ecosystem.

The World Wide Web began with simple, static pages. Applications soon started to produce pages on demand. The evolution of Web-related technologies has grown to include significant reliance on JavaScript (also known as ECMAScript¹) through the use of AJAX and other techniques, as well as the use of Java and other plug-ins.

17 · 2 MOBILE CODE

The challenge is that such code is often delivered by outside agencies as it is needed (e.g., JavaScript elements are downloaded from the supplier or other Web server as pages are loaded; apps for mobile devices are installed on the fly at little or no nominal cost when desired by the owner of the device). Thus, there is often little or no opportunity to vet the behaviors of such code, or even to maintain a semblance of control. One version of the code may be well-behaved; the next version may enable a compromise of the device, whether inadvertent or deliberate. The Apple App Store used with iPhones[®], iPods[®], and iPads[®] has an approval and vetting process, but the process has not been totally without flaw.² As an example, it is not uncommon to reference external JavaScript elements using unencrypted hypertext transfer protocol (HTTP), rendering the Web page inherently vulnerable to masquerading, man-in-the-middle, domain name impersonation, and other attacks. If nothing else, the integrity of an externally supplied element is dependent on the integrity and security of every element in the network, a daunting reality.

At the most basic level, mobile code is a set of instructions that are delivered to a remote computing device for dynamic execution or installation on the device. Such prepackaged components are a boon to applications on desktops and mobile devices; however, the inherent power of the approach comes with significant hazards. The hazards associated mobile code stem from its inherent ability to do more than just display characters on the remote display.

It is this dynamic nature of mobile code that causes policy and implementation difficulties. A blanket prohibition on mobile code is secure, but that prohibition would prevent users of the dynamic Web from performing their tasks and deny users of mobile devices much of the device's utility. The tension among integrity, flexibility, and dynamism is at the heart of the issue.

The advent of mass-market appliances, from personal devices (e.g., smart phones, tablets) to out-of-the-box appliances (e.g., file servers) makes blanket prohibitions often infeasible. Such devices are delivered with prepackaged or downloaded software, which can then be enhanced via the downloading of entire new versions, or extensions known as *apps*. In both cases, the software elements developed by the manufacturer or third parties are prepackaged, with little or no possibility for customer organization testing. Although IT consumerization has benefits, one of the significant drawbacks is the loss of user and corporate visibility into what software is in use, and what access the software has to information.^{3,4,5,6}

Smart phones and tablets are emblematic of IT consumerization. Without the enhancements provided by apps these devices provide a faint shadow of their true capability. However, a rogue or weakly defended app can be downloaded by an unsuspecting user, compromising sensitive data. Apps are supplied as prepackaged, binary installation files, typically delivered over wireless communications pathways (e.g., Wi-Fi or the cellular communications network).

Several definitions, as used by United States military forces but applicable to all, are useful in considering the content of this chapter:

Enclave. An information system environment that is end to end under the control of a single authority and has a uniform security policy, including personnel and physical security. Local and remote elements that access resources within an enclave must satisfy the policy of the enclave.

Mobile code. Software obtained from remote systems outside the enclave boundary, transferred across a network, and then downloaded and executed on a local system without explicit installation or execution by the recipient. Mobile code is a powerful software tool that enhances cross-platform capabilities, sharing of resources, and Web-based solutions. Its use

is widespread and increasing in both commercial and government applications. . . . Mobile code, unfortunately, has the potential to severely degrade . . . operations if improperly used or controlled.

Malicious mobile code. Mobile code software modules designed, employed, distributed, or activated with the intention of compromising the performance or security of information systems, increasing access to those systems, providing the unauthorized disclosure of information, corrupting information, denying service, or stealing resources.⁷

17.1.1 Mobile Code from the World Wide Web. In discussions of the World Wide Web, the phrase *mobile code* generally refers to executable code, other than HTML and related languages (e.g., Extensible Markup Language, or XML), delivered electronically over a communications network (e.g., Web, email) for execution on the client's computer. The most common packaging technologies for mobile code are apps, ActiveX, Java, and JavaScript.

Mobile code can directly perform covert functions on a client system, accessing information or altering the operation or persistent state of the system; it can create accidental or deliberate vulnerabilities that can be exploited at a later time.

The widespread use of mail clients that support executable email content (e.g., HTML email, with either embedded or referenced program code), has become a significant source of vulnerability.

Pop-ups can also be a source of vulnerability in many ways; in particular, they can access other WWW sites and pages and may give rise to log entries that can cause legal problems. The experience of Julie Amero, a Norwich, Connecticut, substitute teacher, is as troubling as it is cautionary. Ms. Amero was accused⁸ and convicted of using a classroom computer to access inappropriate material. The worst charges were subsequently withdrawn when it became clear that the classroom computer at the center of the incident had been infected with malware days before the incident, the antivirus subscription had lapsed, and the testimony of willful access was demonstrated to be factually incorrect. However, Ms. Amero was subjected to an extended prosecution and pilloried in the press. Settling the case required Ms. Amero to plead guilty to a misdemeanor, surrender her teaching license, and pay a fine.^{9,10,11}

Although malicious software such as viruses, worms, and Trojan horse programs written in compiled, interpreted, or scripting languages such as Visual Basic also might be considered mobile code, these pests are not generally labeled as such; this chapter deals only with *apps*, ActiveX controls, Java applets, and JavaScript programs. See Chapter 16 in this *Handbook* for details of other kinds of malicious code.

Today's increasingly dynamic and rich Internet applications rely on AJAX,¹² WebSockets,¹³ and other technologies, which in turn rely on JavaScript and other mobile code technologies. These applications increase the scope of the threat while also making it more difficult to ban the use of the vulnerable technologies.

Although systems or applications crashes are the most spectacular problems with mobile code, they are not the most dangerous. Persistent, silent, and covert access or modification of client system data pose far more serious threats. For example, some Web sites have covertly obtained email addresses from users' browsers, resulting later in unwanted commercial email. Similar attacks have been made against mobile devices phonebooks and contact lists. As the motivations for such attacks have migrated from pranks to criminal and nation-state-sponsored espionage, the importance of undetected covert access to data has correspondingly increased.

In the past, antimalware tactics have relied heavily on widespread distribution of threats. The expected emergence of designer mobile code, specifically targeted to a

17 · 4 MOBILE CODE

particular system or a small number of systems, is a dangerous trend.¹⁴ These targeted attacks often slip through signature scanning systems; widespread distribution and publicity are not part of their intended use.

Fraudulent electronic mail attacks are generally referred to as *phishing*, reportedly derived from the combination of phreaking (as in phone phreaking, bypassing long-distance billing systems) and fishing. With some sense of humor, targeted phishing is referred to as *spearphishing*; attacks against senior managers (e.g., CEOs) are referred to as *whaling* or *harpooning*. The nomenclature may be humorous, but well-executed harpooning attacks can be difficult to detect or prevent. Such attacks have been found at the center of several important compromises (e.g., the 2011 spear phishing attack against RSA¹⁵) at major corporations. High-value targets are not only senior executives; individuals with access to or authority over high-value information are equally at risk.

One of the earliest documented episodes of this type is the 2004 use of Trojan horse software, discussed in §2.10.5 in this *Handbook*, for extensive data theft. This case was not an isolated incident. The trend of targeted attacks against senior personnel, rather than random attacks, has accelerated.¹⁶

Investigative agencies have also entered the fray. In July 2007, an affidavit filed by the Federal Bureau of Investigation in connection with a series of bomb threats described the use of spyware to infiltrate a suspect's computer and return information to investigators.¹⁷

Mobile code presents a complex set of issues to information technology (IT) professionals. Allowing mobile code into an operating environment compromises any enclave; however, even commercial off-the-shelf (COTS) programs breach the integrity of an enclave. The differences between mobile code and other forms of code are primarily in the way these external programs are obtained, installed, documented, and controlled. In an enterprise computing environment, COTS acquisition normally involves conscious and explicit evaluation of the costs and benefits of installing a particular named and documented program. In contrast, mobile code programs are installed largely without notification to the user, and generally without documentation, change control, or review of any kind. Unless client-system firewalls are set to reject mobile code automatically (which is increasingly difficult, if not a technical and practical impossibility), system administrators cannot be certain exactly which software has been executed on client machines under their nominal control. The use of Secure Sockets Layer (SSL)-based technologies such as HTTPS to otherwise secure connections used by applications also has the side effect of preventing the detection of mobile code at the firewall level. Although such control is often illusory, due to user circumvention of restrictions on installation of unauthorized software, the use of mobile code, installed by external Web sites, seriously compromises any remaining control over employee software configurations.

Mobile code has also been used in some cases to enforce proprietary rights in content, as was the case in a 2005 affair involving Sony Music.¹⁸ The Sony Music case involved software contained on music CD-ROMs; precisely the same effect could have occurred with a downloaded file or Web page. The covert installation of software of any kind is a serious hazard to integrity, security, and privacy. Malfunction or misuse of such software would likely fit within the criminal statutes defining illegal, unauthorized alteration of systems. The attorney general of Texas,¹⁹ as well as private class actions in New York²⁰ and California,²¹ all filed cases against Sony. All of these actions were settled by Sony BMG in December 2006.²² In January 2007, the U.S. Federal

Trade Commission announced a settlement with Sony BMG on the charges of installing software without permission.²³ Investigations were also opened by the attorneys general of Massachusetts and Florida, as well as overseas in Italy and Canada.

There are also reports that the Sony Root Kit was exploited by the Backdoor.IRC.Snyd.A exploit²⁴ and others to hide files from malware scans. The widespread nature of this induced vulnerability should also give pause. A widespread vulnerability provides an ecological niche ready for exploitation.

17.1.2 Motivations and Goals. The motivations and goals of malware propagators have continued an evolutionary trend from the unintentionally destructive to the vengeful, vindictive, and criminal. Unsurprisingly, the actors have migrated from rogue individual pranksters to criminals and nation states and proxies.

In the beginning, many incidents were randomly damaging, or pranks with unintended side effects. This is no longer the case. Now malevolent mobile code is often code with a purpose. That purpose may be embarrassment, it may be blackmail, it may be corporate espionage, or it may be out-and-out theft. In a different dimension, the goal may be the subordination of otherwise innocent computer resources for a criminal enterprise against unrelated third parties.

The change in goals also has a dramatic impact on counter strategies. When the goal was mass publicity, the same infection was widespread, and scanning technologies could be used to identify known threats. When the goal is no longer publicity, publicity and widespread infection are maladaptive. Covert infection is then a far more attractive strategy than mass distribution. Custom mobile code designed to achieve selective covert infections is unlikely to quickly appear in the crosshairs of scanning software. This follows the evolutionary trajectory common in the biological world, where pathogens tend to mutate into less fatal forms over time. It is maladaptive for a parasite, which is what most malware is, to fatally damage its host. The downside of this effect is that the chronic infections with no apparent side effects are often overlooked.

Going forward, technologies and operational routines that make it difficult for unauthorized code to take up residence in or compromise the persistent state of the system are far more desirable counterstrategies than approaches based on scanning for known infections.

17.1.3 Design and Implementation Errors. Design and implementation errors take a variety of forms. The simplest cases involve software that malfunctions on a constant predictable basis. More pernicious and more dangerous are those errors that silently compromise the strict containment of a multiuser environment. Errors in such prophylactic layers, known as brick walls or sandboxes, compromise the integrity of the protection scheme. In the worst cases, they permit unfettered access to system-level resources by unprivileged user programs.

Design and implementation errors can occur within any program or procedure, and mobile code is no exception. *Sandboxes* (nonprivileged, restricted operating environments) are intended to prevent unauthorized operations. *Authentication* determines which organization takes responsibility for such errors.

This chapter looks at a security model based on authentication of mobile code and then examines how restricted operating environments help to limit damage from harmful mobile code.

17·6 MOBILE CODE

These concerns are appropriate to both widely distributed and targeted attacks. The challenge of targeted attacks lies in their small population; targeted attacks are unlikely to appear on the radar of general distribution scanning programs.

17.2 SIGNED CODE. Authentication technologies are designed to ensure that information supplied by an organization has not been altered without authorization. The technology used to implement this assurance is based on use of the Public Key Infrastructure (PKI), as discussed in detail in Chapter 37 in this *Handbook*. Code authenticated using PKI-based mechanisms often is referred to as *signed*. Signed code generally is immune to unauthorized modification; however, a signature guarantees integrity only from the point in time that the code is signed; the signing process does not imply safety or quality of the code prior to the point of signing.

Once signed, a file cannot be altered without invalidating the original signature; without the cooperation of someone holding access to the private key associated with the creating organization's X.509 certificate, the signature cannot realistically be tweaked to look legitimate. (An X.509 certificate, digitally signed by an authorized user, authenticates the binding between a user's name and the user's public key.) However, looking below the surface, such precautions do not address a variety of vulnerabilities:

- Unauthorized access to private (signing) keys
- Access to the code base prior to signing
- Fraudulent certificates
- Design and implementation errors

17.2.1 Authenticode. Microsoft's Authenticode technology is an example of an authentication-based approach.²⁵ Developers wishing to distribute code obtain an appropriate digital certificate from a Certification Authority (CA) and use the digital certificate to sign the code. The signature is then checked by the client system each time that the code is executed.

Authenticode relies on several components:

- PKI and the X.509 certificates issued by a Certification Authority.
- Limited access to the private keys associated with the issuing organization's X.509 certificate. In Microsoft terminology, the term Software Publishing Certificate or SPC refers to a PKCS #7 object, which in turn contains a collection of X.509 certificates used to sign code.
- The integrity of the processes used by the CA to ensure that requests for X.509 certificates are legitimate.

Authenticode does not address issues relating to the safety or accuracy of signed code, merely that it is authentic and unaltered since signing. For example, signing does not provide any guard against employee malfeasance.

17.2.2 Fundamental Limitations of Signed Code. Signing technologies, regardless of the context (e.g., email, applets, and archives), do not directly address questions of accuracy or correctness; they merely address questions of origin. The

biggest danger in signing schemes is the all-or-nothing approach taken to trust. Signed items are presumed to be trustworthy to the fullest extent of the requesting user's authority. The signed item can perform any operation that the user would be permitted to execute. There is no concept of *partial trust*. In an attorney's words, such an acceptance would be a *general power of attorney*. In the words of the CERT/Coordination Center (CERT/CC)—sponsored *Security in ActiveX Workshop*: "A digital signature does not, however, provide any guarantee of benevolence or competence."²⁶

At the same time, the inherent power and apparent legitimacy of a digital signature place a heavy burden on signers and the higher levels of the PKI to ensure the integrity of the mechanisms and secrets.

The key to the integrity of signed code is the signing process and the process that generates the object to be signed; the security of the secret keys required for its implementation determines the degree of trust in attribution of the signed code. In the truest sense, the private keys associated with the X.509 certificate represent the keys to the kingdom, as valuable as a signature chop in the Far East or a facsimile signature plate for a bank account.

On a practical level, accepting code signed by an organization is an explicit acceptance that the signing organization has good controls on the use of its signing keys. Organizations that take security seriously, segregating access to privileged accounts and controlling access to systems, are well positioned to manage the procedures for signing code.

Thus, the procedures and systems used for signing code should be treated with the same caution as is used for the aforementioned signing plates or the maximum security cryptographic facilities familiar to those in the national security area.

Unfortunately, despite years of publicity about the dangers of shared passwords and accounts, many IT installations continue to use shared accounts and passwords. There is little reason to assume that the secrets relating to PKI are better protected, despite extensive recommendations that those details be well guarded.

17.2.3 Specific Problems with the ActiveX Security Model. The CERT/CC workshop on Security in ActiveX summarized the security issues in three major areas: importing and installing controls, running controls, and the use of controls by scripts.²⁷ The key findings from this report are as follows:

- Importing and Installing Controls
 - As discussed, the sole basis for trusting a signed control is its presumed origin. However, the originator of the code may have incorporated a design flaw in the control or may not have done adequate software quality assurance to prevent serious bugs.
 - A trusting user may install a signed control that contains a vulnerability making it useful for attackers simply because it is signed.
 - On Windows systems with multiple users, once a control has been permitted by one user, it remains available for all users, even if their security stances differ.
- Running Controls
 - An ActiveX control has no limitations on what it can do on the client machine, and it runs with the same privileges as those of the user process that initiated the control.

17 · 8 MOBILE CODE

- Although ActiveX security measures are available in Internet Explorer, other client software may run controls without necessarily implementing such security. Internet Explorer security levels tend to be all or nothing, making it difficult to allow a specific control without allowing all controls of that type. Remote activation of controls can bypass normal security perimeters such as those imposed by firewalls.
- There is no basis for deciding whether a particular control is safe to execute or not, in any particular context.
- Scripting Concerns
 - Lacking a general basis for limiting the actions of controls, ActiveX programmers must effectively determine their own precautions to prevent harmful actions. It is difficult enough to develop a good set of boundaries on program activity, even if one uses a general model such as the sandbox described later; it is extremely difficult to see how individual developers can be expected or, more importantly, trusted to create their own equivalent of the sandbox for each individual control. In light of these hazards, the authors of the CERT/CC report stated that “there is a large number of potential failure points.”

17.2.4 Case Studies. Several security breaches or demonstrations mediated through ActiveX have occurred since the introduction of this technology in the mid-1990s.

17.2.4.1 Internet Exploder. In 1996, Fred McLain wrote Internet Exploder, an ActiveX control designed to illustrate the broad degree of trust conferred on an ActiveX control by virtue of its having been signed. Exploder, when downloaded for execution by Internet Explorer, will shut down the browser’s computer (the equivalent of the *Shut down* | *Shut down* sequence from the Start menu on a Windows system). This operation is operationally disruptive but does not actually corrupt the system. McLain notes in his frequently asked questions (FAQ) on Exploder that it is easy to build destructive or malicious controls.²⁸

Exploder raises an important question: Who and what are the limits on trust when using signed code? In normal commercial matters, there is a large difference between an inauthentic signature, a forgery, and a properly signed but unpayable check. In software, the difference between an inauthentic control and a dangerous one is far less clear.

17.2.4.2 Chaos Computer Club Demonstration. On January 27, 1997, a German television program showed members of the Chaos Computer Club demonstrating how they could use an ActiveX control to steal money from a bank account. The control, available on the Web, was written to subvert the popular accounting package Quicken using what amounts to an electronic version of tailgating. A victim need merely visit a site and download the ActiveX control in question; the control then automatically checked to see if Quicken was installed. If so, the control ordered Quicken to issue a transfer order to be saved in its list of pending transfers. The next time the victim connected to the appropriate bank and sent all pending transfer orders to the bank, all the transfers would be executed as a single transaction. The user’s personal identification number (PIN) and transaction authorization number (TAN) would apply to all the transfers, including the fraudulent one in the pile of orders. Most

victims would be unaware of the theft until they received their next statement—if then.²⁹

Dan Wallach of Princeton University, commenting on this case, wrote:

When you accept an ActiveX control, you're allowing completely arbitrary code to rummage around your machine and do anything it pleases. That same code could make extremely expensive phone calls, to 900 numbers or over long distances, with your modem; it can read, write, and delete any file on your computer; it can install Trojan horses and viruses. All without any of the subterfuge and hackery required to do it with Java. ActiveX hands away the keys to your computer.³⁰

Responding to criticisms of the ActiveX security model, Bob Atkinson, architect and primary implementer of Authenticode, wrote a lengthy essay explaining his point of view. Among the key points:

- Microsoft never claimed that it would certify the safety of other people's code.
- Authentication is designed solely to permit identification of the culprits *after* malicious code is detected.
- Explorer-based distribution of software is no more risky than conventional purchases through software retailers.³¹

Subsequent correspondence in the RISKS Forum chastised Mr. Atkinson for omitting several other key points, such as:

- Interactions among ActiveX controls can violate system security even though individual controls appear harmless.
- There is no precedent in fact for laying liability at the feet of software developers even when you can find them.
- Under attack, evidence of digital signature is likely to evaporate from the system being damaged.
- Latency of execution of harmful payloads will complicate identification of the source of damage.
- Malice is not as important a threat from code as incompetence.
- Microsoft has a history of including security-threatening options, such as automatic execution of macros in Word, without offering any way of turning off the feature.
- A Web site can invoke an ActiveX control that is located on a different site or that already has been downloaded from another site, and can pass, by means of that control, unexpected arguments that could cause harm.³²

Wallach's criticisms of ActiveX are generally applicable to signed code technologies, not peculiar to Microsoft's ActiveX.

17.2.4.3 Certificates Obtained by Imposters. In January 2001, VeriSign issued two *Class 3 Digital Certificates* for signing ActiveX controls and other code to someone impersonating a Microsoft employee. As a result, users receiving code signed using these certificates would receive a request for acceptance or rejection of a certificate apparently signed by Microsoft on January 30 or 31, 2001. As Russ Cooper

commented on the NTBUGTRAQ Usenet group when the news came out in March 2001:

The fact that unless you actually check the date on the Certificate you won't know whether or not its [*sic*] one you can trust is a Bad Thing(tm)[*sic*], as obviously not everyone (read: next to nobody) is going to check every Certificate they get presented with.

You gotta wonder how VeriSign's issuance mechanism could be so poorly designed and/or implemented to let something like this happen.

Meanwhile, Microsoft are [*sic*] working on a patch that will stick its finger in this dam.

Basically, VeriSign Code-Signing Certificates do not employ a Certificate Revocation List (CRL) feature called CDP, or CRL Distribution Point, which causes the Certificate to be checked for revocation each time its read. Even if you have CRL turned on in IE, VeriSign Code-Signing Certificates aren't checked.

Microsoft's update is going to shim in some mechanism which causes some/all Code-Signing Certificates to check some local file/registry key for a CRL, which will (at least initially) contain the details of these Certificates. Assuming this works as advertised, any attempt to trust the mis-issued Certificates should fail.³³

Roger Thompson, Chief Technical Officer for Exploit Prevention Labs, explained that the imposters' motives would determine how bad the results would be from the fraudulent certificates. "If it was someone with a purpose in mind, then six weeks is a long time to do something," he said. "If the job was to install a sniffer, then there could be a zillion backdoors as a result of it." Published reports indicated that the failure of authentication occurred due to a flaw in the issuing process at VeriSign: The certificates were issued *before* receiving verification by email that the official customer contact authorized the certificates. This case was the first detected failure of authentication in over 500,000 certificates issued by VeriSign.³⁴

Some recent cases involving stolen or forged certificates include the following:

- In November 2011, antimalware vendor F-Secure's Mikko Hypponen reported "finding a piece of malicious software that was cryptographically signed by a forged Adobe certificate originating with Government of Malaysia: Malaysian Agricultural Research and Development Institute ..."³⁵
- In September 2012, Adobe reported that they "... received two malicious utilities that appeared to be digitally signed using a valid Adobe code signing certificate."³⁶ The company explained, "Sophisticated threat actors use malicious utilities like the signed samples during highly targeted attacks for privilege escalation and lateral movement within an environment following an initial machine compromise."
- In February 2013, Bit9 Systems revealed that "Due to an operational oversight within Bit9, we failed to install our own product on a handful of computers within our network. As a result, a malicious third party was able to illegally gain temporary access to one of our digital code-signing certificates that they then used to illegitimately sign malware. There is no indication that this was the result of an issue with our product. Our investigation also shows that our product was not compromised."³⁷

17.2.4.4 Certificate Forgery. Certificate forgery is another hazard. Certificates are not magical; they are merely documented cryptographically signed by a recognized Certification Authority. The cryptographic techniques used to sign certificates

are subject to attack. A research result demonstrating the hazard of MD-5 collisions leading to forged certificates was originally published in 2008.³⁸ For this reason, many authorities have recommended that MD-5 signed certificates be withdrawn from use. In August 2011, an MD-5 signed fraudulent certificate for *.google.com was reported by Iranian Internet users.³⁹

17.3 RESTRICTED OPERATING ENVIRONMENTS. From a Web perspective, the term *sandbox* defines what could be referred to as a restricted operating environment. Restricted operating environments are not new; they have existed for nearly 50 years in the form of multiuser operating systems, including MULTICS, OS/360 and its descendants, OpenVMS, UNIX, and others.

In simple terms, a restricted, or nonprivileged, operating environment prohibits normal users and their programs from executing operations that can compromise the overall system. In such an environment, normal users are prohibited from executing operations such as HALT that directly affect hardware. User programs are prevented from executing instructions that can compromise the operating system memory allocation and processor state and from accessing or modifying files belonging to the operating system or to other users. Implemented and managed carefully, such systems are highly effective at protecting information and data from unauthorized modification and access. The National Computer Security Center (NCSC) *Orange Book* contains criteria for classifying and evaluating trusted systems.⁴⁰

The strengths and weaknesses of protected systems are well understood. Permitting ordinary users unrestricted access to system files compromises the integrity of the system. Privileged users (i.e., those with legitimate access to system files and physical hardware) must be careful that the programs they run do not compromise the operating system. Most protected systems contain a collection of freestanding programs that implement useful system functions requiring some form of privilege to operate. Often these programs have been the source of security vulnerabilities. This is the underlying reasoning behind the universal recommendation that programs not run as root or Administrator or with similar privileges unless absolutely necessary.

17.3.1 Java. Java is a language developed by Sun Microsystems for platform independent execution of code, typically within the context of a Web browser. The basic Java environment includes a Java Virtual Machine (JVM) and a set of supporting software referred to as the Java Run Time Environment. Applets downloaded via the World Wide Web (intranet or Internet) have strict limitations on their ability to access system resources. In particular, these restrictions prevent the execution of external commands and read or write access to files.

The Java environment does provide for *signed applets* that are permitted wider access to files. Dynamically downloaded applets also are restricted to initiating connections to the system that supplied them, theoretically limiting some types of third-party attacks.

In concept, the Java approach, which also includes other validity tests on the JVM pseudocode, should be adequate to ensure security. However, the collection of trusted applets found locally on the client system and signed downloaded applets represent ways in which the security system can be subverted. Without signature, the Java approach is also vulnerable to attack by Domain Name System (DNS) spoofing.

Multiuser protection and virtual machine protection schemes also are totally dependent on the integrity of the code that separates the nonprivileged users from privileged, system-compromising, operations. Java has not been an exception to this rule. In 1996,

17 · 12 MOBILE CODE

a bug in the Java environment contained in Netscape Navigator Version 2.0 permitted connections to arbitrary Universal Resource Locators (URLs).⁴¹ Later, in 2000, errors were discovered in the code that protected various resources.⁴² Although the Java environment is less widely exploitable than ActiveX, vulnerabilities continue to be uncovered. In 2007, at least two vulnerabilities were reported by US-CERT.⁴³ Significantly, both of these reported vulnerabilities involved the ability of untrusted applets to compromise the security envelope.

Additionally, since unsigned code can take advantage of errors in underlying signed code, there is no guarantee that complex combinations of untrusted and trusted code will not lead to security compromises.

17.3.2 Virtual Machines. Isolation can also be realized using virtual machines. Theoretically, each virtual machine runs its own copy of an operating system on a separate virtual copy of the hardware. Properly implemented, mainframe systems have run multiple, independent machines on a single physical system for decades. Virtual machine technology is a foundational technology for so-called cloud computing. In such configurations, the Achilles' heel is the layer that separates the different virtual machines. If there is a deficiency in that layer, or in its interfaces, the compartmentalization may be subject to compromise.

In 2012, just such an incident occurred with multiple virtual machine implementations implementing virtual machines on Intel's x86 processors.⁴⁴ In these cases, a specially crafted stack frame could lead to a break of the virtual machine's containment mechanisms. Virtual machines from Xen, FreeBSD, Red Hat, and Microsoft Windows were subject to this attack.

17.3.3 Operating Environment Summary. The details of virtualization are significant in this context. Errors in virtualization software implementation can create security compromises in the separation between different virtual machines, or indeed it may compromise the underlying integrity of the host. Such hazards are not theoretical; they occur in application-level sandboxes and in systems-level virtual machines.

17.4 DISCUSSION. Mobile code security raises important issues about how to handle relationships in an increasingly interconnected computing environment.

17.4.1 Asymmetric, and Transitive or Derivative, Trust. It is common for cyberrelationships to be *asymmetric* with regard to the size or power of the parties. This fact increases the potential for catastrophic interactions. It also creates opportunities for mass infection across organization boundaries. Large or critical organizations often can unilaterally impose limitations on the ability of partner organizations to defend their information infrastructure against damage.

The combination of a powerful organization and insufficient controls on signing authority, or, alternatively, the obligatory execution of unsigned (or self-signed) ActiveX controls, is a recipe for serious problems. The powerful organization is able to obligate its partners to accept a low security level, such as would result, for example, from using unsigned ActiveX controls, while abdicating responsibility for the resulting repercussions.

All organizations should, for security and performance reasons, use the technology that requires the least degree of privilege to accomplish the desired result. JavaScript/ECMAScript can provide many functions, without the need for the

functionality provided by Java, much less ActiveX. It remains common for large organizations to force the download of ActiveX controls for purposes that do not require the power of ActiveX, merely using the justification that they perceive Internet Explorer to be the more prevalent browser. Often this requires running the installation script from an account with Administrator privileges, a second security violation. This is particularly surprising since these same organizations often offer parallel support for Firefox, Opera, Safari, and other non-ActiveX supporting browsers on Linux, Apple, and other platforms. This Trust Me concept forces the risk and burden of consequences on the end user, who is far less able to deal with the consequences.

As noted earlier in this chapter, Web servers represent an attractive vector for attacks. Signing (authentication) methods are a way to control damage potential, if the mechanisms used for admitting executable code are properly controlled. Failure to control these mechanisms leads to severe side effects.

In Chapter 30 in this *Handbook*, it is noted that protecting Web servers requires that the server contents be managed with care. It is appropriate and often necessary to isolate Web servers on separate network segments, separated from both the Internet and the organizational intranet by firewalls. These precautions are even more necessary when servers are responsible for supplying executable code to clients.

Security practitioners should carefully examine the different functions performed by each server. In some cases, such as OpenVMS hosts, where network servers commonly run as unprivileged processes in separate contexts and directory trees, it is feasible to run multiple services on a single server. In other systems, such as UNIX and Windows, where it is common for applications services to execute as privileged, with full access to all system files, a logic error in a network service can compromise the security of the entire server, including the collection of downloadable applets.

Far more serious and equally subtle is *transitive* (or derivative) trust: Alpha trusts Beta who trusts Gamma. A security compromise—for example, an unsigned Java applet or a malfunctioning or malevolent ActiveX control supplied by Gamma—compromises Beta. Beta then causes problems with Alpha's systems. This cascade can continue repeatedly, leading to numerous compromised Web services and systems far removed geographically and organizationally from the original incident.

17.4.2 Misappropriation and Subversion. The threat space has mutated over the last several years. Where the main danger from mobile code was attacks on the target machine, today's threat is far more diverse. In November 2007, John Schiefer of Los Angeles pled guilty to installing software designed to capture usernames and passwords. According to news reports, he was also involved in running a number of networks of compromised computers, often referred to as bots, which are often used to initiate distributed denial-of-service (DDoS) and other attacks.⁴⁵ In this particular case, the announcement by the U.S. Department of Justice⁴⁶ mentions two specific episodes: 250,000 machines infected with spybots to obtain user's usernames and passwords for PayPal and other systems; and a separate scheme involving a Dutch Internet advertising company in which a network of 150,000 infected computers were used to sign up for one of the advertising company's programs.

This was one of the cases stemming from Bot Roast II,⁴⁷ an FBI operation against several botnet networks.

17.4.3 Multidimensional Threat. Mobile code is a multidimensional threat, with several different aspects that must each be treated separately. Signing code, such as Java applets or ActiveX controls, addresses the problem of authenticity and authority

to release the code. However, the integrity of the signature mechanism requires that the integrity of the PKI infrastructure be beyond reproach. In a very real sense, the PKI infrastructure is beyond the control of the organization itself. Any compromise or procedural slip on the part of the Certificate Authority or signer invalidates the presumptions of safety.

Signing, however much it contributes to resolving the question of authenticity, does not address safety or validity. As an example, the Windows Update ActiveX control, distributed by Microsoft as part of the various Windows operating systems, has as its underlying purpose the update of the operating system. A failure of that control would be catastrophic. Fortunately, Microsoft gives users the choice of using the automatic update facility or doing updates manually. Many Web applications are not so accommodating.

The problem is not solely a question of malfunctioning applets. It is possible that a collection of applets involved in a client's overall business activities may collide in some unanticipated fashion, from attempting to use the same Windows registry key in contradictory ways, to inadvertently using the same temporary file name. Similar problems often occur with applications that presume they have a monopoly on the use of the system, an all-too-common syndrome.

These issues are, for the most part, completely unrelated to each other. A solution in one area would neither improve nor worsen the situation with regard to the other issues.

17.4.4 Client Responsibilities. The expanding threat presents a challenge to those responsible for ensuring the integrity of desktop computing. Put simply, there is a complex, multidimensional threat, and it is not easily defended against using the techniques of portals, firewalls, and scanners.

The danger from browsing the World Wide Web is the danger that the browser will permit an attacker, directly or indirectly, to cause a modification to the persistent state of the system. The simplest step in the correct direction is not to browse the World Wide Web from within a protection context that has access to critical system files and settings. Limiting this access by using a nonprivileged user account for browsing significantly decreases the hazard, provided of course that the system files are protected from access by such an account.

The mass availability of *virtual machine* technology presents an additional alternative. Virtual machine technology, pioneered by IBM in the 1960s on mainframes, has emerged in a new guise on platforms down to the desktop level. The general availability of this capability in the desktop world opens up a whole new defensive strategy against mobile malware: the expendable Web browser.

An expendable WWW browser is an instantiated desktop within a virtual machine environment, from a known system image. If it is compromised, it is merely rewritten from a known, uncompromised system image. It allows one to create a low-security, at-risk, browsing enclave within an otherwise higher security environment. This is an approach that has been used, in a physical sense to be sure, by some organizations providing public access personal computers. Rather than attempting to fortify the machines against compromise or attack, they are reinitialized from a known image after each user. This allows the end user to indulge the foibles of trading partners' attempts to impose unsafe computing practices in an expendable environment that can be isolated. Using Windows as an example, while it is an unsafe practice to install software as Administrator, it is far less damaging to do so in a virtual machine, where the machine can be deleted at convenience with little side effect.

Similarly, *disposable virtual machines*^{48,49} can be used by normal users to separate the normal operating environment from one where there is a perceived increase in risk exposure (e.g., browsing suspect sites; forced installation of ActiveX controls of uncertain provenance or safety).

17.4.5 Server Responsibilities. As noted earlier in this chapter, Web servers represent an attractive vector for attacks. Signing (authentication) methods are a way to control damage potential, provided the mechanisms used for admitting executable code are properly controlled. Failure to control these mechanisms leads to severe side effects.

The concept of *minimum necessary privilege* applies to mobile code. There is little reason to impose the use of ActiveX for the purposes of changing the color of a banner advertisement. This effect can often be accomplished using Cascading Style Sheets (CSS). JavaScript/ECMAScript is capable of many powerful, display-related operations with a high degree of safety in situations where CSS is not adequate. Using Java to maintain a shopping cart (price, quantities, and contents) is reasonable and does not require the use of a signed applet, with its attendant greater capabilities and risks. At the other end of the scale, it is plausible that a system update function (e.g., the Windows Update function, which automatically downloads and installs changes to the Windows operating system) requires the unbridled power of a signed ActiveX control.

When the power of signed applets or controls is required, good software engineering practice provides excellent examples of how to limit the potential for damage and mischief, as discussed in Chapter 38 in this *Handbook*.

These problems extend beyond an individual organization's direct exposure. An increasing trend over the past several years has been to use third-party Web servers as an infection vector, a springboard for infecting Website visitors. If components are downloaded from third-party servers, the integrity of your WWW site may be vulnerable to compromise.

Good software implementation isolates functions and limits the scope of operations that require privileged access or operations. Payroll applications do not directly manipulate printer ports, video display cards, network adapters, or disk drives. Privileged operating system components, such as device drivers and file systems, are responsible for the actual operation. This separation, together with careful parameter checking by the operating system kernel and the privileged components, ensures safety.

The same techniques can be used with applets and controls. Because they require more access, they should be programmed carefully, using the same defensive measures as are used when implementing privileged additions to operating systems. As an example, there is little reason for a Simple Mail Transfer Protocol (SMTP) server to be privileged. An SMTP server requires privileges for a single function, the delivery of an individual email message to a recipient's mailbox. This can be accomplished in two ways:

1. Implement the application in a nonprivileged way, by marking users' email files and directories with the necessary access permissions for the mail delivery program to create and modify email files and directories. Such a mechanism is fully in conformance with the NCSC *Orange Book*'s C2-level of security.
2. Implement a separate subcomponent whose sole responsibility is the actual message delivery of the message. The subcomponent must be written defensively to check all of its parameters, and does not provide an interface for the execution of arbitrary code. This approach is used by HP's OpenVMS operating system.

The UNIX *sendmail* program, by contrast, is a large, multifunctional program that executes with privileges. *sendmail* has been the subject of numerous security problems for over a decade and has spawned efforts to produce more secure replacements.⁵⁰

17.5 SUMMARY. Mobile code provides many flexible and useful capabilities. The different mechanisms for implementing mobile code range from the innocuous (HTML), to fairly safe (JavaScript/ECMAScript), and with increasing degrees of power and risk through Java and ActiveX.

Ensuring security and integrity with the use of mobile code requires cooperation on the part of both the provider and the client. Clients should not accept random signed code and controls. Providers have a positive responsibility to:

- Follow good software engineering practices
- Grant minimum necessary privileges and access
- Use defensive programming
- Limit privileged access, with no open-ended interfaces
- Ensure the integrity of the signing process and the associated private keys

With appropriate caution, mobile code can be a constructive, powerful part of intranet and Internet applications, both within an organization and in cooperation with its customers and other stakeholders.

18 · 2 DENIAL-OF-SERVICE ATTACKS

18.1 INTRODUCTION. This chapter discusses denial-of-service (DoS) and distributed denial-of-service (DDoS) attacks. These attacks seek to render target systems and networks unusable or inaccessible by saturating resources or causing catastrophic errors that halt processes or entire systems. Furthermore, they are increasingly easy for even *script kiddies* (persons who follow explicit attack instructions or execute attack programs) to launch. Successful prevention of and defense against these attacks will come only when there is widespread cooperation among all Internet service providers (ISPs) and other Internet-connected systems worldwide and when antimalware software is universally installed and kept up to date on user systems.

Working in a variety of ways, the DoS attacker selects an intended target system and launches a concentrated attack against it. Although initially deemed to be primarily a nuisance, DoS attacks can incapacitate an entire network, especially those with hosts that rely on Transmission Control Protocol/Internet Protocol (TCP/IP). DoS attacks on corporate networks and ISPs have resulted in significant damage to productivity and revenues. DoS attacks can be launched against any hardware or operating system platform because they generally aim at the heart of Internet Protocol (IP) implementations. Because IP is the typical target, the DoS attack tools that run under one operating system (Linux is a common choice) can be aimed at any operating system running IP. Additionally, because IP implementations are similar for different platforms, one DoS attack may target several operating systems and work on each. Once written for one platform and released, new DoS attacks appear to evolve (via the examination and participation of hackers and crackers) so that in a short period of time (approximately two weeks) mutations of the DoS attack appear that work on virtually all platforms.

Because of the critical impact that DoS attacks can have, they cannot be taken lightly. Targeted DoS attacks have been around in one form or another since the 1980s; in 1999, they evolved into DDoS attacks, primarily due to the heavy use of internal networks and the Internet. DDoS tools launch coordinated DoS attacks from many sources against one or more targets simultaneously.

This chapter describes first DoS and then DDoS attacks because DoS attacks historically predate DDoS attacks. In addition, some DDoS attacks make use of DoS techniques. However, the attacks themselves, the terminology, and the defenses are sufficiently different that they warrant separate discussion.

18.2 HISTORY OF DENIAL-OF-SERVICE ATTACKS. Historically, any act that prevented use of a system could be called a denial of service. For example, in some mainframe and minicomputer systems, typing a malformed command could cause a system failure; for example, on the HP3000 minicomputer around 1982, using a faulty TERMTYPE parameter in the logon string could instantly crash the system. On the HP3000, typing one or more characters on the system console without pressing the RETURN key would block all further system messages on the console, causing system buffers to fill up with undisplayed messages; when the system buffers (16 by default) were full, no system action requiring notification to the console could take place (e.g., logons, logoffs, special-form requests, or tape-mount requests). A classic DoS without software could be the result of having a cleaner unplug a power cord from a wall socket without realizing that the cord was powering one or more workstations. Configuring a permanent lockout of users after a certain number of bad-password attempts (instead of a timed lockout) led to DoS; malicious users could even try to lockout root users by deliberately entering bad passwords on their accounts. However, such events were usually the result of bugs in the operating system, inadequate numbers of system resources, poor system management, or accident.

One of the first major DoS incidents that made headlines and ripples was probably accidental. It took place in December 1987, when an employee of IBM in Europe sent out a holiday greeting email message. The email message, however, contained a program that drew a nice Christmas tree on the recipient's terminal—and read the recipient's NAMES and NETLOG files listing the user's address book as well as the email addresses of individuals that this user had recently sent mail to or received mail from. The Christmas Tree program then triggered the automatic transmission of copies of itself to all email addresses found in NAMES and NETLOG—and failed to prevent remailing to systems that had already received or sent the greeting. The resulting mailstorm overloaded the IBM corporate network worldwide and brought it crashing down both in Europe and the United States. In addition, messages escaped from IBM's corporate network and wreaked havoc on the BITNET/EARN education and research networks in North America and Europe. Although the cause of the outage was originally thought to be a computer virus, and the incident has been referred to as a virus, a worm, and a prank, the result was a true denial of service.

Perhaps the most famous Internet DoS resulted from the Morris Worm, also referred to as the Internet Worm, which was released in November 1988. Cornell graduate student Robert T. Morris had cowritten an article about vulnerabilities in *Sendmail* and *fingerd* on UNIX systems during the previous year. Most of the TCP/IP community dismissed the vulnerabilities as theoretical; apparently Morris wanted to demonstrate that the vulnerabilities actually could be practically exploited. To demonstrate the problem, his program had to invade another system, guess some passwords, and then replicate itself. Morris said after the incident that he wanted the program to replicate just a few times to demonstrate that it was real, and he included code to prevent rapid spread; unfortunately, a programming error led the worm to replicate often and quickly, in addition to superinfecting already-infected systems. The worm clogged the Internet with hundreds of thousands of messages and effectively brought the entire network down; most sites that did not actually crash were disconnected from the network by their system administrators to avoid being infected and to allow disinfection. Regardless of intent, the Morris Worm inadvertently caused a DoS. Because sites administrators did not have a way to communicate with other admins, and because solutions that Morris himself posted could not be trusted, there was a lot of time spent in eradicating the worm. One result was the creation of Computer Emergency Response Team Coordination Center, now CERT/CC, at Carnegie Mellon University.

On Friday, September 6, 1996, PANIX, a public access Internet provider in Manhattan, was struck by a DoS attack that consisted of many messages flooding the server with massive amounts of data. The attacks were made against mail, news, name, and Web servers as well as user shell account machines. The attackers successfully eluded tracking and the attacks went on for several days. About a week after the attacks began, PANIX went public with the story, and dozens of other online service providers acknowledged that they too were the victims of similar attacks.

In 1997, a disgruntled former employee of Forbes, Inc., used a former colleague's password to remotely access the firm's computer systems. Deliberately tampering with the system, he deleted budgets and salary information and caused five of the eight network servers to crash. When Federal Bureau of Investigation (FBI) agents caught the perpetrator, his home was filled with hacking tools, proprietary information from Forbes, Inc., and other incriminating material.

In February 1998, hackers from Israel and Northern California attacked the U.S. Department of Defense (DoD). In a carefully organized attack that exploited buffer

18 · 4 DENIAL-OF-SERVICE ATTACKS

overflow, these hackers systematically perpetrated a DoS attack that lasted over a week on 11 DoD sites.

In March 1998, all across the United States, system administrators found their Windows NT servers under apparently automated attack. Systems crashed repeatedly until they were updated to the latest patches from Microsoft. There appeared to be no file damage from the attacks, which lasted more than a day. Sites affected included several NASA and other military sites, as well as several University of California and other college campuses.

Yet another mail storm erupted in May 1998 when an Australian official set autoreply on his email package while he was away. Unfortunately, he inadvertently set his destination for these largely useless messages to be all 2,000 users on his network—and requested auto confirmation of delivery of each autoreply, which generated yet another autoreply, and so on *ad infinitum*. Within four hours, his endless positive-feedback loop had generated 150,000 messages before his autoreply was shut down. The ripples lasted for days, with the perpetrator saddled with 48,000 messages in his IN basket and a stream of 1,500 a day pouring in. This was another case of an inadvertent DoS attack.

In January 1999, someone launched a sustained DoS attack on Ozemail, an important Australian Internet service provider. Email service was disrupted for users in Sydney.

In March 1999, the Melissa email-enabled virus/worm swept the world in a few days as it sent copies of itself to the first 50 addresses in victims' email address books. Because of this high replication rate, the virus spread faster than any previous virus in history. On many corporate systems, the rapid rate of internal replication saturated email servers with outbound automated junk email. Initial estimates were in the range of 100,000 downed systems. Antivirus companies rallied immediately, and updates for all the standard products were available within hours of the first notices from the CERT/CC. The Melissa macro virus was quickly followed by the PAPA MS-Excel macro virus with similar properties but that, in addition, launched DoS attacks on two specific IP addresses.

And after all of the publicity dealing with the Y2 K problems prior to the turn of the millennium, the ILOVEYOU, or Love Letter, worm was released in May 2000. The Love Letter worm was in a Visual BASIC attachment to emails with the subject line "ILOVEYOU." This worm used a so-called double extension exploit; the attachment was named LOVE-LETTER-FOR-YOU.txt.vbs, but because the default Windows setting is to not display the extension, many (or most) recipients thought that this was a harmless text file. The worm modified the infected system's registry to autostart the program on system startup, replaced files with certain extensions with copies of itself, and sent copies of itself to the first 50 entries in the Outlook address book.

More recent attacks are discussed in the sections describing modern DoS tools.

18.3 COSTS OF DENIAL-OF-SERVICE ATTACKS. What are the effects of these DoS attacks in terms of productivity and actual financial costs? It is difficult to place an exact monetary figure on DoS attacks. DoS attacks can interrupt critical processes in an organization, and such interruption can be costly. When a company's computer network is inaccessible to legitimate users and they cannot conduct their normal business, productivity is lowered. The negative effect is bound to carry over to the financial aspects of the business. However, putting exact figures to these effects is uncertain at best, and the estimates are widely disputed, even among security and business experts. In addition, many companies do not comment on the exact losses they suffer because they fear that the negative publicity will decrease their market share. This latter point is significant: In an early 1990s study of Wall Street firms, some of

the companies suggested that if they were to be without their network for two to three days, they might never reopen their doors.

In the case of the Christmas Tree worm, it took IBM several days to clean up its network and resulted in the loss of millions of dollars, both for cleansing the system and for lost business because of lost connectivity and related productivity. Additionally, there was the embarrassment suffered by IBM, a noted technology company. The individual who launched the worm was identified and denied access to any computer account, while IBM had to write a letter of apology to the European Academic and Research Network (EARN) administrators.

In 1988, at the time of the Morris Worm, the Internet consisted of 5,000 to 10,000 hosts, primarily at research and academic institutions. As a result, although the Morris Worm succeeded in bringing many sites to a halt and gained worldwide notoriety, the financial and productivity impact on the commercial world was minimal. A similar incident today would wreak havoc and cost tens or hundreds of millions of dollars in losses.

By 1996, however, commercial reliance on the Internet was already becoming a matter of course. Working around the clock, the management at PANIX and Cisco, the ISP's router vendor, kept the service provider up and running, but the network received 210 fraudulent requests per minute. Although the systems did not crash, thousands of subscribers were unable to receive their email messages. Other sites were attacked in the same time frame as PANIX, including Voters Telecommunication Watch. No one took responsibility for these attacks and it has been widely assumed that they were triggered by articles on SYN DoS attacks (see the description below) that had recently appeared in *2600 Magazine* and *Phrack*, journals that cater to hackers.

According to Forbes, Inc., the losses suffered by the firm because of the DoS attack perpetrated by the disgruntled former employee exceeded \$100,000. Could it have been prevented? According to the firm, it is highly unlikely, since Forbes had no reason to suspect the individual was maintaining either the firm's confidential and sensitive material at home or that he was thinking of hacking into the computer system and deliberately doing damage. Although the firm had security on its systems, the perpetrator used the password of a legitimate, authorized user.

The DoS attack launched against the Department of Defense computers in 1998 proved that attackers could deny access to vital military information. In this particular instance, the attack was directed at unclassified machines that had only administrative and accounting records, but it was a blow to the confidence of the Department of Defense. Tying up the computers for over a week presumably reduced productivity, but the government would not comment on the actual cost from loss of machine time and personnel productivity.

These cases show that a DoS attack on a computer or network can be devastating to an organization. Important equipment and networks and even an entire organization can be disabled by such attacks.

Early DoS incidents often were described as annoying, frustrating, or a nuisance. However, with increasing sophistication and dependency on networking, it has become difficult to keep a sense of humor about such incidents. Especially in corporations, where the mission is to make a profit for the shareholder, company managers find it increasingly difficult to excuse being incapacitated because of a DoS or DDoS attack.

As these forms of attack become more sophisticated, so must the tools and methods for detecting and fighting them. Current products scan equipment and networks for vulnerabilities, trigger alerts when an abnormality is found, and frequently assist in eliminating the discovered problem.

18 · 6 DENIAL-OF-SERVICE ATTACKS

18.4 TYPES OF DENIAL-OF-SERVICE ATTACKS. DoS attacks, whether accidental or deliberate, result in loss of service; either a host or a server system is rendered inoperable or a network is rendered inaccessible. DoS attacks are launched deliberately by an *intruder* (the preferred term for attacker in this context). Systems and networks that are compromised are referred to as the *victims*. And while DoS attacks can be launched from the intruder's system, they often are launched by an automated process that allows the intruder to start the attack remotely with a few keystrokes. These programs are known as *daemons*, and they are often placed on another system that the hacker has already compromised.

There are four basic types or categories of DoS attack:

1. **Saturation.** This type of attack seeks to deprive computers and networks of scarce, limited, or nonrenewable resources that are essential in order for the computers or networks to operate. Resources of this type include CPU time, disk space, memory, data structures, network bandwidth, access to other networks and computers, and environmental resources such as cool air and power.
2. **Misconfiguration.** This type of attack destroys or alters configuration information in host systems, servers, or routers. Because poor or improperly configured computers may fail to operate or operate inadequately, this type of attack can be very severe.
3. **Destruction.** This type of attack results in network components being physically destroyed or altered. To guard against this type of attack, it is necessary to have good physical security to safeguard the computers and other network components. This chapter does not deal with physical damage, but Chapters 22 and 23 of this *Handbook* do so in some detail.
4. **Disruption.** This attack interrupts the communications between two devices by altering state information—such as the state of a TCP virtual connection—such that effective data transfer is impossible.

18.5 SPECIFIC DENIAL-OF-SERVICE ATTACKS. The discussion below describes some specific DoS attacks as examples of the general methods that can be employed in a DoS or DDoS. The list is not exhaustive.

18.5.1 Destructive Devices. Destructive devices are programs that accomplish either harassment or destruction of data. There are mixed opinions regarding how severe destructive devices are, but if they threaten a computer's or network's ability to function properly and efficiently, then they may be the instruments of DoS attacks. Viruses, email bombs, and DoS tools all can be considered destructive devices. In fact, viruses and email bombs are known to cause DoS attacks. Some viruses or other malware are known to attack control systems for hardware, such as those employed the Stuxnet and Flame attacks. Viruses and other malicious software and their actions are covered in Chapter 16 of this *Handbook*; nonreplicating or *traditional* DoS and DDoS tools are discussed here.

18.5.2 Email (and Email Subscription) Bombing. Email and email subscription *bombings* were among the first documented DoS attacks. An *email bomb* consists of large numbers of email messages that fill up a victim's electronic mailbox. A huge number of messages can tie up an online connection, slow down mail delivery, and even overload the email server system until the system crashes. Most email bombings

are thought to be deliberate attacks by disgruntled people; specific targets may be victims of someone with a particular grudge. For example, a San Francisco stockbroker received 25,000 messages on September 23, 1996, consisting of the word “Idiot” from a consultant with whom he had had a disagreement. The flood of messages prevented him from using his computer, so in December the victim sued the perpetrator’s employer for \$25,000 of damages. On occasions in the past, such as with the Christmas Tree worm and the Internet Worm, the DoS is thought to have been accidental.

Email bomb packages automate the process of launching and carrying out an *email bombing* DoS attack. With names like Up Yours, Kaboom, Avalanche, Gatemail, and the Unabomber, these packages can be placed on a network server during a DoS attack and used to attack other systems. Administrators who are aware of these names and others should regularly scan their drives for associated filenames and eliminate them.

To safeguard computers and/or servers, mail filters and exclusionary schemes can automatically filter and reject mail sent from a source address using email bomb packages. Mail filters are available for UNIX, Windows, Macintosh, and Linux systems. Most computer operating systems and most ISPs now offer filtering tools for eliminating unsolicited commercial email and other email. Although perpetrators often disguise their identity and location by using a false address, most filters can be set to screen and eliminate these addresses.

With *email subscription bombing*, also known as *list linking*, a user is subscribed to dozens of mailing lists by the attacker without the user’s knowledge. For example, someone calling himself “johnny xchaotic” perpetrated one of the earliest subscription-bombing incidents. In August 1996, he claimed the blame for a massive mail-bombing run based on fraudulently subscribing dozens of victims to hundreds of mailing lists. In a rambling and incoherent letter posted on the Internet, he made rude remarks about famous and not-so-famous people whose capacity to receive meaningful email was obliterated by up to thousands of unwanted messages a day. Today, filtering packages have point-and-click mechanisms that provide automatic list linking. A user could, conceivably, start to receive hundreds or thousands of mail messages per day if linked to just 50 to 100 lists. Once linked to the various lists, the victim has to manually unsubscribe from each individual mailing list. If an attack takes place while the victim is away and without access to email, a user could have a backlog of thousands of messages by the time he or she returns.

List server software should never accept subscriptions without sending a request for confirmation to the supposed subscriber; in the current environment, most list servers require confirmation from the supposed subscriber before initiating regular mailings. The default for the confirmation messages is to ignore the announcement if it is fraudulent. However, even this safety mechanism can generate a wave of many single email messages if a mail bomber abuses the list servers. As a result, many sites have incorporated Completely Automated Public Turing test to tell Computers and Humans Apart (CAPTCHA) images to interfere with bots that attempt to subscribe victims to their mailings.

Speaking of being away, vacation messages and return receipts are another way in which individuals can inadvertently start an *email storm*. Many users set their email clients to automatically request a return receipt of all messages sent. Then the users go on vacation and set up an auto-reply vacation message. When they get a message, the client sends back the vacation message and also requests a receipt. The returned receipts, in turn, generate more auto-reply vacation messages.

Another variant on this feedback loop occurs when an employee goes on vacation and forwards all email to an external ISP that has a local access number in the locale

18 · 8 DENIAL-OF-SERVICE ATTACKS

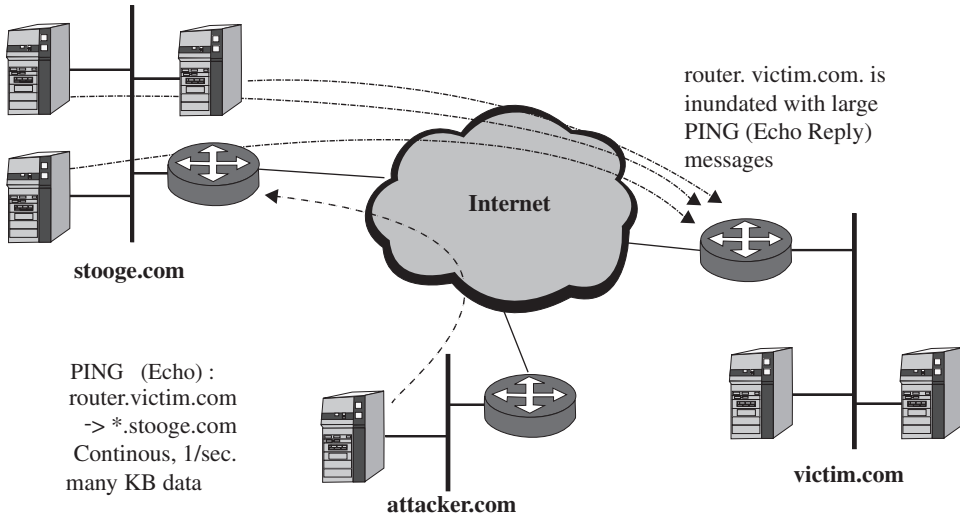

of the vacation. If the employee decides not to check the mail while away, either due to a high local access fee or so as not to interfere with the vacation, the ISP mailbox will fill up with forwarded messages. If the mailbox fills up, the ISP will send a bounce message back to the corporate server—which then forwards the bounce message back to the ISP, which generates yet another bounce message. Eventually, even the corporate mail server will fill up with a single individual's messages, causing an email DoS.

18.5.3 Buffer Overflow. *Buffer overflow* attacks can be insidious and damaging. It is possible to send an input string to a target program that contains actual code and is long enough to overflow the memory space or input buffer. Sometimes this surreptitious code is placed on the process stack (the area in a computer's memory where the operating system keeps track of the program's input and related code used for processing the inputs), and the code then is processed. An overflow can occur when the input data overflows its buffer space and flows into the stack, where it overwrites the previous data and return address. If the program is written so that the stack address points to the malicious code located in the return buffer, the code executes with the original program's privileges. Buffer overflow is the result of poor programming, where the programmer does not check the size of the input compared to the input buffer. Although the bad-programming basis of buffer overflows should have been eradicated by now, new buffer overflow attacks pop up monthly. As of January 2013, the National Vulnerability Database¹ included 6,273 buffer overflows out of a total of 64,398 vulnerabilities—about 10 percent. This percentage has been dropping over the years; in the period from January 2010 through December 2012, 1,281 of the 14,510 records were for buffer overflows—only 9 percent; in contrast, of the 39,822 records for vulnerabilities entered before 2010, 5,047 (13 percent) involved buffer overflows.

Not all buffer overflows allow the user to insert executable code. DoS attacks such as the *ping of Death* merely attach a data block that is larger than allowed by the IP protocol (i.e., greater than 65,536 bytes). Because the packets are broken into fragments for transmission, they manage to get through the network and, probably, the router and firewall. Once reassembled at the target, however, the packets cause the IP kernel's buffer to overflow and, if not managed properly, the system crashes.

Another example is an old flaw in Microsoft's Internet Information Services² (IIS) that could be exploited to allow the Web service to be halted. To do this, an attacker would request a document with a very long URL from an IIS-based Website (and how does one identify an IIS site? If a Website use pages with the .htm or .asp extensions, it is a good guess that the site is running IIS). Upon receipt of the request, an access violation occurred and the server would halt. Although Microsoft issued a patch for this vulnerability, successful attacks continued to take place for years.

18.5.4 Bandwidth Consumption. *Bandwidth consumption* involves generating a large number of packets directed to the network under attack. Such attacks can take place on a local network or can be perpetrated remotely. If the attacker has, or can access, greater bandwidth than the victim has available, the attacker can flood the victim's network connection. Such saturation can happen to both high-speed and low-speed network connections. Although any type of packet may be used, the most common are Internet Control Message Protocol (ICMP) *echo* messages (generated by *pinging*). By engaging multiple sites to flood the victim's network connection, attackers can amplify the DoS attack. To do this successfully, the attackers convince the amplifying system to send traffic to the victim's network. Tracing the intruder who

**EXHIBIT 18.1** smurf DoS Attack

perpetrates a bandwidth consumption attack can be difficult since attackers can spoof their source addresses.

One very common bandwidth consumption attack is the *smurf attack*. This attack is particularly interesting (and clever) since it uses tools that reside on every IP system and employs a third-party site without actually having to take control of any system anywhere. As Exhibit 18.1 shows, the smurf attack starts when the intruder (at *attacker.com*) sends a continuous string of very large *ping* messages to the IP broadcast address (* in the exhibit, representing the all-ones, or broadcast, IP address) of the unsuspecting third party, *stooge.com*. The intruder spoofs the source IP address of the *ping* message so that it appears that these messages come from, say, the router at the target network, *router.victim.com*. If the intruder sends a single 10,000-byte *ping* message to the broadcast address of an intermediate site with 50 hosts, for example, the responses will consume 4 megabits (Mb).³ Even if *victim.com* has a T1 line (with a bandwidth of 1.544 Mb per second), the attacker can swamp a victim's line merely by sending a single large *ping* per second to the right stooge site. The intermediate site is called, for obvious reasons, the *amplifying network*; note that the attacker does not need to compromise any systems there. The ratio of originally transmitted packets to the number of systems that respond is known as the *amplification ratio*.

A variant of the smurf attack is called *fraggle*. In this variant, the attackers send spoofed User Datagram Protocol (UDP) packets instead of *echo* messages to the broadcast address of the amplifying network. Each system on the amplifying network that has the specific broadcast address port enabled will create large amount of traffic by responding to the victim's host; if the port is not enabled, the system on the amplifying network will generate ICMP *host unreachable* messages to the victim's host. In either case, the victim's bandwidth is consumed.

Kernel panic attacks are not due to programming error, per se, but to a hole in a program's logic. As an example, the Intel Pentium chip that could not correctly divide two particular legal inputs had a programming flaw. An IP kernel that fails when receiving a packet that should never occur in the first place is, indeed, a gap in the program's logic but not the same as failing to handle legal input. In this case, the program did not know how to fail gracefully when it received unexpected input.

18 · 10 DENIAL-OF-SERVICE ATTACKS

A specific example of kernel panic occurs in Linux kernel v.2.2.0 when a program usually used for printing shared library dependencies is used instead to print some core files. Under certain circumstances, *munmap()*, a function call used to map and unmap devices into memory, overwrites critical areas of kernel memory and causes the system to panic and reboot.

And there are other examples of these kinds of attacks. A *land attack* occurs when a spoofed packet is sent to a target host where the TCP source and destination ports are set to the same value, and the IP source and destination addresses are set to the same value. Since this is confusing to the host operating system, it results in 100 percent CPU utilization and then a halt. Land attacks have been directed at just about all operating systems.

Teardrop attacks are also the result of behavior when receiving impossible packets. If an IP packet is too large for a particular network to handle, the packet will be fragmented into smaller pieces. Information in the IP packet header tells the destination host how to reassemble the packet. In a Teardrop attack, the attacker deliberately crafts IP packets that appear to overlap when reassembled. This, too, can cause the host to crash. Teardrop attacks have been targeted against Microsoft operating systems and all variants of UNIX.

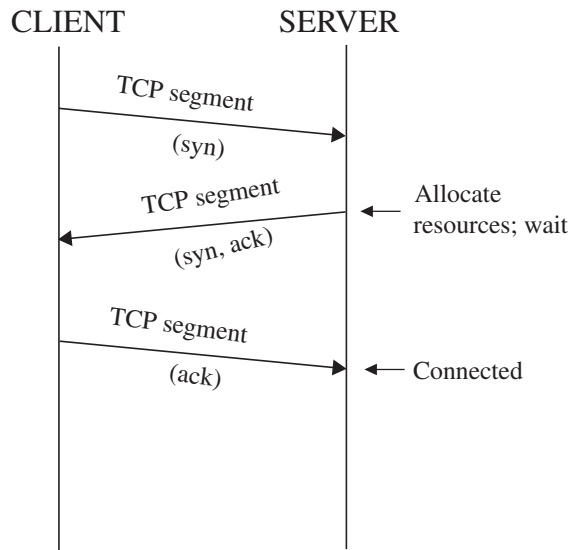

18.5.5 Routing and Domain Name System Attacks. *Routing and Domain Name System (DNS) attacks* are clever attacks that are achieved repeatedly. By tampering with the DNS, a site's domain name resolves to the IP address of any other site that the attacker wishes. In August 1999, for example, a disgruntled engineer for PairGain Technologies provided a direct link to a bogus but authentic-looking Bloomberg News Service page he had created. The engineer, who owned PairGain shares, posted false information about PairGain's supposed acquisition by an Israeli company, pumping up the price of PairGain stock worldwide and creating havoc in the market through his page-jacking exploits. Although a nontraditional DoS attack, these actions did deny users access to the site that they desired, with serious consequences.

Another example occurred in July 1997, when Eugene Kashpureff filed fraudulent information with InterNIC for its DNS updates for that month, forcing domain name servers around the globe to recognize temporary and unauthorized Internet addresses ending in .xxx, .mall, .nic, and .per. A few weeks later, Kashpureff inserted false information that forced people trying to access the Website of Network Solutions Inc. to end up at the AlterNIC site, which he owned. He was arrested later that year on charges of wire fraud.

In another example—this from 2000—of a routing and DNS attack, RSA Security, Inc., after announcing that it had developed a method to combat Website hackers, found that users were unwittingly being rerouted to a counterfeit RSA Website. The fraudulent site looked exactly like the original RSA Website but made fun of the fact that the hacker had managed to achieve his DoS goal.

As far back as 1997, weaknesses were found in and documented about BIND implementations in versions preceding 4.9.5+P1. The earlier versions would cache bogus DNS information when DNS recursion was enabled. The vulnerability enabled attackers to exploit the process of mapping IP addresses to hostnames in what is known as *pointer (PTR) record spoofing*. This type of spoofing provides the potential for a DNS DoS attack.

DNS attacks are still seen widely today. *Phishing* is a form of social engineering attack whereby users are directed to bogus, but authentic-looking, bank or credit card company Websites and enticed to enter personal information used for identity theft.

**EXHIBIT 18.2** Normal TCP 3-Way Handshake

If users were to look closely at the URL of the site, however, they would observe a suspicious URL. *Pharming* is a variant of phishing that relies on some form of DNS poisoning so that a user going to the actual URL of a bank or credit card company will be redirected to the bogus site. Other variants of phishing have also emerged, such as *spearphishing* (directing a phishing attack at a specific person, job function, or group), *vishing* (a phishing attack via the telecommunications network, such as Voice-over-IP [VoIP]), and *smishing* (phishing via Short Message Service [SMS], or text, messages). For more details of such social engineering attacks, see Chapter 19 in this *Handbook*.

18.5.6 SYN Flooding. *SYN flooding* is a DoS attack that fits into the consumption-of-scarce-resource category. This DoS attack exploits the three-way handshake used by TCP hosts to synchronize the logical connection prior to data exchange. In a normal TCP host-to-host connection, the two hosts exchange three TCP segments prior to exchanging data, as shown in Exhibit 18.2:

1. The client sends a segment to the server with its initial sequence number (ISN). The SYN (synchronization) flag is set in this segment.
2. The server responds by sending a segment containing its ISN and acknowledges the client's ISN. This segment will have both the SYN and ACK (acknowledgment) flags set. At this point, the server allocates resources for the soon-to-be-established connection and waits for the third segment.
3. The client sends a segment acknowledging the server's ISN. This and all subsequent segments until the end of the session will have only the ACK flag set.

A SYN flood takes advantage of the three-way handshake and the fact that a server can have only a finite number of open TCP connections. The attack is launched when an attacker initiates connections for which there will never be a third segment (see Exhibit 18.3). After the server sends the segment in step 2, it waits for a response. Under normal circumstances, the client will respond within a few seconds. The server

18 · 12 DENIAL-OF-SERVICE ATTACKS

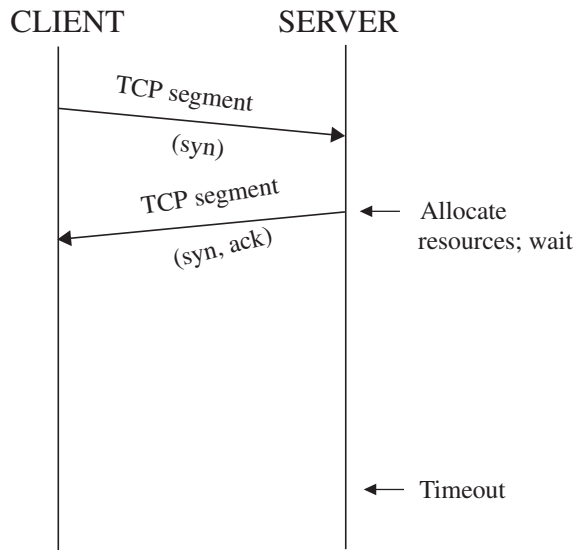

EXHIBIT 18.3 TCP SYN DoS Attack

might wait, say, 10 seconds before timing out and releasing the resources. But suppose the attacker sends hundreds of connection messages per second on a sustained basis. When these bogus connection attempts flood the target faster than they can time out, there will not be any resource left in which to establish a legitimate connection. This is the type of attack that was launched against PANIX in 1996.

18.5.7 Resource Starvation. *Resource starvation* is a catchall category for many other types of DoS attacks that are the result of some scarce resource—be it bandwidth, processing power, disk space—being consumed and exhausted. One example uses a novel UDP DoS attack, where an intruder forges UDP packets and uses them to connect the *echo* service of one machine (UDP port 7) to the character generator (*chargen*) service on another machine (UDP port 19). When this occurs, the two machines consume all available network bandwidth, and all machines on the same networks as the target machines can be affected and starved for resources.

But such attacks can happen locally, as well. Unfortunately, many authorized users carry out *local DoS attacks* that either consume system resources or deny users access. Numerous resource starvation attacks and programming flaws attack specific systems. For instance, by exceeding imposed quotas on disk space, multiuser systems can suffer from a resource starvation attack. Most operating systems limit the amount by which a user can exceed disk quota. Windows 2000 has a twist on this; although individual files can exceed their quota by only a small amount, if *every* file exceeds the quota, a user can consume a lot of extra disk space.

Another variant of this type of attack is called *Slowloris*, which targets Web servers and uses a relatively low amount of bandwidth by the attacker. Using the Slowloris scheme, an attacker sends a large number of connection requests to a target Web server and holds them open as long as possible. Under some circumstances, the affected Web server will exhaust its pool of connection resources on unfulfilled requests, thus denying legitimate requests. Many types of Web servers are susceptible to Slowloris, including several versions of Apache.

A Slowloris-variant is called *R-U-Dead-Yet* (RUDY). RUDY sucks connections resources from a Web server by sending large numbers of POST messages and randomly large Content-Length values in the HTTP message header.

18.5.8 Java, PHP, and ASP Attacks. There are many attacks that target program vulnerabilities in Websites that use Java, PHP (PHP: Hypertext Preprocessor), Active Server Pages (ASP), and other server-side scripting languages. One example is a 2011 DOS attack that resulted in CPU resource exhaustion. In this particular attack, an attacker would send variables to a Web server using the Hypertext Transfer Protocol (HTTP) POST method. By sending tens or hundreds of thousands of specially selected variable names, collisions in the hash table names could be forced, eventually consuming all CPU cycles on handling a single HTTP POST request.

18.5.9 Router Attacks. *Router attacks* have been developed for a wide variety of routers. Because routers are the backbone of the Internet and the gateway through which organizations connect to the Internet, killing a router denies network service for hundreds of machines. Productivity and financial repercussions from a hardware attack can be very severe. Popular targets for these kinds of attacks are routers from Ascend, Cisco, Juniper, Lucent, and 3Com. Unfortunately, many network managers make the attacks easy by employing Telnet or HTTP for remote access and not properly securing the network against remote access by anyone over the Internet.

18.5.10 Other Denial-of-Service Attacks. Even this list of specific DoS attacks is not exhaustive. For example, *Bonk* and *boink* (aka *bonk.c*) are DoS attacks that cause a target Windows 9x/NT system to crash. *Arnudp* (*arnudp100.c*) forges UDP packets to implement a DoS against UDP ports 7 (*echo*), 13 (*daytime*), 19 (*chargen*), and 37 (*time*), services that frequently run on UNIX and Windows NT systems. And *cbcb.c* is a *cancelbot* that destroys existing Usenet news postings that fit certain criteria. (Some argue that *cbcb.c* does not actually carry out a DoS attack; however, once activated, the program denies access to postings for targeted Usenet users.)

An example of network-based attack on a non-network resource would be *billion laughs* (an XML bomb), a DoS attack targeting Extensible Markup Language (XML) parsers. In XML, an *entity* is a piece of code that allows the programmer to define something that can be easily modified or reused in other documents, not unlike a programming object. In *billion laughs*, the attacker creates an XML document containing 10 entities, each defined as being composed of 10 instances of the previous entity ($10^{10} \approx 1$ billion, hence the name). Billion laughs was first introduced as early as 2003 but remained a problem late into at least the first decade of the 2000s.

On a final note, DoS attacks are not limited to networks. A *black fax* attack, for example, is a simple yet effective resource depletion attack; the attacker merely faxes a page containing a large black box to the victim, which causes the victim's fax to use a large amount of black toner. Sending a large number of these faxes will ultimately deplete the toner at the victim's fax and/or prevent legitimate faxes from being delivered. A security expert once glued the ends of a long strip of paper together to create an endless loop in a fax machine to attack a fax-spammer who refused to stop sending him unwanted travel offers. Another attack on faxes uses automated scripts for a computer to dial and redial the target machine with thousands of copies of (usually offensive) faxes; irritated nerds have been known to use this attack on fax-spammers unwise enough to use real telephone numbers for their own fax machines.

18 · 14 DENIAL-OF-SERVICE ATTACKS

18.6 PREVENTING AND RESPONDING TO DENIAL-OF-SERVICE ATTACKS. DoS attacks are best prevented; handling them in real time is very difficult. And the most important way to protect a system is to harden the operating systems:

- Install them with security in mind.
- Monitor sites to be aware of security vulnerabilities.
- Maintain the latest versions of software where possible.
- Install all relevant security patches.

But a large measure of the prevention consists of packet filtering at network routers. Because attackers frequently hide the identity of the machines used to carry out the attacks by falsifying the source address of the network connection, techniques known as *egress filtering* and *ingress filtering* are commonly used as protective measures. As discussed later in this chapter, egress and ingress filtering are methods of preventing packets from leaving or entering the network, respectively, with an invalid source address. Blocking addresses that do not fit the criteria for legitimate source addresses and making certain that all packets leaving an organization's site contain legitimate addresses can thwart many DoS attacks.

Other packet-filtering methods that will help prevent DoS are to block all broadcast messages and most ICMP messages. There is no reason that a site should accept messages being broadcast to all hosts on the site. Furthermore, there is probably no good reason to allow all hosts to respond to *ping* or traceroute messages; in fact, most ICMP messages probably can be blocked.

In some instances, victims have set up response letters triggered to send and resend in large quantities so that they flood the attacker's address. Doing this is generally not a good idea. If these messages are sent to a legitimate address, the attacker may get the message and stop. But the attackers generally spoof the source IP address, so responding back to a possibly bogus IP network is not a good defensive posture because it may harm innocent victims. The best defense will involve the ISP.

In instances where the attacker's service provider can be identified and contacted, the victim can request that the service provider intervene. In these instances, it is usual for the ISPs to take appropriate action to stop the attack and find the perpetrator. However, in instances where a DoS appears to emulate or mimic another form of attack or when it continues for an unusually long period of time, the victim may want to take more aggressive action by contacting CERT/CC, the FBI, and other authorities that have experience with DoS attacks and some jurisdiction if the perpetrators are caught.

Real-time defenses are difficult but possible. Many routers and external intrusion detection systems (IDSs) can detect an attack in real time, such as too many connection requests per unit time from a given IP host or network address. A router might block the connection requests or an IDS might send a pager message to a security administrator.

However, attacks such as smurfs can suck up all of the bandwidth even before the packets get to the target site. Cooperation by ISPs and end-user sites is required to fully combat DoS attacks. This will be addressed further as part of the discussion of responding to DDoS.

18.7 DISTRIBUTED DENIAL-OF-SERVICE ATTACKS. DDoS tools use amplification to augment the power of the attacker. By subverting poorly secured systems

into sending coordinated waves of fraudulent traffic aimed at specific targets, intruders can overwhelm the bandwidth of any given victim.

In a DDoS attack, the attacking packets come from tens or hundreds of addresses rather than just one, as in a standard DoS attack. Any DoS defense that is based on monitoring the volume of packets coming from a single address or single network will fail since the attacks come from all over. Rather than receiving, for example, 1,000 gigantic *pings* per second from an attacking site, the victim might receive one *ping* per second from each of 1,000 attacking sites.

One of the other disconcerting things about DDoS attacks is that the handler can choose the location of the agents. So, for example, a handler could target several North Atlantic Treaty Organization (NATO) sites as victims and employ agents that are all in countries known to be hostile to NATO. The human attacker might be sitting in, say, Canada.

Like DoS attacks, all of the DDoS attacks employ standard TCP/IP messages—but employ them in some nonstandard ways. Common DDoS attacks include *Tribe Flood Network* (TFN), *Trin00*, *Stacheldraht*, and *Trinity*. The sections that follow present some details about these attacks.

18.7.1 Short History of Distributed Denial of Service. Denial-of-service attacks under a number of guises have been around for decades. Distributed DoS attacks are much newer. In late June and early July 1999, groups of hackers installed and tested a DDoS tool called *Trinoo* (see Section 18.7.3.1) to launch medium to large DDoS attacks. Their tests involved over 2,000 compromised systems and targets around the world.

Most of the literature suggests that the first documented large-scale DDoS attack occurred in August 1999, when *Trinoo* was deployed in at least 227 systems (114 of which were on Internet2) to flood a single University of Minnesota computer; this system was down for more than two days.

On December 28, 1999, CERT/CC issued its Advisory CA-1999-17 (www.cert.org/advisories/CA-1999-17.html) reviewing DDoS.

On February 7, 2000, Yahoo! was the victim of a DDoS during which its Internet portal was inaccessible for three hours. On February 8, Amazon, Buy.com, CNN, and eBay were all hit by DDoS attacks that caused them either to stop functioning completely or to slow down significantly. And on February 9, 2000, E*Trade and ZDNet both suffered DDoS attacks. Analysts estimated that during the three hours Yahoo! was down, it suffered a loss of e-commerce and advertising revenue that amounted to about \$500,000. According to bookseller Amazon.com, its widely publicized attack resulted in a loss of \$600,000 during the 10 hours it was down. During their DDoS attacks, Buy.com went from 100 percent availability to 9.4 percent, while CNN.com's users went down to below 5 percent of normal volume and Zdnet.com and E*Trade.com were virtually unreachable. Schwab.com, the online venue of the discount broker Charles Schwab, was also hit but refused to give out exact figures for losses. One can only assume that to a company that does \$2 billion weekly in online trades, the downtime loss was huge. Another type of damage caused indirectly by the DDoS was the decline in stock values in the 10 days following the attacks: eBay suffered a 24 percent decline, Yahoo! dropped 15 percent, and Buy.com dropped 44 percent.

These attacks were orchestrated by 15-year-old Michael Calce, a youngster living in the west end of Montreal island in Quebec whose pseudonym was *Mafiaboy*. He eventually pled guilty to 56 charges of computer crime and served eight months of juvenile detention.⁴

18 · 16 DENIAL-OF-SERVICE ATTACKS

These types of DDoS attacks have continued since the summer of 1999. One of the best-known incidents was a series of DDoS attacks against Steve Gibson's GRC.com Website in May 2001. The attacker was a 13-year-old using an Internet Relay Chat (IRC) bot, automated programs that exploit systems using IRC clients to become DDoS zombies.

The DDoS attack that had the highest potentially devastating impact, however, occurred on October 21, 2002, when all of the top-level DNS root servers were subjected to a sustained attack by thousands of zombies. Nine of the 13 DNS root servers were knocked off the Internet; the remaining four were able to keep operating during the attack. All of the major ISPs and many large private networks maintain their own DNS systems, although most servers ultimately rely on the root servers to find noncached DNS entries. The attack lasted for just an hour or two; had it continued for much longer, the remaining servers probably would have been overwhelmed, effectively blocking DNS host name/address translation.

A disturbing and growing trend is the use of DDoS as an extortion tool. An increasing number of criminals are using DDoS tools as a way to threaten an attack rather than actually disrupting a target organization's network. Although several providers of network, security, and consulting services claim that they and many of their customers have received such extortion demands, few are public about naming the targets—many of which are acceding to the threats and paying the blackmail.⁵ Most experts agree that the extortion demands should not be met; doing so only encourages the criminal behavior. If such a threat is received, the organization's ISP and law enforcement authorities should be contacted immediately.

18.7.2 Distributed Denial-of-Service Terminology and Overview. To describe and understand DDoS attacks, it is important to understand the terminology that is used to describe the attacks and the tools. Although the industry has more or less settled on some common terms, that consensus did not come about until well after many DoS/DDoS attacks had already appeared in the hacker and mainstream literature. Early descriptions of DDoS tools used a jumble of terms to describe the various roles of the systems involved in the attack. At the CERT/CC Distributed System Intruder Tools Workshop held in November 1999, some standard terminology was introduced and those terms are used in the paragraphs below. To align those terms and the terms used by the hacker literature as well as early descriptions, here are some synonyms:

Intruder—also called the *attacker* or *client*.

Master—also called the *handler*.

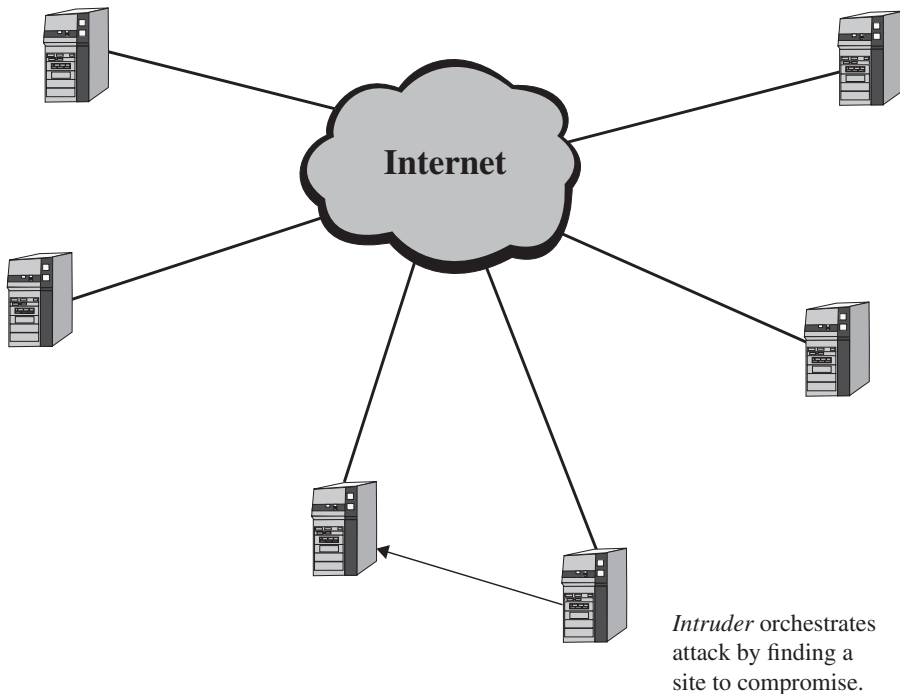

Daemon—also called an agent, bcast (broadcast) program, or zombie.

Victim—also called the *target*.

DoS/DDoS attacks actually have two victims: the ultimate target and the intermediate system(s) that were exploited and loaded with daemon software. In this chapter, the focus is on the end-of-the-line DoS/DDoS victim.

DDoS attacks always involve a number of systems. A typical DDoS attack scenario might follow roughly these three steps:

1. The *intruder* finds one or more systems on the Internet that can be compromised and exploited (see Exhibit 18.4). This is generally accomplished using a stolen

**EXHIBIT 18.4** DDoS Phase 1

account on a system with a large number of users or inattentive administrators, preferably with a high-bandwidth connection to the Internet. (Many such systems can be found on college and university campuses.)

2. The compromised system is loaded with any number of hacking and cracking tools, such as scanners, exploit tools, operating system detectors, rootkits, and DoS/DDoS programs. This system becomes the DDoS *master*. The master software allows it to find a number of other systems that can themselves be compromised and exploited. The attacker scans large ranges of IP network address blocks to find systems running services known to have security vulnerabilities. This *initial mass-intrusion phase* employs automated tools to remotely compromise several hundred to several thousand hosts, and installs DDoS agents on those systems. The automated tools to perform this compromise are not part of the DDoS toolkit but are exchanged within groups of criminal hackers. These compromised systems are the initial victims of the DDoS attack. These subsequently exploited systems will be loaded with the DDoS *daemons* that carry out the actual attack (see Exhibit 18.5).
3. The intruder maintains a list of *owned systems* (sometimes spelled *pwned* by hackers), the compromised systems with the DDoS daemon. The actual *denial-of-service attack phase* occurs when the attacker runs a program at the master system that communicates with the DDoS daemons to launch the attack. Here is where the intended DDoS victim comes into the scenario (see Exhibit 18.6).

Communication between the master and daemons can be obscured so that it becomes difficult to locate the master computer. Although some evidence may exist on one or more machines in the DDoS network regarding the location of the master, the daemons

18 · 18 DENIAL-OF-SERVICE ATTACKS

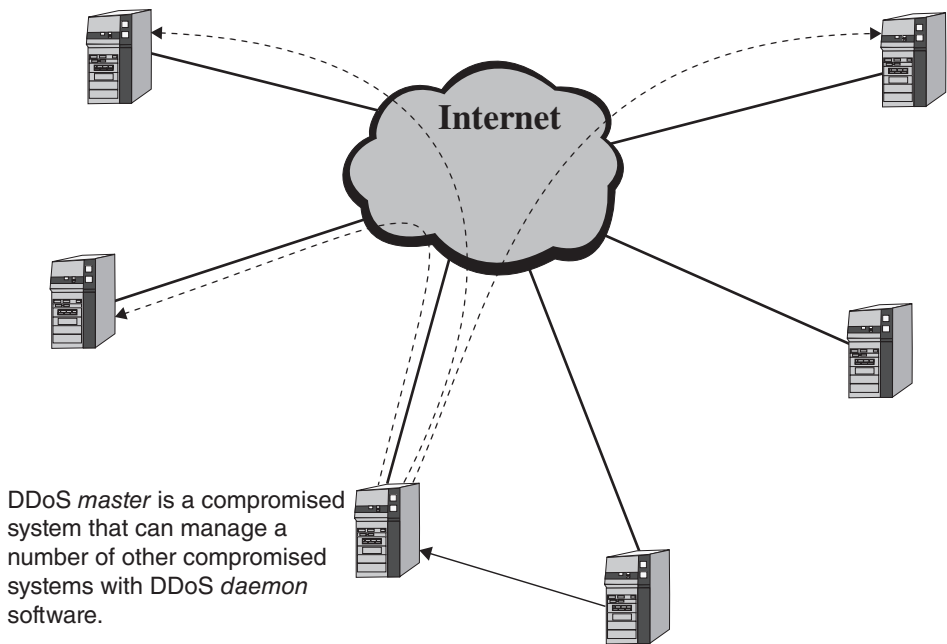

EXHIBIT 18.5 DDoS Phase 2

normally are automated so that it is not necessary for an ongoing dialog to take place between the master and the rest of the DDoS network. In fact, typically techniques are employed to deliberately camouflage the identity and location of the master within the DDoS network. These techniques make it difficult to analyze an attack in progress and difficult to block attacking traffic and trace it back to its source.

In most cases, the system administrators of the infected systems do not even know that the daemons have been put in place. Even if they do find and eradicate the DDoS

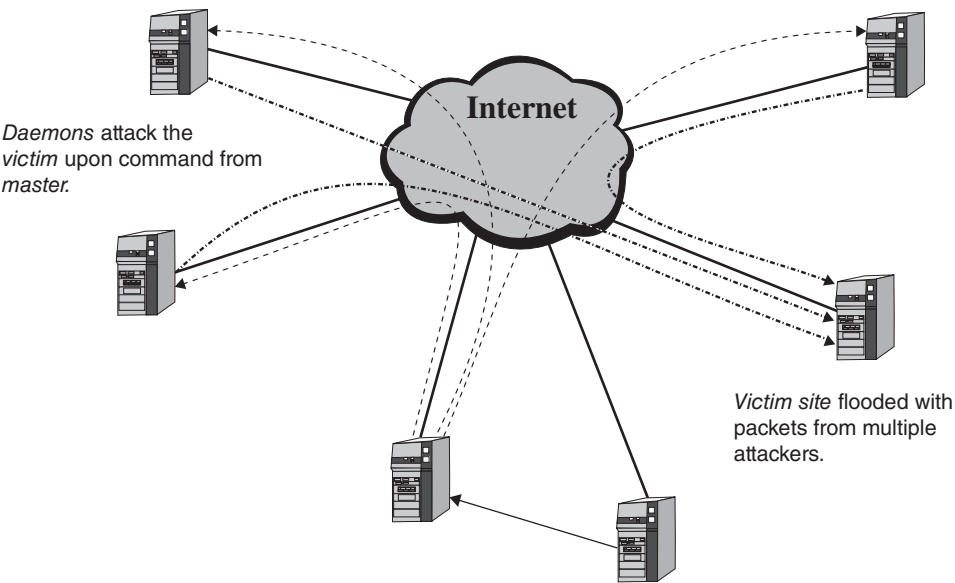

EXHIBIT 18.6 DDoS Phase 3

software, they cannot help anyone determine where else the software may have been placed. Popular systems to exploit are a site's Web, email, name, or other servers, since these systems are likely to have a large number of open ports, a large amount of traffic, and are unlikely to be quickly pulled off-line even if an attack can be traced to them.

18.7.3 Distributed Denial-of-Service Tool Descriptions. This section provides some details on how some of the major DDoS tools work.

18.7.3.1 Trinoo (Trin00). *Trinoo* or *Trin00* was the first known DDoS tool, appearing in the summer of 1999. The typical installation of Trinoo is similar to the scenario painted above where an attacker plants handler software on a system and the handler, in turn, loads the attack software on the agents. Trinoo is a distributed SYN DoS attack.

Trinoo uses a number of TCP and UDP ports:

- Masters listen on TCP port 27665 for attacker-to-master communication.
- Daemons listen on UDP port 27444 for master-to-daemon communication.
- Masters listen on UDP port 31335 for daemon-to-master communication.

These are default port numbers, and variants used other ports. The human attacker can control a Trinoo master (the handler) remotely via a connection to TCP port 27665. After connecting, the attacker gives the expected password, *betaalmostdone*.

The Trinoo master program is typically named *master.c* and the daemon is *ns.c*. Communication between the Trinoo master (handler) and daemons (agents) is via UDP. Master-to-daemon communications employ UDP datagrams on port 27444. All commands contain a password, the default being *l44adsl*. All valid commands contain the substring *l44*.

Communication from the Trinoo daemons to the master use UDP datagrams on port 31335. When the daemon starts, it sends a message to the master containing the string **HELLO**. The Trinoo *keep alive* function is accomplished by an exchange between the master and daemon: The master sends a Trinoo *mping* command, which sends the string *png* to a daemon; the daemon responds by sending the string *PONG* to the master.

The passwords are there to prevent system administrators from being able to take control of the masters and daemons that form the Trinoo network. Other default passwords in the initial attacks were *gOrave* to start the Trinoo master server and *killme* to control the master's *mdie* command to kill the Trinoo processes. Like the port numbers, the passwords can be changed easily by the attackers.

Intrusion detection software or system management routine analysis can look for a number of things that might indicate the presence of Trinoo:

- A system listening on UDP port 27444 could be a Trinoo daemon.
 - Trinoo daemon communication will contain the string *l44*.
 - The SYN flood mechanism picks the destination port using a random number generator function.
 - A Trinoo daemon will send the string *PONG* if it receives a *png* command.
- A system listening on TCP port 27665 could be a Trinoo master.

- A system listening on UDP port 27444 could be a Trinoo master.
- UDP packets will contain the string *l44adsl*.

18.7.3.2 Tribe Flood Network. The *Tribe Flood Network* (TFN) appeared after Trinoo. TFN runs primarily on compromised UNIX systems exploited using buffer overrun bugs in the remote procedure call (RPC) service. TFN client and daemon programs implement a DDoS network capable of employing a number of attacks, such as ICMP flood, SYN flood, UDP flood, and smurf-style attacks.

TFN is noticeably different from Trinoo in that all communication between the client (attacker), handlers, and agents uses *ICMP echo* and *echo reply* packets. Communication from the TFN client to daemons is accomplished via *ICMP echo reply* packets. The absence of TCP and UDP traffic sometimes makes these packets difficult to detect because many protocol monitoring tools are not configured to capture and display the ICMP traffic.

Remote control of the TFN network is accomplished by executing a program on the client system. The program also can be executed at the handler system by the client via some host-to-host connection method, such as connecting to an exploited TCP port or using a UDP- or ICMP-based remote shell. The program must be supplied:

- The IP address list of hosts that are ready to carry out the flood attack
- The type of attack to be launched
- The IP address list of target hosts
- The port number for SYN attack

No password protection is associated with TFN. Each command to the daemons is sent in the Identifier field of the ICMP packet; values *345*, *890*, and *901* start the *SYN*, *UDP*, and *ICMP* flood attacks, respectively. The Sequence Number field in the *echo reply* message is always set to *0x0000*, which make it look like the response to the initial *echo* packet sent out by the *ping* command.

The TFN client program typically is named *tribe.c* and the daemon is *td.c*.

18.7.3.3 Stacheldraht. Stacheldraht (German for *barbed wire*) is a DDoS tool that appeared in August 1999 and combines features of Trinoo and TFN. It also contains some advanced features, such as encrypted attacker–master communication and automated agent updates.

Stacheldraht uses a Trinoo-like client/server architecture. The handler listens on TCP port 16660 for client (intruder) commands, and the agents listen on TCP port 65000 for commands from the handler. Agent responses to the handler employ *ICMP echo reply* messages. The possible attacks are similar to those of TFN; namely, ICMP flood, SYN flood, UDP flood, and smurf attacks.

Trinoo and TFN exchange commands in plaintext. Trinoo, being TCP-based, is also subject to common TCP attacks, such as session hijacking. Stacheldraht addresses these deficiencies by employing an encrypting *telnet alike* client. (*Telnet alike* is a Stacheldraht term.) The client uses secret-key cryptography.

The Stacheldraht network comprises a number of programs. The attacker uses an encrypting client called *telnetc/client.c* to control to one or more handlers. The handler program is called *mserv.c*, and each handler can control up to 1,000 agents. The agent software, *leaf/td.c*, coordinates the attack against one or more victims upon command from the handler.

18.7.3.4 TFN2K. *Tribe Flood Network 2 K* (TFN2 K) was released in December 1999 and targets UNIX and Windows NT servers. TFN2 K is a complex variant of the original TFN with features designed specifically to:

- Make TFN2 K traffic difficult to recognize and filter
- Remotely execute commands
- Hide the true source of the attack using IP address spoofing
- Transport TFN2 K traffic over multiple transport protocols including UDP, TCP, and ICMP
- Confuse attempts to locate other nodes in a TFN2 K network by sending “decoy” packets

TFN2 K, like TFN, can consume all of a system’s bandwidth by flooding the victim machine with data. But TFN2 K, unlike TFN, also includes attacks designed to crash or introduce instabilities in systems by sending malformed or invalid packets, such as those found in the Teardrop and Land attacks.

TFN2 K uses a client server architecture in which a single client issues commands simultaneously to a set of TFN2 K agents. The agents then conduct the DoS attacks against the victim(s). The agent software is installed in a machine that already has been compromised by the attacker.

18.7.3.5 Shaft. Trinoo, TFN/TFN2 K, and Stacheldraht were the first, and possibly best studied, DDoS tools. Other tools followed, of course, and have become increasingly more complex, but these early tools remain available and some systems remain vulnerable to these forms of attack.

In November 1999, for example, the *Shaft* DDoS tool became available. A Shaft network looks conceptually similar to a Trinoo network with client-managing handler programs (*shaftmaster*) that, in turn, manage agent programs (*shaftnode*). Like Trinoo, handler-agent communication uses UDP, with the handler(s) listening on port 20433 and the agent(s) listening on port 18753. The client communicates with the handler by telnetting to TCP port 20432. The attack itself is a packet flooding attack, and the client controls the size of the flooding packets and duration of the attack. One signature of Shaft is that the sequence number for all TCP packets is always 0x28374839.

18.7.3.6 HTTP Apache Attack. In August 2000, a DDoS attack against Apache Web servers was first detected. The attack took advantage of a vulnerability whereby a URL sent to an Apache Web server containing thousands of forward slashes (/) would put the server into a state that would consume enormous CPU time. This particular attack was launched by over 500 compromised Windows computers and would, presumably, succeed against Apache Web servers prior to version 1.2.5.

18.7.3.7 Trinity. In September 2000, a new DDoS tool called *Trinity* was reported. Trinity is capable of launching several types of flooding attacks on a victim site, including ACK, fragment, RST, SYN, UDP, and other floods. Trinity agent software must be placed on Linux systems compromised by a buffer overflow vulnerability. The agent binary code typically is found in */usr/lib/idle.so*. Communication from the handler or intruder to the agent, however, is accomplished via Internet Relay Chat (IRC) or America Online’s ICQ instant messaging software. Whereas the attacker has

18 · 22 DENIAL-OF-SERVICE ATTACKS

to keep track of the IP addresses of compromised systems with Trinoo and TFN, all of the Trinity agents report back to the attacker by appearing in the same chat room. The original reports were that the Trinity agent communicated over an IRC channel called *#b3eblebr0x*; other IRC channels presumably are being used for DDoS, as well. IRC uses TCP ports 6665 to –6669, and Trinity appears to use port 6667. In addition, a binary called */var/spool/uucp/uucico* is a backdoor program that listens on TCP port 33270 for connections; an attacker connecting on that port and providing the password *!@#* will achieve rootshell on the affected system.

18.7.3.8 SubSeven. Zombie software is not always distributed by an attacker exploiting a vulnerability of an exposed system. Indeed, very often the user is the culprit. Trojan horses are often the mechanism for distributing the zombie code. The *SubSeven* software, for example, is a backdoor virus. SubSeven often gets on a user's system because it is distributed within programs available via Usenet and other Internet sites, such as some game or pornography programs (e.g., *SexxyMovie.mpeg.exe*). Potential attackers frequently scan computer systems today, particularly residential systems connected to the Internet via DSL or cable modem, for the presence of SubSeven, which provides a potential backdoor into users' systems; system administrators also are learning to scan for this dangerous program on their own systems.

18.7.3.9 Mydoom. The description above of some of the first DDoS tools is meant to show the early baseline from which later tools evolved, many of which are simply a variant of the early tools. *Mydoom* (aka *W32.MyDoom@mm* and other aliases) is an example of a DoS attack via an email worm, first launched in 2004. Mydoom appears as an email with some sort of error-type message in the subject line (e.g., "Error" or "Mail System Failure"). Interestingly, the email could be prepared in several different languages, including English, French, and German. The email contained an attachment that, if executed, forwarded the worm to addresses found in a variety of files on the local system, including the email address book. The worm could also be copied to shared folders of a user's peer-to-peer networking sites. Early versions of Mydoom contained a payload that would launch a DoS attack against the SCO Group on February 1, 2004; the SCO Group was unpopular because they asserted, in a \$1 billion lawsuit against IBM, that several Linux distributions were violating SCO's UNIX intellectual assets. Other variants of Mydoom were subsequently released, including a version employed in attacks on South Korea and the United States in July 2009 that included the launching of a botnet.

18.7.3.10 LOIC, HOIC, and HULK. Another variant of these types of attacks is the *Low Orbit Ion Cannon* (LOIC). Designed to be used as a network stress test, it can also be deployed as a DoS or DDoS tool. LOIC works, basically, by flooding a target with TCP and UDP packets in order to learn whether the routers can handle the load and how they will respond—or to usurp all of the bandwidth. Originally written in C#, a JavaScript variant (LS LOIC) and Web version (Low Orbit Web Cannon) have also appeared. LOIC has been used extensively by the hacktivist collective *Anonymous*.

The *High Orbit Ion Cannon* (HOIC) is a modification of LOIC. It has an easy-to-use graphical user interface that allows attackers to specify targets and *booster* scripts to target multiple pages on the targeted server, much like a shotgun instead of a rifle. The *intensity* setting defines the number of requests per second (2/sec for *low* and 8/sec for *high*).

The *HTTP Unbearable Load King* (HULK) is a variant of other tools that bombard a Web server with a overwhelming number of packets. Most prior tools, however, send TCP SYN requests or other predictable packets, which allows the firewall and/or server to detect the attack and mount a defense. HULK generates a unique, nonpredictable set of requests designed to frustrate defenses based on pattern recognition and packet filtering.

18.8 DENIAL-OF-SERVICE USING EXPLOITABLE SOFTWARE.

The tools just discussed employ a common DoS approach: An attacker exploits a vulnerability of a potential victim and uses that system to launch attacks on the intended victim. Later rounds of DDoS attacks, however, use code that is commonly available and that has known vulnerabilities. And all too often, the vulnerabilities are exploited after a patch to fix them has been released but ignored by some system administrators. A case in point is the flurry of such releases in mid-2001.

In May 2001, a buffer overflow exploit was discovered in the Microsoft IIS Indexing Service. In mid-June, Microsoft released a security bulletin warning that administrative scripts (.ida files) and Internet data queries (.idq files) did not do proper bounds checking. As it happens, what seems like the vast majority of IIS servers did not get the patch, and, in essence, every unpatched IIS server became a DDoS zombie.

18.8.1 Code Red.

In July 2001, eEye Digital Security and several other security organizations around the Internet saw an alarming number of TCP port 80 scans on the Internet. What they eventually discovered was what became known as the *Code Red Worm*.

Code Red had three distinct phases. The *propagation phase* occurred during the first 19 days of the month. During this phase, the attacking system scanned target systems on TCP port 80 and sent a specially crafted HTTP GET request that exploited the IIS buffer overflow (even if the Index Service is not running). A common log entry might appear as:

[illegible]

If the exploit was successful, the worm ran in RAM of the infected server and spawned 99 new threads to attack a quasi-random set of IP addresses. If the exploited server's native language was English, the server's Web page was defaced with a message that said "Welcome to <http://www.worm.com>! Hacked by Chinese!" This message would stay up for 10 hours and then disappear.

The *flood phase* occurred on days 20 to 27 of the month. This is when the attack really happened; every day between 8:00 and 11:59 P.M. UTC, the compromised servers sent 100 KB packets to the IP address 198.137.240.91, which formerly was assigned to www.whitehouse.gov. (Once the actions of Code Red were discovered, the IP address of www.whitehouse.gov was changed from the targeted address.)

Days 28 to 31 of the month were the *termination phase*, when the worm became dormant. Code Red was relatively innocuous, compared to what it could have been;

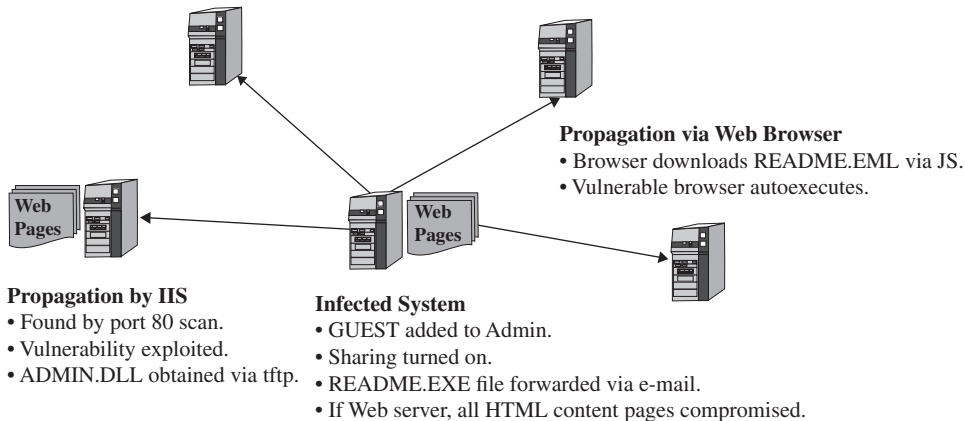

EXHIBIT 18.7 NIMDA Propagation Vectors

once asleep, the worm stayed asleep, although it could be reawakened. Removing the worm program from RAM required only a reboot, and the patch from Microsoft would prevent further infection.

As an aside, although only IIS servers could be exploited, many other devices that listen on port 80 were also affected. Cisco 600 DSL routers and HP JetDirect devices, for example, listen on port 80 and would crash when they received the buffer overflow packet.

Three different variants of Code Red existed on the Internet, all acting as described. In August 2001, a couple of new variants appeared that were called *Code Red II*. Unlike Code Red, Code Red II did not deface Web pages nor did it launch a DDoS attack on any given site. Instead, this worm was destructive, installing backdoors on infected servers, changing many registry settings, installing a Trojan horse version of *explorer.exe* (Windows Explorer), and disabling the System File Checker (SFC) utility. The worm also spread quickly, employing up to 300 threads at a time looking for other systems to infect.

18.8.2 NIMDA. The next evolution appeared in September 2001 and was called *NIMDA*. *NIMDA* (*admin* backward) was unique because it exploited multiple vulnerabilities in Microsoft code, namely IIS, Internet Explorer (IE), and the Message Application Program Interface (MAPI). As a result, NIMDA had four distinct propagation vectors (see Exhibit 18.7):

1. **IIS.** When a Web server was found, the attacker attempted to exploit various IIS vulnerabilities, including IIS *sadmind*, a Code Red II *root.exe* or other backdoor program, or IIS Directory Traversal. If successful, the attacker used the Trivial File Transfer Protocol (tftp) from *cmd.exe* to send the worm code (*admin.dll*) to the victim.
2. **Web browser.** The worm on an infected server created a copy of itself in a file called *readme.eml*. The worm also altered every Web-content file at the infected site with a small JavaScript code that pointed to this file. When a user browsed to

the infected Web server, the infected page's JS code was activated, and *readme.eml* was downloaded. Vulnerable versions of Internet Explorer would auto-execute the file while most other browsers would not.

3. **Email.** NIMDA sent itself to all of the email addresses found in the InBox and Address Book of an infected server in a MIME-encoded, 56KB attached file named *readme.exe*. The file had an "audio/x-wav" section that contained the worm. Email clients using IE 5.1 or earlier to display HTML would automatically execute the attachment if the message was opened or previewed.
4. **Network shares.** When on an infected system, the worm copied itself to all local directories on the victim host and to all open, writeable network shares. The worm also set up shares on the victim host.

In addition, the GUEST account on the infected system was activated and made a member of Administrator group. (Interestingly, after a summer of increasing DDoS worms, almost all such activity ceased after 9/11 for many months.)

Over the years, DDoS attacks have continued, but there is a dual purpose. Some DDoS attacks are intended to knock a server or network off the Net the old-fashioned way, namely by sucking up all of the bandwidth or other resource. Other attacks, however, use the target site's defenses against itself; by performing reconnaissance to understand how a site will respond to various stimuli, the attacker can actually send a crafted set of packets to the target site that will cause the target to self-limit bandwidth and/or acceptable source addresses.

18.9 DEFENSES AGAINST DISTRIBUTED DENIAL-OF-SERVICE ATTACKS.

As with DoS attacks, a site cannot in isolation defend itself from DDoS attacks. Members of the Internet community must work together to protect every site against becoming the source of attacks or forwarding the attacks. This section discusses some ways to help prevent the spread of DDoS attacks by limiting the distribution of the tools and by limiting the propagation of the offending attack packets.

Although not discussed in detail here, another point needs to be made about DDoS attack responses. As discussed in Chapter 53 in this *Handbook*, victims of such an attack should maintain detailed logs of all actions they take and events they detect. These logs may prove invaluable in understanding the attack, in preventing other attacks at the initial target and others, and in aiding law enforcement efforts to track down the perpetrators.

18.9.1 User and System Administrator Actions. These steps should be taken to minimize the potential that an individual system will be compromised and attacked or used as a stepping-stone to attack others:

1. Keep abreast of the security vulnerabilities for all of the site's hardware, operating systems, and application and other software. This sounds like a Herculean task, but it is essential to safeguarding the network. Apply patches and updates as soon as possible. Standardize on certain hardware, operating systems, and software where feasible to help manage the problem.
2. Use host-based firewall software on workstations to detect an attack.
3. Monitor systems frequently to test for known operating system vulnerabilities. Regularly check to see what TCP/UDP ports are in use using the *netstat -a*

18 · 26 DENIAL-OF-SERVICE ATTACKS

command; every open port should be associated with a known application. Turn off all unused applications.

- 4. Regularly monitor system logs and look for suspicious activity.
- 5. Use available tools to periodically audit systems, particularly servers, to ensure that there have been no unauthorized/unknown changes to the file system, registry, user account database, and so on.
- 6. Every client system must use anti-malware software that updates itself continuously to keep abreast of the constantly changing threat landscape. Effective anti-malware tools include integration with browsers for automatically blocking access to Websites that are known to harbor dangerous code. Such tools also integrate into email clients to block automatic opening of attachments. Users should not be permitted to disable the anti-malware software.
- 7. Do not download software from unknown, untrusted sites. If possible, know the author of the code. Even better, download source code, review it, and compile it on a trustworthy system rather than downloading binaries or executables.
- 8. Keep up with and follow recommendations from NIST, US-CERT, anti-virus research labs, hardware and software vendors, and other sources of best practices.

18.9.2 Local Network Actions. Even if users lock down their systems so that no vulnerability has gone unpatched and no exposure unprotected, the local network itself still can be at risk. Local network managers and network administrators can take several steps to protect all of their own users as well as the rest of the Internet community:

- 1. Every network connected to the Internet should perform egress address filtering at the router. *Egress filtering* means that the router should examine the Source Address field of every outgoing IP packet sent to the Internet to be sure that the NET_ID matches the NET_ID of the network. Historically, firewalls have been used to protect networks from attacks from the outside world. But those attacks come from somewhere, so sites should also use the firewall to *protect* the outside world.
- 2. Networks should block incoming packets addressed to the broadcast address (the all-ones HOST_ID). There is no legitimate reason that an external network device should be sending a broadcast message to every host on a network.
- 3. To prevent a site from being used as a broadcast amplification point, turn off the Directed Broadcast capability at the router unless it is absolutely essential. If it is essential, reexamine the network to see if there is not a better way or if the broadcast scope can be minimized. Even where Directed Broadcasts are useful, typically they are needed only *within* the enterprise and are not required for hosts on the outside.
- 4. RFC 1918 defines three blocks within the IP address space that are reserved for private IP networks; these addresses are not to be routed on the Internet.

IP Address Range	Network ID/ Subnet Mask	Number of Equivalent Classful IP Networks
10.0.0.0–10.255.255.255	10/8 prefix	1 Class A network
172.16.0.0–172.31.255.255	172.16/12 prefix	16 Class B networks
192.168.0.0–192.168.255.255	192.168/16 prefix	256 Class C networks

In addition, there are a number of reserved IP addresses per RFC 3330 that are never assigned to public networks or hosts, including:

0.0.0.0/32	Historical broadcast address
127.0.0.0/8	Loopback network identifier
169.254.0.0/16	Link-local networks
192.0.2.0/24	TEST-NET
224.0.0.0/4	Multicast address range
240.0.0.0/5	Reserved for future use
255.255.255.255/32	Broadcast

Attackers commonly use IP address spoofing, generally by using one of the RFC 1918 private addresses or one of the other reserved addresses. Firewalls should immediately discard *any* packet that contains any RFC 1918 or reserved IP address in the Source Address or Destination Address field; such packets should never be sent to the Internet.

5. Block all unused application ports at the firewall, particularly such ports as IRC (6665–6669/tcp) and those known to be associated with DDoS software.
6. Use stateful firewalls that can better examine a packet within the context of the entire packet exchange. Stateless firewalls only look at packets according to a simple set of rules but are not aware of the overall packet traffic on the network (e.g., a stateless packet filter might forward an ICMP *echo* Reply packet to be sent out because the rules allow it; a stateful packet filter will forward the packet only if the rule allows it *and* there was a corresponding ICMP *echo* Request).
7. Use intrusion detection and intrusion prevention to protect the network. For example, personal firewall software can be installed on every workstation to help detect an attack on individual systems; this strategy is particularly useful at sites that have a large number of systems *in front* of a firewall (e.g., colleges). It is no coincidence that so many daemons reside on college and university computers that have been *Owned* (i.e., taken over by hackers).
8. Regularly monitor network activity so that aberrations in traffic flow can be detected quickly.
9. Educate users about events to watch for on their systems and how to report any irregularity that might indicate that someone or something has tampered with their system. Educate the help desk and technical support to assist those users who make such reports. Have an intelligence-gathering system within the organization so that such reports can be coordinated centrally to spot trends and to devise responses.
10. Follow NIST, US-CERT, and other best practices procedures.

18.9.3 Internet Service Provider Actions. ISPs offer the last hope in defeating the spread of a DDoS attack. Although the ISP cannot take responsibility for locking down every customer’s host systems, ISPs have—and should accept—the responsibility to ensure that their network does not carry packets that contain obviously “bad” packets. Some of the steps that ISPs can take include:

1. As mentioned, attackers commonly employ IP address spoofing using an RFC 1918 private address or other reserved address. Amazingly, many ISPs will route

18 · 28 DENIAL-OF-SERVICE ATTACKS

these packets. Indeed, there is no entry in their routing table telling them where to send the packets; they merely forward them to a default upstream ISP. *Any* packet that contains any RFC 1918 or reserved IP address in the IP Source Address or Destination Address field should be discarded immediately.

2. Perform ingress (and egress) address filtering. *Ingress filtering* means that ISPs should examine every incoming packet to their network from a customer's site and examine the IP Source Address field to be sure that the NET.ID matches the NET.ID assigned to that customer. Doing this will require additional configuration at the router and may even result in slight performance degradation, but the trade-off is certainly well worth the effort. The ISPs also should perform egress filtering to check their outbound packets to upstream and peer ISPs.
3. Disable IP directed broadcasts.
4. Pay careful attention to high-profile systems (servers) and customers.
5. Educate customers about security and work with them to help protect themselves.

Most of the ISP community takes at least some of these steps. Users should insist that their ISPs provide at least these protections and should not do business with those that do not. RFC 3013 and the North American Network Operators' Group (NANOG) are good sources of information for ISPs.

18.9.4 Exploited Software Defensive Actions. There are a number of defensive steps that can be taken to avoid or mitigate problems due to Code Red/NIMDA-like attacks that exploit software. Several of these recommendations are controversial due to their implicit boycott of products from a specific vendor.

- If using IIS, consider using alternate Web server software. If use of IIS is essential, keep IIS and the operating system up to the latest patch revision. Microsoft's IIS Cumulative Patch, for example, does *not* clean a system of many of the backdoors used for exploits.
- If using Internet Explorer, consider using alternate browser software. If you must use IE, secure it against MIME auto-execution. Note that as late as September 2012, unpatched vulnerabilities were being reported by US-CERT in IE6, IE7, IE8, and IE9, and some authorities (e.g., the government of Germany) were recommending against the use of any version of IE.
- Disable all unused accounts on servers and other systems. In particular, enable the Guest account or anonymous access only if absolutely necessary.
- Disable JavaScript, Java, and ActiveX on browsers unless absolutely necessary.
- Do not execute or open *any* email attachment unless expected, known, and verified.
- Use the most up-to-date antivirus signature files.
- Unbind file and print sharing from TCP/IP. In some cases, this will require installing NetBEUI for file and print sharing.

18.9.5 Other Tools under Development or Consideration. Responses to DDoS attacks are not limited to the defensive steps just listed. Indeed, proactive responses to the prevention and detection of DDoS attacks are an active area of research. These proposals are merely samples of some ways for dealing with DDoS attacks; the first adds new hardware to the Internet, the second requires changing Web server and

client software, and the latter two require incrementally changing software in all of the Internet's routers and hosts, respectively. Upgrading Web browsers is probably the most practical strategy even though there are millions of copies in distribution; the vast majority come from just a handful of vendors, and users tend to upgrade frequently anyway.

18.9.5.1 Distributed Traffic Monitor. One method that has been proposed is to examine the network at the ISP level and build a type of intelligent, distributed network traffic monitor; in some sense, this would be like an IDS for the Internet. ISPs, peering points, and/or major host servers would have traffic monitor hardware using IP and the Internet for communications, much like today's routing protocols. Each node would examine packets and their contents, doing a statistical analysis of traffic to learn the normal patterns. These devices would have enough intelligence to be able to detect changes in traffic level and determine whether those changes reflected a normal condition or not. As an example, suppose that such hardware at Amazon.com were to identify a DoS attack launched from an ISP in Gondwanaland; the traffic-monitoring network would shut off traffic to Amazon coming from that ISP as close to the ISP as possible. In this way, the distributed network of monitors could shut traffic off at the source.

The hardware would need to be informed about traffic-level changes due to normal events, such as a new Super Bowl commercial being posted on YouTube or a new fashion show at Victoria Secret's Website. The hardware also would need to prevent the attacker community from operating under the cover of these normal events.

18.9.5.2 Client Puzzle Protocol. RSA Laboratories has proposed cryptographic methods as a potential defense to DDoS attacks against Web servers. This approach would use a *client puzzle* protocol designed to allow servers to accept connection requests from legitimate clients and block those from attackers. A client puzzle is a cryptographic problem that is generated in such a way as to be dependent on time and information unique to the server and client request.

Under normal conditions, a server accepts any connection request from any client. If an attack is detected, the server selectively accepts connection requests by responding to each request with a puzzle. The server allocates the resources necessary to support a connection only to those clients that respond correctly to the puzzle within some regular TCP time-out period. A bona fide client will experience only a modest delay getting a connection during an attack, while the attacker will expend an incredible amount of processing power to continue sending the number of requests necessary for a noticeable interruption in service at the target site, quickly rendering the attack ineffective (in effect, a reverse DoS). This scheme might be effective against a DDoS attack from a relatively small number of hosts each sending a high volume of packets but might have limited effectiveness against a low-volume attack from a large number of systems or from a botnet.

18.9.5.3 IP Traceback. A third mechanism that was the subject of considerable research during the early to mid-2000s was *IP Traceback*. The problem with DoS/DDoS attacks is that packets come from a large number of sources, and IP address spoofing masks those sources. Traceback marking, in concept, is a relatively straightforward idea. Every packet on the Internet goes through some number of ISP routers. Processing power, memory, and storage are available for routers to mark packets with partial path information as they arrive. Since DoS/DDoS attacks generally comprise a large number

18 · 30 DENIAL-OF-SERVICE ATTACKS

of packets, the traceback mechanism does not need to mark every packet, but only a sample size that is statistically likely to include attack packets (e.g., 1 packet out of every 20,000, or 0.005% of the IP traffic). This feature would allow the victim to locate the approximate source of the attack without the aid of outside agencies and even after the attack had ended. Another traceback proposal would define an ICMP Traceback message that would be sent to the victim site containing partial route information about the sampled packet. There are many issues related to traceback that need to be resolved, such as the minimum number of marked packets required to reconstruct the path back to the attacker, the actual processing overhead, and the ability to perform traceback while an attack is under way. In addition, any traceback solution will require a change to tens of thousands of routers in the Internet; how effective can traceback be during a period of gradual implementation? The upside, of course, is that the solution is backward compatible and results in no negative effects on users.

18.9.5.4 Host Identity Payload. A fourth proposal was to modify IP to be less prone to address spoofing by making the protocol less dependent on the address field for anything more than routing. The Host Identity Payload (HIP), for example, defines a protocol for the exchange of a cryptographic *Host Identity* between two communicating systems. This feature relegates the IP address for use solely as a mechanism for packet forwarding rather than as an identifier of the sender. Sender identification, instead, is accomplished by the Host Identity value, and all of the higher layer protocols are bound to the Host Identity. HIP is not yet widely deployed but is available in some TCP/IP implementations.

18.10 MANAGEMENT ISSUES. One of the greatest shortcomings in many organizations is that the highest levels of management do not truly understand the critical role that computers, networks, information, and the Internet play in the life of the organization. It is difficult to explain that there is an intruder community that is actively working on new tools all the time; and history has shown that as the tools mature and become more sophisticated, the technical knowledge required of the potential attacker goes down and the number of attacks overall goes up. Too many companies insist that “no one would bother us” without realizing that *any site* can become a target just by being there.

DoS attacks come in a variety of forms and aim at a variety of services, causing increased complexity and difficulty for system defense. DoS attacks should be taken seriously because of the potential threat they present, and attempts should be made to educate operational staff before such attacks occur, to document DoS attacks if they do occur, and to review the documentation and actions taken after the incident is over. Discussion of what steps were taken, what actions went into effect, and what the overall result was will help in determining whether the procedures carried out and techniques utilized were those best suited to the situation. A frank review and discussion will help achieve the best, most rapid, and most effective deployment of resources.

If anything proves the intertwined nature of the Internet, it is the defense against DDoS attacks. DDoS attacks require the subversion and coordination of hundreds or thousands of computers to attack a few victims. Defense against DDoS attacks requires the cooperation of thousands of ISPs and customer networks. Fighting DDoS requires continued diligence in locking down all of the hosts connected to the Internet as well as fundamental changes in the nature of TCP/IP connection protocols. In addition, many of the same techniques used to insert viruses and worms that lead to DoS and DDoS attacks are being used to insert Advanced Persistent Threat (APT)–class malware.

As with most security concerns on the Internet, a large part of the solution lies in user education. Users must be educated as to what current threats are currently on the Internet and affecting relevant applications, what to do if something suspicious occurs, and how to respond to attackers that are increasingly creative. The world of everyone having their own computers, mobile devices with an incredible amount of intelligence, and a bring-your-own-device (BYOD) corporate atmosphere requires that every user in the enterprise is a potential vulnerable point and needs to be properly educated.

19.1 INTRODUCTION. According to Greek mythology, the Greeks defeated the Trojans in the Trojan War with the help of a wooden statue. After fighting a decade-long war in vain, the Greeks withdrew from their stronghold on the beach. Outside the gates of Troy, they left a giant wooden horse. The statue confused the Trojan soldiers, but it was brought within the fortified walls of Troy. Inside the statue hid several Greek soldiers. When darkness fell, these soldiers emerged from the statue and opened the

19 · 2 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

gates of Troy. The Greek army entered Troy and took the soldiers and citizens of Troy by surprise. After the deception, Greece won the war quickly.

The Trojan horse built by the Greeks was effective because it used deception to achieve the desired result: penetrating the enemy's established defenses. The Trojan horse accomplished what those in information security label *social engineering*.

Social engineering may be defined as obtaining information or resources from victims using coercion or deceit.

Social engineering refers to lying, cheating, tricking, seducing, extorting, intimidating, and even threatening employees into revealing confidential information that can then be used to break into systems. Social engineering is based on deception and on violation of social norms of fairness and honesty.¹

During a social-engineering attack, attackers do not depend on subverting technology, for example, scanning networks, cracking passwords using brute force, or exploiting software vulnerabilities. Rather, social engineers operate in the social world by manipulating the trust or gullibility of human beings. Thus, social engineering relies on manipulating human nature to extract information or access by tricking a victim. Related to social engineering are low-tech attacks, and the two often go hand-in-hand. Low-tech attacks are similar to social-engineering attacks in that they do not utilize technology. They are physical attacks performed against companies or individuals' property.

Not all social-engineering and low-tech attacks will give attackers all the information they are seeking at once. Social engineers will collect small pieces of information that seem innocuous to the individuals that divulge them. Social engineers may gather these snippets of information in a seemingly random order but then assemble them into intelligence that is used to launch larger attacks that can be devastating to an organization's information security, resources, finances, reputation, or competitive advantage. Indeed, the purpose of a social-engineering attack can be as varied as the attack method employed. The result, however, is generally the same: a loss of intellectual property, money, business advantage, credibility, or all of the above.

Social-engineering attacks have been and will remain successful due to the weakest security link in an organization: the people. They are important because they exploit human nature, which is immutable and therefore perpetually vulnerable.

This chapter presents the history of social-engineering and low-tech attacks, its methods, the social science behind it, and its business impact. In addition, it covers detection and mitigation policies for managers and information security officers to defend against and mitigate social-engineering and low-tech attacks.

The purpose of a social-engineering attack can be as diverse as the attack method. Nevertheless, the result to the victims is generally the same, loss of intellectual property, money or business, credibility, or all of the previous. This chapter presents the history of social-engineering and low-tech attacks, its methods, the social science behind it, and its business impact. In addition, it covers detection and mitigation policies for managers and information security officers to defend against social-engineering and low-tech attacks.

19.2 BACKGROUND AND HISTORY. Social engineering is not a new tactic, nor is it an invention of modern-day hackers. The term has its foundations in political history, where a person or group manipulates a group of people, large or small, in an attempt to persuade or manipulate social attitudes or beliefs. Often, governments or political parties engage in this practice. The modern term's origins date back before World War II began, and the Nazis are thought to have actually coined the term.² To this day,

the term carries a negative connotation because of its roots in history, especially during Nazi-controlled Germany. Some researchers also consider the realm of social engineering to cover everything from advertising and modern media to political action groups.

Social engineering today is better known for its use as a security-penetration technique.

Deception has been integral to espionage through the centuries. Sun Tzu wrote in the fifth century BCE,

- “All warfare is deception.”
- “Having doomed spies, doing certain things openly for purposes of deception, and allowing our spies to know of them and report them to the enemy.”³

Deception—specifically, feeding false information to the enemy’s spies—was an integral part of the Second Punic War between Rome and Carthage in the third century BCE.⁴ During the Second World War, the Allies used “Operation Bodyguard” to deceive the Axis powers into believing that the D-Day invasion would occur at a different time and place from its true schedule and target.⁵ Deception was integral to the spy vs. counter-spy competition between the Communist block and the West during the Cold War.⁶

A well-known example of social engineering is the escapades of Frank W. Abagnale, subject of the fictionalized movie *Catch Me If You Can*.⁷ Abagnale was able to successfully impersonate authority figures, including a physician, pilot, attorney, and teacher, even though he was a teenager. He also used social-engineering techniques to persuade and manipulate innocent and good-natured individuals to help him carry out many of his frauds. Many of Abagnale’s techniques were highly successful and well engineered. Today, he helps organizations recognize and defend against such attacks through his speaking engagements and consulting business.⁸

One of the best-known social engineers is Kevin Mitnick. Though Mitnick is now a computer security consultant, lecturer, and author, his present career was preceded by a number of years spent as a computer hacker and social engineer. Long reformed, Mitnick has written several books discussing his observations and techniques as a computer hacker. Mitnick maintains that social engineering is the most powerful tool in the hacker’s toolbox.

Ever since social engineering has become a popular, and more importantly, successful, technique, its frequency of use has increased. One of the most visible reminders of this is the large number of phishing and pharming attacks, discussed in detail in Chapter 20 in this *Handbook*.

Social engineering has even become a spectator sport at some criminal-hacker conventions. At the 2012 DEF CON in Las Vegas, Shane MacDougall won the Social-Engineering Capture-the-Flag Contest by tricking a Walmart executive in a Canadian store into revealing every single piece of confidential information listed in the contest objectives.

Darnell asked the manager about all of his store’s physical logistics: its janitorial contractor, cafeteria food-services provider, employee pay cycle, and staff shift schedules. He learned what time the managers take their breaks and where they usually go for lunch.

Keeping up a steady patter about the new project and life in Bentonville, Darnell got the manager to give up some key details about the type of PC he used. Darnell quickly found out the make and version numbers of the computer’s operating system, Web browser, and antivirus software.⁹

19 · 4 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

Social engineering, when used by itself as a standalone attack tool, is very effective. But this tool can be used as part of a larger attack, or even as part of a technical attack. Social engineering is commonly used at the beginning of a larger, more substantial attack. It is important to remember that some attacks have taken place over weeks, months, or years. This is not always the case, and just because a specific social-engineering attempt was averted, the larger attack may not be completely mitigated. An example of this may be that an initial attack was unsuccessful because the attacker did not have sufficient or accurate information to carry out the attack. The attacker may revert once again to social engineering and low-tech attack strategies to gather information for a different, possibly successful, technical attack.

Even though an organization may have the best firewall, intrusion detection system, and risk management tools in the world, an attacker may use social engineering to circumvent these technical defenses. The attacker will not be stopped by the best technical defenses if the attacker is able to extract a valid user name and password from an unsuspecting employee. Once the attacker has this information, it may be enough information to carry out a massive attack on an organization's information systems—possibly undetected.

Computer criminals have been able to use pure social engineering and low-tech attack techniques, without relying on any serious technology, to cause large-scale damage to an organization as well. An action as simple as taking discarded, potentially damaging, information out of a dumpster and sending it to local media can cause substantial damage to an organization's image. This act might be part of a larger campaign or operation by a group of individuals seeking political or social action against an organization. An example of this was recently chronicled by Home Box Office (HBO) involving a group of citizens who routinely gathered the trash from county election centers and city halls in an effort to collect evidence that they could present to the media to prove voter fraud. Documents that were improperly disposed of have had extremely negative consequences for election officials.¹⁰

19.3 SOCIAL-ENGINEERING METHODS. Social-engineering attacks can take many different forms and expert social engineers are capable of changing their methods of attack very quickly in order to succeed. The underlying principle of most attacks is *pretexting*, which is defined as “the collection of information ... under false pretenses.”¹¹ Two distinct underlying methodologies are used during social-engineering attacks, impersonation and seduction. The basis for most attacks is either of these two methods. Certain low-tech attacks, which do not involve any human contact, are exceptions.

Targets of social-engineering attacks also vary widely. Depending on how complex the attack is or how much knowledge the attacker has will help determine the target for the attack. However, in many instances, a social-engineering attack is an attack of opportunity and the victim will be randomly chosen. In certain well-planned attacks, a particular target may be identified as the victim.

19.3.1 Impersonation. Impersonation is defined as pretending to be someone else, and it is one of the most popular methods that social engineers employ. Social engineers may use cross-functional impersonation attacks to target an employee at any level within the targeted organization. They may pretend to be a real, named individual, or they may pretend to have a particular role or authority.

Corporate executives are common targets of social engineering.¹² Helpdesk employees and systems administrators are also common targets of impersonation. Most

organizations have helpdesks for assisting employees with issues related to information technology (IT). Employees generally will follow the instructions from helpdesk personnel simply because they are perceived as technologically well-informed and trustworthy. Social engineers understand this trust and will exploit it to steal information. The attacker will impersonate helpdesk personnel and abuse this blind trust to gather whatever information the attacker needs.

Helpdesk personnel can also be the victims of social-engineering attacks with the social engineer impersonating a user in need of technical assistance. An attack against the AOL helpdesk is a historical example of a successful social-engineering attack against helpdesk personnel. An attacker posing as a customer was able to infiltrate the AOL environment by conning an AOL helpdesk staff member.¹³

There have also been instances where social engineers impersonate corporate officers or managers. In one case, the payroll giant ADP released personnel and brokerage account information on hundreds of thousands of customers. The attacker impersonated a corporate board member, requested and received the information.¹⁴ This case highlights the need for controls and education for all levels of employees. The victim in this case might have been concerned about not pleasing a powerful member of the organization and may have feared retribution.

It is important to note that attackers will also impersonate regular employees of an organization by dressing, speaking, and blending into the organization's environment. In doing so, the attacker may gain physical access to a facility by piggybacking or tailgating. In one case reported by a student in a 1993 security course, a social engineer collaborating with a corrupt manager was able to commandeer an unused desk in a large company for several *months* before a security guard asked for his company identification. The criminal disappeared immediately, but not before ingratiating himself to the employees as a new employee and even being invited out to social events by the unsuspecting victims.¹⁵

For a social engineer, there are no boundaries for impersonation; they may try to gain information via physical access to an organization using any number of ruses including impersonation of:

- Temporary employees (e.g., contractors or auditors)
- Utility or telecommunications company employees
- Emergency personnel
- Janitorial or maintenance employees
- New employees
- Delivery personnel

Physical access can greatly increase the success rate of an attack depending on whether the organization has proper controls in place. Highly motivated social engineers may go so far as to gain employment at the company, or at a company that is a client of the company, in order to have easier access to the victim.

19.3.2 Seduction. The word seduce is defined as “to lead away from duty, accepted principles, or proper conduct”.¹⁶ In general, a social-engineering attack using seduction will take longer to complete than an impersonation attack. The attacker, using seduction, will identify a target and will form a bond with that individual, through social settings, online, or through another mechanism. It is during this relationship that the victim's information is divulged to the attacker.

19.6 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

For example, a social engineer who wishes to gain access to a building may befriend a security guard of that organization. After some time has passed and the relationship has progressed, the attacker may request a tour of the facility. The security guard, wanting to please the new friend, may allow a tour. The social engineer, once inside, can plant clandestine listening devices, look for usernames or passwords, and read documents left in the open.

19.3.3 Intimidation. Social engineers can use fear to achieve their ends. For example, in 2012, scammers spread alarming emails about FBI prosecutions to innocent victims.

A new extortion technique is being deployed by cybercriminals using the Citadel malware platform to deliver Reveton ransomware. The latest version of the ransomware uses the name of the Internet Crime Complaint Center to frighten victims into sending money to the perpetrators. In addition to instilling a fear of prosecution, this version of the malware also claims that the user's computer activity is being recorded using audio, video, and other devices.

As described in prior alerts on this malware, it lures the victim to a drive-by download Website, at which time the ransomware is installed on the user's computer. Once installed, the computer freezes and a screen is displayed warning the user they have violated United States Federal Law. The message further declares that a law enforcement agency has determined that a computer using the victim's IP address has accessed child pornography and other illegal content.

To unlock the computer, the user is instructed to pay a fine using prepaid money card services. The geographic location of the user's PC determines what payment services are offered. In addition to the ransomware, the Citadel malware continues to operate on the compromised computer and can be used to commit online banking and credit card fraud.¹⁷

Another social-engineering attack using intimidation is the phony office-supply scam.¹⁸ A low-level employee accepts an offer of free printer toner, glass cleaner, or paper and receives a box of materials—followed by an invoice. Attempts to return the unwanted, no-longer-free materials are refused and the criminals use increasingly strong threats to intimidate the employee into passing the invoice along for payment. Employees may be told that their employer will be sued or that a complaint about their behavior will be sent to upper echelons of the organization. A variation involves sending a gift to the victim in the hope that accepting it can be used to embarrass the recipient into complying with the scammers' demands. Such scams succeed often enough to generate millions of dollars of revenue for the criminals.¹⁹

19.3.4 Low-Tech Attacks. Low-tech attacks are invaluable to an attacker as part of reconnaissance, information theft, and surveying for easy targets. On occasion, these methods may even reward the attacker with a very large amount of useful information in a very short amount of time. Low-tech attack methods may seem simple or improbable, but the methods described can easily be overlooked by security managers. They are not urban legends—they have been used in the past and continue to be utilized today.

19.3.4.1 Dumpster® Diving. In the context of social engineering, *Dumpster® diving* is the social engineer's act of searching through an organization's garbage in an attempt to find documents, hardware, software, or anything that could be of value to meet the goals of the attacker. Even with the widening use of sensitive document destruction, *Dumpster® diving* is a popular social-engineering technique because it is easy and often successful. Oracle hired detectives to purchase Microsoft's trash during

Microsoft's antitrust trial. (The detectives were unsuccessful.)²⁰ Social engineers do not need to deceive anyone to perform the attack. In many cases, the materials disposed may sit in open containers for weeks. Dumpster[®] diving is most often carried out at night when no one is around, as there is less risk of being caught. So as to not draw attention to themselves, Dumpster[®] divers have been known to dress in dark clothing or even use janitorial uniforms.

All organizations must understand the legal ramifications of Dumpster[®] diving. Local and state laws may vary widely and be murky; however, no organization or individual should have *any* realistic expectation of privacy relating to materials in refuse containers. It may even be legal for an attacker to remove and take ownership of anything left in a garbage receptacle if it is placed outside the limits of private property. Confidential information must be destroyed, not simply discarded.

An unfortunate example of making confidential data accessible in garbage came to light in November 2012, when strips of confetti thrown into the crowd at the Macy's Thanksgiving parade were discovered to have intact, readable confidential data:

Among the easily identifiable records from the Nassau County Police Department were what appears to be details of Mitt Romney's motorcade route to and from the final presidential debate at Hofstra University.

Confetti collected by spectators near 65th Street and Central Park West also contained arrest records, incident reports, and personal information, and identified undercover officers, WPIX-TV says.

"There are phone numbers, addresses, more Social Security numbers, license plate numbers," said Ethan Finkelstein, 18, of Manhattan, who gathered up some of the confetti with friends. "And then we find all these incident reports from police."²¹

The papers had been shredded the wrong way in a single-cut shredder, leaving horizontal strips of readable data for anyone to see.

19.3.4.2 Theft. The age-old crime of theft is another popular social-engineering technique. Social engineers may pick up anything they can get their hands on, literally, and leverage the information obtained to carry out other attacks. Targets of theft include, but are not limited to, printed materials, CD-ROMs, USB flash drives, backup media, tablets, smart devices, and laptops. Thieves may obtain objects on or off company premises. While on company premises, they may look for objects they can grab and quickly conceal. An attacker may bring in empty laptop cases, backpacks, or even large purses to aid in their efforts. Most employees are more likely aware of theft techniques outside of the organization, such as taxicabs, airports, and other public places. Employees may not realize that a social engineer or other criminal may also be an insider.

19.3.4.3 Leveraging Social Settings. Social engineers may use social settings to gain information because people relax in social settings and may believe that information security practices are for the workplace only. A social engineer may use a social setting, such as a bar, to take advantage of drinking employees to gain information. The attacker may actively engage a target or passively eavesdrop on a conversation. While this type of attack may seem far-fetched, there are many situations where the attacker may be in the right place at the right time to gain knowledge that can be later used as part of a larger attack. People in social settings are less likely to have their defenses up and security on their minds.

19 · 8 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

Restaurants, corporate functions, impromptu meetings outside of a company building, or loud phone conversations are all areas or situations where eavesdropping can occur. Many times, employees will work on commuter trains or conduct business in other public areas. A social engineer can exploit an organization's mobile workforce to gain information. Employees should be cognizant of who is around them while performing any work-related task.

19.3.4.4 Exploiting Curiosity or Naïveté. Social engineers may trick a victim into unknowingly aiding in an attack by piquing the user's curiosity. For example, an attacker may leave an intriguingly labeled CD-ROM in a break room, hoping that a victim is curious about the contents. When the victim places the CD-ROM in his or her computer, a malicious program, such as a virus, could automatically execute and spread. This technique has also been executed using USB drives, iPods, and corrupted music CDs.²²

19.3.4.5 Data Mining and Data Grinding. Search engines can catalogue a surprising amount of information that is sensitive and confidential. Social engineers can create special searches, use search engine application programming interfaces (APIs), and use advanced search capabilities of many search engines to mine information about a company. Another attack vector is the caching feature of many search engines. A search engine may cache a Web page with sensitive information. If an organization requests the cache be removed, still there is a delay before the search engine cache is updated, during which time the organization's information is exposed. Social engineers could also exploit data about individuals or organizations gathered from social media. See Section 19.3.5.6, "Social Media," in this *Handbook* for details about the use of this method. Attackers could mine this data for victims' behavioral trends. They could garner more information about the victims than was readily presented by social media data.

Documents published by a company are another source of unintended information disclosure. In a technique known as data grinding, social engineers can use metadata-reader software to extract information such as the author's name, organization, computer name, network name, email address, user identification (ID), and comments from Microsoft Office documents.²³ This potentially damaging information is included in most document types.

19.3.4.6 Piggybacking or Tailgating. A common and very successful method of social engineering is *piggybacking* or *tailgating*. The method allows an attacker access to a facility without showing proper credentials. The victim in these cases is being polite and holding the door for the attacker who enters the facility using the credentials of the victim. Once inside a facility, an attacker is free to roam the building in search for information. If questioned upon entering, attackers may use the excuse of forgetting their credentials or being new employees. In general, if a piggybacking is going to be attempted, social engineers will dress and act according to other members of the organization so they can blend into the facility. If a facility is secured by multiple layers of physical security, attackers may try to use social engineering to breach the first few layers then proceed to use other attack methods.

19.3.5 Network and Voice Methods. The Internet has taken off, and so have social-engineering attacks. These attacks differ from traditional social-engineering attacks due to minimal or no human interaction. Still, the basis of the attacks still relies

on the trusting nature of humans. The annoying Nigerian 419 attack is a combination attack using both email and human interaction.²⁴

The methods used for these attacks include *phishing*, *pharming*, *spim*, *malware*, and *vishing*. Phishing and Trojans are discussed in detail in Chapter 20 in this *Handbook*.

19.3.5.1 Phishing. Phishing is one of the most widely used and successful social-engineering attacks. It is defined as the “act of sending an email to a user falsely claiming to be an established legitimate enterprise in an attempt to scam the user into surrendering private information.”²⁵ Phishing, as with all social-engineering attacks, relies on the trusting nature of people. Naïveté about using the Internet also plays a role in the success of this attack.

An interesting new wrinkle is that being *misrepresented as the origin* of phishing emails was the second most common type of attack reported by respondents (39 percent) to the Computer Security Institute’s “2010/2011 Computer Crime and Security Survey.”²⁶

Newer, more targeted phishing attacks called *spear phishing* are also gaining in popularity. Spear phishing is used in a dangerous type of threats known as Advanced Persistent Threats (APTs). Spear phishing was used in a portion of a breach of the security firm RSA in 2011.²⁷

19.3.5.2 Spim. Many people and businesses rely on the synchronous communication that instant messaging (IM) offers. Social engineers have noted the increase in the use of IM software and developed *spim*. Spim is “instant spam or IM spam.”²⁸ A spim attack is very similar to a phishing attack except the vector is IM software instead of email. For example, an attacker will develop a fraudulent Website that resembles a legitimate one and send its link to many IM accounts. Victims will visit the Website and login, revealing their credentials to the attacker. The fraudulent site could contain malicious software that infects the victim’s computer. Surprisingly, despite the increasing use of IM software, the growth of spim has been slow.²⁹

19.3.5.3 Pharming. In *pharming* attacks, attackers attempt to make victims visit spoofed Websites to reveal sensitive personal information. Attackers achieve this by manipulating the victim’s local or global DNS directory. Pharming attacks may fool users more easily than other low-tech attacks because the user may be given no indication that an attack is under way. Users may type in the URLs of their banking or credit card Websites into their browsers as usual and not normally notice that they are in fact visiting fraudulent sites. In 1997, Dan Parisi registered the domain *whitehouse.com* and snared people mistakenly looking for *whitehouse.gov* into viewing pornography—an early form of pharming.³⁰ In a 2005 pharming attack, users of the Internet mail service Hushmail were redirected to a fraudulent site where their information was harvested. Hushmail suffered negative publicity from this attack and was forced to update its users daily about its investigation into the attack.³¹

19.3.5.4 Malware. Malware are programs or files that are harmful or dangerous to the end user. Social engineers frequently use Trojans and viruses. Although the programs themselves do not make up a pure social-engineering attack, the basis of the attack still relies on manipulating a victim’s trust. For example, a social engineer may send a victim a phishing email with a link to a malicious Website. If the user visits the malicious Website, a Trojan is installed on the victim’s computer and the malicious program will begin gathering the victim’s information. Another example involves a

19 · 10 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

USB drive loaded with auto-executing malware. A victim curious about the contents will plug the drive into a machine and execute the malicious code.³² Any number of vectors can be used, including documents, email messages, Websites, CDs, and USB drives. The premise is the same for all types of these attacks: The unsuspecting users, curious about the content, will inadvertently install these dangerous programs. Malware infections were the most common type of attack reported by respondents (67 percent) to the Computer Security Institute's "2010/2011 Computer Crime and Security Survey," and bots or zombies were reported by 29 percent.³³

Malware has recently begun to use a type of social-engineering attack whereby the trust placed in a valid certificate is exploited in conjunction with a long-known vulnerability called Data Link Library (DLL) preloading. In this attack, a package is prepared that includes a valid, trusted application that has a valid signature. In this package, however, a malicious DLL is included. Most users, who may know to look for a valid certificate, will indeed find one in the application and therefore trust the entire package. The victim launches the valid, trusted application, and due to the preloading vulnerability, the malicious DLL is loaded from the local directory before the valid DLL is loaded from its regular path.³⁴

See Chapters 16, 17, and 18 in this *Handbook* for details of malware.

19.3.5.5 Vishing. Attackers who lure victims with the use of email and the telephone or just the telephone are performing a *vishing* attack.³⁵ Social engineers may send an email or call victims in an organization about an issue and request a call back. The number given is either staffed by accomplices or answered by a legitimate-sounding automated system. Victims are prompted to release potentially damaging information, about themselves in the case of identity theft, or about their company.

In another example, an attacker can leverage automated phone answering systems which allow the caller to input the first few letters of the last name of a contact to reach their extension. The attacker can try multiple extensions and stumble on some that reveal details regarding a person's position, title, or office status (e.g., "I'm out on vacation until April 4"). A social engineer can leverage that information and call other employees to gain additional information or access.

It should also be noted that with the proliferation of Voice over Internet Protocol (IP) (VoIP) there is now Voice Phishing, which is propagating a vishing-phishing attack. Since the call is routed over IP, the call number can be changed easily. This is analogous to how phishing Websites operate. Since this is primarily a voice-based social-engineering attack, it is considered a voice attack instead of a Web attack.

VoIP has also internationalized the occurrence of such frauds. In an incident in 2013, criminals thought to be in Africa who were advertising nonexistent free kittens in thousands of pages on the Web used VoIP to contact victims in an attempt to fool well-meaning cat-lovers into paying for imaginary air-shipments of imaginary cats.³⁶

19.3.5.6 Social Media. Social media have exploded in popularity in recent years, and so have the opportunities for the social engineer to victimize that frequent these outlets.³⁷

Useful details may be easily harvested just from searching the victim's social media page, or the pages of relatives who include the victim on their pages. Data harvested could include things such as:

- Event dates
- Friends/relatives/colleagues of interest

- Pictures
- Contact information
- Locations frequented

In addition to strictly harvesting data, a social engineer could use impersonation to befriend the individual, so that details hidden from public view are viewable. This may allow the attacker to target his attack to his needs more effectively.

Of particular concern is the LinkedIn network, which reached 187 million members worldwide by the end of 2012; 57 percent were located in the United States and 63 percent elsewhere.³⁸ LinkedIn makes it possible to track job titles, job history, technical background, education, and linkages to other people in any given organization—ideal information for social engineers to commandeer. Although details are supposed to be kept away from people who have not linked to each other, some LinkedIn users routinely accept link requests from anyone who sends them an invitation—even though LinkedIn’s User Agreement explicitly states that members must not “Invite people you do not know to join your network.”³⁹ Criminals have demonstrated their interest in LinkedIn contacts by selling catalogs of information gleaned on this network.⁴⁰

19.3.6 Reverse Social Engineering. Reverse social engineering is an effective attack usually executed by an experienced social engineer. A reverse social-engineering attack has three distinct parts. First, a social engineer will create a problem, for example, a user ID issue. Second, the social engineer will publicize that they are the only person capable of fixing the issue. In the final part of the attack, the social engineer will assist the victim and “fix” the issue. It is during the third segment of the attack that a social engineer will gather information. The success rate of reverse social-engineering attacks tends to be high simply because the victim is satisfied that the fabricated problem is fixed.⁴¹

For example, the attacker may change the name of a file (the problem). The victim searches for and cannot find the file. The attacker will announce that they have been able to retrieve lost information but will require a user ID and password to gain access to the system (the publicity). The victim, flustered by the thought of losing an important document, will divulge the information. Finally, the attacker will “find” the missing file (the fix). The victim, being pleased that the file is returned, will forget having let out access credentials to the system.⁴²

19.4 THE PSYCHOLOGY OF SOCIAL ENGINEERING

19.4.1 Introduction. Well-known security expert Bruce Schneier identified that behavioral economics, psychology of decision making, psychology of risk, and neuroscience can help explain why our feeling of security deviates from reality.⁴³ This section focuses on one of these aspects—psychology—and studies the science underlying the success of social engineering. Section 19.4.2 uses some well-established principles of psychology and social psychology to analyze social engineering from two angles, the psychological perspective of the victim and social-psychological perspective of the social engineer and victim. Section 19.4.3 explains that there is no single social-engineer stereotype. The terms used in this section can be found in undergraduate psychology and social psychology textbooks and therefore academic references have been minimized.

19 · 12 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

Social engineering succeeds because of human nature: In this section, examples of social-engineering attacks illustrate scientific terms used to characterize social engineering.

19.4.2 Psychology. A *cognitive bias* is defined as a mental error caused by humans' simplified information-processing strategies.⁴⁴ People become victims of social-engineering attacks due to cognitive tendencies, also called "heuristics" or rules of thumb, which are inherent in all humans. These cognitive tendencies are useful, mostly. Psychologist Robert Cialdini writes:

We can't be expected to recognize and analyze all the aspects in each person, event, and situation we encounter in even one day. We haven't the time, energy, or capacity for it. Instead, we must very often use our stereotypes, our rules of thumb, to classify things according to a few key features and then to respond mindlessly when one or another of these trigger features is present.⁴⁵

Although cognitive biases are found in everyone, the universal presence of cognitive biases does not imply that they are impossible to counter.

Following are some cognitive biases that can explain why people fall prey to social-engineering attacks:

- **Choice-supportive bias.** People tend to remember an option they chose that had more positive aspects than negative aspects.⁴⁶ Information technology (IT) helpdesk operators may provide employee names, extensions, or both without verifying the identity of callers. Helpdesk operators remember this practice as being good because most callers are genuine and the callers thank them for providing the information. Social engineers can masquerade as genuine callers to exploit helpdesk operators' choice-support bias. According to an article on security analysis site SecurityFocus, a demonstration of this attack by the Computer Security Institute actually succeeded.⁴⁷
- **Confirmation bias.** People tend to collect and interpret evidence in a way that confirms their conceptions.⁴⁸ If an organization has a contract with a custodial service and employees see custodians all wearing the same uniform, then a social engineer wearing the uniform may not be challenged to identify himself because of the employees' confirmation bias. The movie *Ocean's Eleven* contains many scenes in which the owner and employees of three Las Vegas casinos are conned by picaresque protagonists dressed to blend into their roles and environment.⁴⁹
- **Exposure effect.** People tend to like things that are familiar.⁵⁰ A social engineer may call victims and explain they are performing a survey for a popular local restaurant and ask about the organization by which the victim is employed. The victims are comfortable providing that information because they are familiar with the restaurant. According to malware researcher Elodie Grandjean, some of the themes of baited emails, URLs, or instant messages used in social-engineering attacks include⁵¹:
 1. Pornographic links and images
 2. Using a female name in the sender field
 3. Political agendas, including solicitations for contributions in the name of a popular candidate

4. Fake emails for banks, online payment services, and other financial services. These request a confirmation or an update of login credentials or credit card information.
 5. Threatening emails, mentioning jail sanctions or jury-duty procedures
 6. Free games and screensavers containing a Trojan, or free antispyware tools, which are often rogue programs themselves
 7. Big events, such as sports, extreme weather disaster, or urgent news
 8. Celebrity names and reports on their adventures and misbehavior
 9. Potentially trusted or secret relationships such as affiliation with a 12-point program
 10. Social networking Websites, fake friends, school classmates or relatives, and secret lovers
- **Anchoring.** People tend to focus on one trait when making decisions.⁵² If a social engineer has a soothing voice, the victim may focus on that attribute versus the questions being asked. Security expert Winn Schwartau describes a successful social-engineering attack where some employees of a New York financial services company fell for a bogus letter written on company letterhead claiming to be from the information security department; 28 percent of the 1,200 employees wrote back with their personal details.⁵³ The employees had focused, to their detriment, too much on the letterhead and had ignored other aspects of the request, such as its suspiciousness, graveness, and suddenness.

19.4.3 Social Psychology. Social psychologists define the *schema* as the inherent picture of reality used by humans to make judgments and decisions. From the perspective of social psychology, social engineers exploit the fact that most peoples' schema includes rules to be trustful of other people and their intentions. People are taught from the very beginning of their socialization that being nice to others is a good thing. In the context of information security, peoples' tendency to blindly trust others can spell disaster.

Below is a list of common errors that people make, and examples of how social engineers will exploit those mistakes to attack an organization.

- **Fundamental attribution error:** In this common error, people assume that the behaviors of others reflect stable, internal characteristics. Someone committing the fundamental attribution error might see a colleague in a bad mood and think, "She is *always* moody." In reality, the colleague might be pleasant in general but be suffering a headache at the time. Social engineers will act pleasant and charming to lead victims to commit the fundamental attribution error, to be impressed that the attackers are nice people *in general* and so to help them.
- **Salience effect:** Given a group of individuals, people tend to guess that the most or least influential person is the one who stands out the most. For example, from a group of ten people, nine of whom are six feet tall and one who is five feet tall, if asked to guess who the most intelligent person in the group is, an observer might say that it is the five-foot-tall person. Social engineers attempt to blend into their victim's environment to take advantage of the salience effect. They are acutely aware of company lingo, events, and regional accents.

19.14 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

- **Conformity, compliance, and obedience:** People respond to the social pressures of conformity, compliance, and obedience by adjusting their behaviors. A social engineer impersonating a high-powered executive demanding admittance into the company premises may persuade a new security guard with the weight of his assumed authority. The authority figure's promise of reward or threat of punishment may further influence the security guard's decision to carry out the request of the attacker.

For more details of the implications of social psychology for information assurance, see Chapter 50 in this *Handbook*.

19.4.4 The Social Engineer Profile. The profile of a social engineer is not that of the stereotypical computer hacker often portrayed in the movies or on television.⁵⁴ Social engineers are most likely not going to be loner teenagers who spend all their time with their computers in a dark basement. A social engineer is often outgoing, confident, an excellent communicator, and well-educated. Social engineers may use their own personality, or adopt a persona that greatly differs from their normal personality—oftentimes a personality they have developed over months or even years. To achieve their goals, they will blend into the environment. Social engineers seek to be unnoticeable, unremarkable. They will dress according to the dress code of the environment in which they operate. Interestingly, social engineers may be excellent actors, able to think on their feet and to adapt quickly to changing conditions. The attacker's confidence will often mask any nervousness or tension during the social-engineering attempt, which may lead to unwarranted credibility.

Social engineers may also exhibit a dark side. Attackers may have very little regard for the consequences of their actions on the victim. Even though the attackers may appear very polite or congenial towards their victims, they actually care very little about the victim or the people utilized to achieve a goal. The victim and others are simply a means to an end; they are only part of the social-engineering attack tool. The social engineer's motivations may vary widely and range from personal financial gain to revenge. There may also be significant external pressure on the attacker from acquaintances or organized crime syndicates.⁵⁵

For more details of the psychology of computer criminals, see Chapters 12 and 13 in this *Handbook*.

19.5 DANGERS OF SOCIAL ENGINEERING AND ITS IMPACT ON BUSINESSES. The ultimate goals of the attacker may be limited to theft but may also include disruption of business or even destruction of a business. An organization must evaluate the potential impact of even a seemingly minor social-engineering attempt.

19.5.1 Consequences. The consequences of a successful social-engineering attack are almost innumerable. Anything one can dream up as an attack vector has probably been attempted by an attacker somewhere. Much like disaster recovery planning, when trying to quantify and understand the impact of social-engineering attacks, all possibilities must be put on the table. Something as seemingly minor as an internal memo that has not been properly destroyed could have the potential to bankrupt an organization. As a result, a simple social-engineering attack can lead to a more complex attack which morphs into a major information security breakdown simply based on the information contained in one misplaced memo.

The danger is especially high for publicly traded companies that can lose value because of a loss of confidence from investors.⁵⁶ Many companies, within the last few years, have come under financial duress because of a security breach or lapse that drew considerable attention from the press. Social engineering was likely part of these security incidents. Many organizations are required by law to have safeguards in place when it comes to data security; more and more of these requirements require security controls that will aid the organization in defending against social-engineering and low-tech attacks.

Another serious consequence of a successful social-engineering attack is the uncertainty that follows and the difficulty of investigating such an attack. Organizations may never fully discover to what extent a social engineer was able to infiltrate the organization. There are so many different vectors and possibilities of intrusion that it may be impossible to fully understand exactly what or who was compromised during the attack. An especially dangerous and frustrating situation is one where an attacker has an insider or accomplice within the organization. Some organizations have never identified these individuals within the organization. This uncertainty is difficult to recover from and defend against in the future. It is also another situation where a company may have substantial credibility problems and a loss of confidence from its shareholders after an attack if such details are disclosed. This exact situation has also led to a tug-of-war between regulators and organizations about disclosure laws. These laws vary widely state to state and between countries. Businesses fight to protect themselves from having to do extensive disclosure for the very reason of protecting the company's image and financial value.

19.5.2 Case Studies—Examples from Business. There are many well-known examples from real-life scenarios from organizations that can demonstrate the effectiveness of social engineering. Here are some well-known examples without any specifics that would embarrass the involved parties. Social-engineering attacks are real—they are not simply computer-security theory.⁵⁷

Case 1: One very well-known social-engineering attack in the business world is piggybacking. In this type of social engineering, an attacker will depend on an individual's sense of courtesy. Most people remember from their early school days that they are taught to hold a door open for someone who is behind him or her. This courtesy is often extended in the workplace, including secure areas such as a datacenter. A potential attacker may attempt to enter a datacenter without proper credentials by following closely behind someone else who is entering a datacenter with proper identification and authorization. The authorized individual will probably exhibit courtesy and hold the door open for the piggybacker, even if that person's identity is unknown. Holding something innocuous often creates confidence.

Result: In this example, the result is that an attacker who is not authorized has gained access to a secure facility by relying on another individual's sense of courtesy. It can be very difficult to demand that employees refrain from allowing piggybacking, but a policy must be in place to demand exactly that. All persons entering a secure facility should be required to fully use identification and authorization mechanisms every time.

Case 2: Another example that has been carried out in different variations involves an attacker using several social-engineering techniques to take advantage of

several coinciding events to exploit data, information, or equipment from an organization. The attacker would often make several telephone calls or send several emails to find a specific date where a company official, perhaps the CFO or director of technology, is out of the office. The attacker would then show up at the organization making claims that the company official authorized the attacker to take a certain computer from the company's premises. Usually the attacker will try to show a sense of urgency and extend a very confident display of authority. Many times the employee will cave into the attacker's demands without checking the story, and now a very important computer has been taken from the company. (A very commonly used twist on this case, and one that is becoming more and more common, is to install malware, remote backdoor software, or a keylogger on the computer instead of physically removing it.)

Result: In this case, the organization has lost control and ownership of a computer and/or its data. If the computer does not have any solid safeguards, such as data encryption mechanisms, the data and the computer could be used for any number of destructive activities. If information about the incident is made public, great damage to the organization's reputation can be done. The data harvested from the computer could also be sold to competitors or used as part of a blackmail scheme.

19.5.3 Success Rate. Although there are few accurate statistics of the success rate of social engineering, as is the case in many areas of information security, most experts believe the rate to be high. If history has anything to teach the security community through example, social engineering will continue to be a powerful and successful tool for criminals. Few organizations are immune to social engineering, no matter their industry or product. If even well-trained military personnel are vulnerable, every organization must take the success rate seriously.

The high success rate must also stress the importance of continued education of employees and reevaluation of the organization's efforts to combat social engineering and protect all data assets. This is an area where many organizations, of all sizes, continue to allocate too few resources. The frequency of social-engineering attempts also dictates the need for proper, efficient, and swift reporting of suspicious activity targeting individuals or the organization. It is very difficult to defend against social-engineering attempts if the organization does not know it is under attack or know where or how to report an incident. The probability of a successful attack can be substantially reduced with properly trained, supported, and motivated employees.

19.5.4 Small Business versus Large Organizations. The impact and dangers of social-engineering and low-tech attacks vary widely between small businesses and large corporations. As discussed above, the consequences can be potentially serious, all the way up to the collapse of the organization. Small businesses are often much less prepared operationally and financially and much less equipped to survive a serious breach of security. Conversely, and perhaps shocking to many, small businesses may have the upper hand over large organizations because of a substantially smaller workforce and collapsed management structure. It is much easier to communicate and engage everyone within a small company when an attack is attempted or carried out. Small businesses also have an advantage of a much smaller workforce to train; this results in much better prepared employees. Small business employees are probably

more likely to identify people who do not belong in the organization or should not be asking for access to sensitive areas or data. They may also be more likely to deny access or question someone whose story does not seem likely or is suspicious.

Large organizations can be mired in bureaucracy, ineffective management, or overly complicated reporting procedures. An attacker could carry out an entire plan before the security team in a large company would be alerted to a social-engineering attempt. Many times an individual is less willing to challenge the credentials of a stranger in a large organization. This is especially true where there are employees that feel they may be punished for questioning someone of a higher rank or preventing someone else from doing his or her job. The employee might be more likely to just let the attacker pass unquestioned rather than risk possible negative ramifications or scrutiny.

Bottom line, all organizations must be on the lookout for this type of attack. Criminals do not always choose easy or obvious targets. Any business, small or large, family-owned or corporate conglomerate, may be a target of an attack that utilizes social engineering.

19.5.5 Trends. While it is important for any information security manager to always keep a skeptical eye toward statistics, it is equally important to keep abreast of security threat trends. Social engineering is no exception. It may be difficult for any survey or poll to gather facts about how many attempts were made in any given year or how many were successful. Many social-engineering attempts are probably never detected, and even less are reported or admitted to on surveys. When it comes to such a powerful and successful attack mechanism, assume the worst: It is increasingly being used by criminals even when organizations know about this type of attack and even train employees to defend against it. Criminals create new forms and tactics every day, and people will probably continue to fall for these tactics.

19.6 DETECTION. Detection of social-engineering and low-tech attacks can be difficult. The nature of most types of social-engineering attacks is to take advantage of people's willingness to trust and help, which allows the perpetrator to circumvent technical controls. In many cases, the detection relies on people's ability to recognize a potential attack, including suspicious activity and respond appropriately. Further complicating detection is the potential that a social-engineering attack may not be a single occurrence, but many smaller events culminating in the attackers accessing restricted resources, hide nefarious activities, or stealing proprietary information. Using slow or multistep social-engineering attacks is even more difficult to detect and potentially more damaging. More recently, successful social-engineering attacks through the targeted email campaigns to senior level personnel have been widely reported. One penetration-testing expert estimates that social-engineering tactics account for less than 20 percent of the time spent in an attack; the rest of the time is spent in technical exploitation of the information originally gathered through deceit.⁵⁸

There are three main avenues of detection for social-engineering attacks: people, audit controls, and technology.

19.6.1 People. Since people are the vector for the attack, they are, in general, the first line of defense. Organizations need to provide employees with the resources and continuous education to help discern a potential attack from a legitimate request. All areas of an organization need the training. Social engineers are using all available resources; there is no department or person that is immune from a potential attack. In addition, organizations need to provide information on what to do during and

19 · 18 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

immediately after an attack. For example, during a phone attack, employees should be trained to remember as many details as possible. Items that the employee should try to remember include:

- Was the attacker male or female?
- Was a caller ID displayed?
- Was there noise in the background?
- Did he or she have an accent?
- What questions were asked?
- What answers were provided?

Employees should also be aware of people asking many questions, some of which may not make sense. In addition, callers or emails requesting names of managers or IT personnel should prompt a phone call to the IT security or investigation department. Organizational culture is also another pivotal piece to help defend against social-engineering attacks. The culture must stress and *reward* proper verification before providing information. Upper management can support a strong culture by praising employees who ask *them* to demonstrate their authenticity, rather than expressing irritation that anyone would have the nerve to do so.

All businesses, including security firms, must adhere to that mantra.⁵⁹ Unfortunately, too often VIPs or senior leaders do not have to follow the same verification process to change passwords or receive information. Finally, employees should be aware of their own policies and business practices. For example, all employees should understand why it is inappropriate that a caller would request a password change via phone or text message.⁶⁰

Organizations also need to provide clear information to their associates as to what to do when confronted with possible social engineering. For example, who should be notified during the actual event, immediately afterward, or both (depending on when the employee recognizes the attack). To help in the notification process, an organization can create an incident-notification information system and disseminate the information across the organization so an employee can immediately and easily determine whom to contact for help.

19.6.2 Audit Controls and Event Logging. Auditing and logging email, Internet content, systems logins, and systems changes of an organization can be used to detect social-engineering attacks. If the review of events does not happen in real time, there will be a delay from the time of the attack and identification of incident. In the instances where notification is not real time, forensic examiners can use the audit information to help piece together the attacks and determine root cause. Awareness teams can also use the log results to help devise additional training for the targeted groups. During real-time auditing, organizations can immediately enact their incident management plans to help limit the potential damage. Modern anti-malware and anti-phishing tools can provide not only defenses against such attacks but can also keep detailed records for analysis.

19.6.3 Technology for Detection. Organizations can implement technology to help limit social-engineering attacks. Content-filtering software can limit email and Website traffic; any identified malware should be blocked or stripped from email.

Email monitoring tools can be used in bidirectional mode to inspect content in both directions. In addition, email-monitoring and content-filtering mechanisms can be used to scan for keywords or phrases that may trigger early warning signals. Any suspicious traffic, attachment, or email should be quarantined and reviewed prior to delivery. By scanning and blocking content, organizations may reduce the number of suspicious emails entering their networks and reduce the number of suspicious Websites that employees visit. Email services and anti-malware products have been improving their spam-blocking capabilities so that even phishing scams are being trapped successfully.

Advances in technology research will provide additional protection from social-engineering attacks, including the development of the Social Engineering Defense Architecture (SEDA). This architecture attempts to detect social-engineering attacks over the phone by identifying a legitimate employee versus a social engineer. The system is referred to as a text-independent voice signature authentication system. The system uses voice recognition technology, which would reduce the risk of a successful helpdesk attack. In addition to detecting an unauthorized caller, it can detect an insider masquerading as an employee with a higher security classification. The logging included in the architecture would aid a forensic examiner during an investigation.⁶¹

Risk-based authentication methods can also help limit potential social-engineering attacks; for example, if a customer or user always calls from a certain area code or phone number and a potential attacker calls from a different area code, systems can identify this and prompt for additional information prior to authenticating the individual.⁶²

Attackers are becoming more sophisticated. Recent phishing attacks are targeting systems, network, and security professionals. In these types of attacks, a phishing email is sent to an organization from a “customer” informing it of a phishing site attempting to steal customer information. Security personnel respond to the email and investigate the site. The site installs malware that allows the attacker to remotely control the machine. This change in attack methodology requires security personnel to be even more suspicious of any seemingly innocuous email telling the organization that there are phishing sites targeting that company.

19.7 RESPONSE. Responding to social-engineering and other low-tech attacks should fit into an organization’s incident-management process and response. As with all incident management plans, the responses should be well-defined, communicated, and tested. It behooves an organization to plan for the inevitable, especially as network and physical attacks are increasingly using multiple vectors in order to be successful.

See Chapter 53 in this *Handbook* for additional information on monitoring and controlling systems and see Chapter 56 for information on computer-security incident-response teams.

19.8 DEFENSE AND MITIGATION. The prevention of social-engineering attacks should be multifaceted, repeatable, and part of an organization’s defense-in-depth strategy. Since the very nature of the attack is to bypass or circumvent technical defenses by using people’s good nature and willingness to trust other human beings, the steps in preventing such attacks should focus on distinct areas, such as policy, training and awareness, technology, and physical defenses.

Focusing on all areas will help mitigate the threat of a successful social-engineering attack. Each area should have a regular process for review and auditing. Well-written policies provide the baseline of behavior that is acceptable and the potential consequences if they are not followed, but they must be accessible to employees. In the case of training, it should be integrated into the organization’s overall security awareness

program, included in all employee's evaluations, and tied to bonus pay and compensation. Organizations must train their employees in acceptable behavior and provide policies and the tools to identify and report potential social-engineering attacks.

Physical defenses can potentially block an intruder from entering a locked building, but people's sense of camaraderie does make the practices such as piggybacking or tailgating relatively easy. A recent study indicated that smokers returning to a building sometimes allow nonemployees into a secure location. Technological advances are also important but cannot be relied on as the only method of defense.

19.8.1 Training and Awareness. Organizations need to provide tools and knowledge to employees to help identify potential attacks and react to suspected attacks. Providing awareness is a continual process and should not be only for new hires. Training and awareness, when possible, should include real-life examples so employees can relate to the issue and understand the level of trust that is implied through their access to the facility and the data used for their positions. Employees should understand the responsibilities the company bestows on them. Essentially, employees need to be retrained that it is acceptable to ask why certain information is being requested or to see the badge of a person behind them.

A basic awareness program could include posters, email communications, and laminated instruction cards (hard cards) containing emergency contact numbers or other information. More mature awareness programs can include videos or brown-bag informational lunches. Whenever possible, teaching employees to defend against social-engineering attacks should be a live presentation with real-world examples. Ideally, the presentation should be tailored specially for each audience. For example, if the audience is helpdesk personnel, examples of potential social-engineering attacks should be described or demonstrated and discussed.

Employee training can also include instruction to keep file cabinets locked when not in use, lock workstations, and use cable locks, and contain instructions on how to create and remember good passwords.

The backbone of awareness training is a well-defined and executed information-security policy program. Please see Chapter 44 in this *Handbook* for additional information regarding information-security policy development, and Chapter 49 for additional information regarding awareness programs.

19.8.2 Technology for Prevention. Technology is emerging as a defense against certain types of social-engineering attacks. The technology enables organizations to identify some social-engineering attacks without relying on employees. This proactive identification enables an organization to mitigate the risk. Technology should comprise only one layer of defense and not be relied on as the sole defense.

Technologies such as content-monitoring systems for both email and Web content can help identify phishing attacks. In addition, organizations can install timely security patches and use up-to-date antivirus and antispyware software to help mitigate the risk of viruses, Trojans, and worms. Most versions of browsers and browser plug-ins are allowing users to evaluate the trustworthiness of Websites.⁶³

Ideally, employees should be prevented from downloading and installing unapproved software. However, organizations can employ inventory systems or other methodologies to detect illegal programs on a network. Certain types of systems can prevent malware-infected machines from entering the network.

Desktop and laptop configuration changes can be made to reduce the risk of a successful attack; changes include disabling pop-up windows in browsers, disallowing

the automatic installation of Active-X controls, multiple versions of Java, limiting the types of cookies that Websites can place on local machines, using automatic password-protected screen savers, and finally, using email certificates for authentication.

In the same regard, organizations should review technology processes and verify that they are not inadvertently supplying information to potential social engineers. For example, metadata in documents should be removed before being accessible to outsiders, and regular Web searches should be conducted to ensure former or current employees are not posting information on the Internet.

19.8.3 Physical Security. Physical security mechanisms can reduce the risk of a successful social-engineering attack. All employees should have identification cards that they are required to display at all times. Secured areas within an organization should be locked, have limited access, and be monitored for noncompliance. Door alarms that can detect tailgating or piggybacking can be installed in areas. Cameras or other closed circuit monitoring technology can thwart potential intruders. Security personnel should watch all facility access points. All office doors, desks, file cabinets, and other storage devices should have keys and remain locked when not being accessed. Dumpsters® or recycling bins should also have locks that would prevent the removal of documents meant for shredding or incineration.

- Desktops, laptops, and other computer hardware should be physically locked in place. Users should be required to have strong passwords, and in the case of laptops or desktops, have automatic screen savers that require a password to unlock. All magnetic media need to have secure storage.
- Most organizations have a certain percentage of mobile workforces. Special training should be provided to them to prevent the loss of equipment or information. Training should include information such as:
 - Laptops should remain with the traveler and not checked in luggage.
 - Laptops should be locked in a safe or to a secure surface at all times.
 - Peripheral devices such as USB drives and handheld devices should have strong passwords.
 - Conversations involving confidential information should be prohibited in public.
 - Travelers should be aware of their surroundings, and special considerations regarding electronic communication and equipment usage should be considered while not in the United States and Europe.

Please see Chapters 22 and 23 of this *Handbook* for more information regarding physical security.

19.9 CONCLUDING REMARKS. Social-engineering attacks are unlike technological computer attacks. The vector of the attack is human, the nature of the attack is to circumvent controls, and the success of the attack depends on people's willingness to trust others. Simply being polite and holding a door open for a stranger can be bad for an organization, if the stranger is a social engineer.

Social-engineering attacks are not new in society; they have been used for millennia. Social engineers use many different methods to execute social-engineering and low-tech attacks. These methods could involve human contact, no human contact, or a combination of technology and social-engineering tactics.

19 · 22 SOCIAL-ENGINEERING AND LOW-TECH ATTACKS

Psychologists and social psychologists have offered a number of reasons for the success of social engineering. They theorize that human nature allows attackers to trick or con reasonable people into divulging information. A social engineer's profile does not fit into a single model, and their attacks are difficult to detect. Social-engineering attacks have grown more prolific, effective, and dangerous to both organizations and individuals.

Even though social-engineering attacks are difficult to defend against, there are technical, process, and personal defenses that an organization can adopt to prevent them and minimize their effects. As with all information security issues, a defense-in-depth strategy can help mitigate the risks associated with social engineering.

Between July and August 2011, Dimensional Research surveyed 835 IT professionals in the Western economies. Some of their findings reinforce the details in this chapter⁶⁴:

- The threat of social engineering is real.
- Financial gains are the primary motivation of social engineering.
- Social-engineering attacks are costly, especially in large organizations.
- [There is a] Lack of proactive training to prevent social-engineering attacks.

Although the focus of information assurance practice seems to be on technical attacks, social-engineering and low-tech attacks will continue to remain relevant and dangerous threats, worthy of attention and mitigation.

20.1 UNWANTED EMAIL AND OTHER PESTS: A SECURITY ISSUE. Three oddly named threats to computer security are addressed in this chapter: *spam*, *phishing*, and *Trojan code*. Spam is unsolicited commercial email. Phishing is the use of deceptive unsolicited email to obtain—to fish electronically for—confidential information. Trojan code, a term derived from the Trojan horse, is software designed to achieve unauthorized access to systems by posing as legitimate applications. In this chapter, we

20 · 2 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

outline the threats posed by spam, phishing, and Trojans, as well as the mitigation of those threats.

These threats might have strange names, but they are no strangers to those whose actions undermine the benefits of information technology. Every year, for at least the last three years, the U.S. Internal Revenue Service (IRS) has had to warn the public about email scams that take the name of the IRS in vain, attempting to defraud taxpayers of their hard-earned money by aping the agency's look and feel in email messages. The fact that the IRS states that the agency never ever uses email, text messaging, or social-media channels to communicate with taxpayers¹ is a sad comment on our society, for there is no good reason why this should be the case. After all, the agency allows electronic filing of annual tax returns, and every day hundreds of millions of people around the world do their banking and bill paying online, in relative safety. The technology exists to make email safe and secure. In many ways, this chapter is a catalog of what has happened because we have not deployed the technology effectively.

20.1.1 Common Elements. Each of these threats is quite different from the other in some respects, but all three have some important elements in common; first, and most notably, they use deception. These threats prey on the gullibility of computer users and achieve their ends more readily when users are ill-trained and ill-informed (albeit aided and abetted, in some cases, by poor system design and poor management of services, such as broadband connectivity).

Second, all three attacks are enabled by system services that are widely used for legitimate purposes. Although the same might be said of computer viruses—they are code and computers are built to run code—the three threats that are the focus of this chapter typically operate at a higher level, the application layer of the Open Systems Interconnection (OSI) model (discussed in Section 6.5.1 in this *Handbook*). Indeed, this fact may contribute to the extent of their deployment—these threats can be carried out with relatively little technical ability, relying more on the skills associated with social engineering than with coding. For example, anyone with an Internet connection and an email program can send spam. That spam can spread a ready-made Trojan. Using a toolkit full of scripts, you can add a Website with an input form to your portfolio and go phishing for personal data to collect and abuse.

Another reason for considering these three phenomena together is the fact that they often are combined in real-world exploits. The same mass emailing techniques used to send spam may be employed to send out messages that spread Trojan code. As described in Chapter 15 in this *Handbook*, Trojan code may be used to aid phishing operations. Systems compromised by Trojan code may be used for spamming, and so on. What we see in these attacks today are the very harmful and costly result of combining relatively simple strategies and techniques with standards of behavior that range from the foolish and irresponsible to the unabashedly criminal.

These three threats also share the distinction of having been underestimated when they first emerged. All three have evolved and expanded in the 21st century. For example, for 2012, Symantec reported that Android-operating-system threats (virtually unknown a decade earlier) against mobile devices increased drastically between January 2010 and the end of 2012, from fewer than 100 unique variants in about 10 families to around 4,500 variants in about 170 families.² In addition, an increasing number of phishing scams in 2012 were being carried out through social media—a term not even mentioned in the corresponding report for the first half of 2006.³ (For more information about viruses and worms, spyware, rootkits, and other malware, see Chapter 16 in this *Handbook*.)

One other factor unites these three threats: their association with the emergence of financial gain as a primary motivator for writing malicious code and abusing Internet connectivity (as discussed in Chapter 2 in this *Handbook*). The hope of making money is the primary driver of spam. Phishing is done to facilitate fraud for gain through theft of personal data and credentials, either for use by the thief or through resale in the underground economy. Trojan code is used to advance the goals of both spammers and perpetrators of phishing scams. In short, all three constitute a very real threat to computer security, the well-being of any computer-using organization, and the online economy.

20.1.2 Chapter Organization. After a brief email anatomy lesson, each of the three threats addressed by this chapter is examined in turn. The email anatomy lesson is provided because email plays such a central role in these threats, enabling spam and phishing and the spread of Trojan code. Responses to the three threats are discussed with respect to each other, along with consideration of broader responses that may be used to mitigate all three.

For an introduction to the general principles of social engineering, see Chapter 19 in this *Handbook*.

20.2 EMAIL: AN ANATOMY LESSON. Email plays a role in numerous threats to information and information systems. Not only does it enable spam and phishing, it is used to spread Trojan code, viruses, and worms. A basic understanding of how email works will help to understand these threats and the various countermeasures that have been developed.

20.2.1 Simple Mail Transport Protocol. All email transmitted across the Internet is sent using an agreed-on industry standard: the Simple Mail Transport Protocol (SMTP). Any server that speaks SMTP is able to act as a Mail Transfer Agent (MTA) and send mail to, and receive mail from, any other server that speaks SMTP. To understand how simple SMTP really is, Exhibit 20.1 presents an example of an SMTP transaction.⁴ The text that follows represents the *actual* data being sent and received by email servers (as viewed in a telnet session, with the words in CAPS, such as HELO and DATA, being the SMTP commands defined in the relevant standards, and the numbers being the standard telnet responses).

Developed at a time when computing resources were relatively expensive, and designed to operate even when a server was processing a dozen or more message connections per second, the SMTP conversation was kept very simple in order to be very brief. However, that simplicity is both a blessing and a curse. As you can see from the example, only two pieces of identity information are received before the mail is delivered: the identity of the sending server, in this case example.com, and the From address, in this case foo@example.com. SMTP has no process for verifying the validity of those identity assertions, so both of those identifiers can be trivially falsified. The remaining contents of the email, including the subject and other header information, are transmitted in the data block and are not considered a meaningful part of the SMTP conversation. In other words, no SMTP mechanism exists to verify assertions such as “this message is from your bank and concerns your account” or “this message contains the tracking number for your online order” or “here is the investment newsletter that you requested.”

As described in more detail later, some email services do perform whitelist or blacklist look-ups on the Internet Protocol (IP) address of the sending server during

20 · 4 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

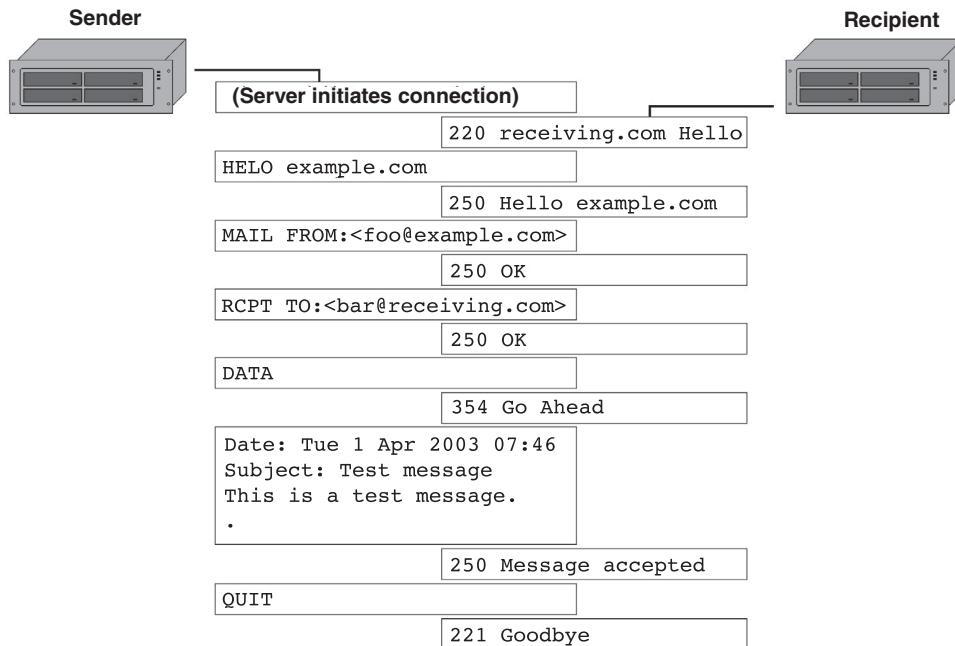

EXHIBIT 20.1 Basic Email Protocol

the SMTP conversation, but those inquiries can dramatically slow mail processing, requiring extra capacity to offset the loss of efficiency. A whitelist identifies email senders that are trusted; a blacklist identifies those that are not trusted. Maintenance of whitelists can be time consuming, and blacklists have a long history of inaccuracies and legal disputes. In short, the need for speed creates a system in which there are virtually no technical consequences for misrepresentations in mail delivery. And this is precisely why spammers have been, and continue to be, incredibly effective at getting unwanted email delivered.

SMTP is, as Winston Churchill might have put it, the worst way of doing email, except for all the others that have been tried. The reality is that SMTP works reliably and has been widely implemented. To supplant SMTP with anything better would mean a wholesale redesign of the entire global email infrastructure, a task that few in the industry have been willing to undertake. Some people have endeavored to develop solutions that can ride atop the existing SMTP infrastructure, allowing SMTP to continue functioning efficiently while giving those who use it the option of engaging more robust features that help differentiate legitimate mail from spam. There is more on these solutions later in the chapter.

20.2.2 Heads-Up. Email cannot be delivered without something called a header, and every email message has one, a section of the message that is not always displayed in the recipient's email program but is there nonetheless, describing where the message came from, how it was addressed, and how it was delivered. Examining the header can tell you a lot about a message. Consider how a message appears in Microsoft Outlook Express, as illustrated in Exhibit 20.2.

At the top you can see the From, the To, and the Subject. For example, you can see part of a message that appears to be from zjjimwalker8467r21@lycos.com

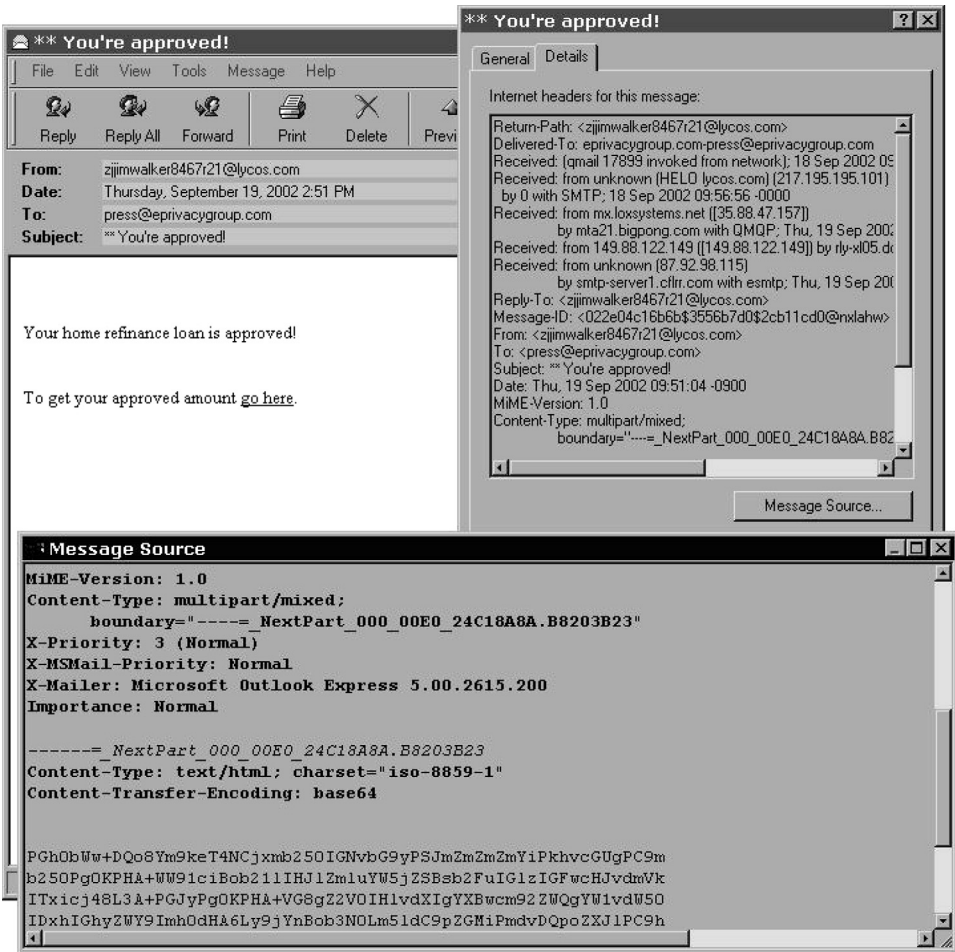

EXHIBIT 20.2 Viewing Message Header Details in Outlook Express

to press@eprivacygroup.com with the subject: *You're approved! As you may have guessed, press@eprivacygroup.com is not a real person. This is just an address that appears on a company Website as a contact for the press, and of course, nobody actually used this address on a mortgage application. The address was harvested by a program that automatically scours the Web for email addresses.

When you open this message in email clients (e.g., Outlook or Outlook Express) and use the File/Properties command or equivalent, you can click on the Details tab to see how the message made its way through the Internet. The first thing you see is a box labeled “headers,” as shown in Exhibit 20.2. Reading this will tell you that the message was routed through several different email servers. Qmail is the company's mail program, which is the first instance of Received. The next three below that are intermediaries, until you get to the last one, smtp-server1.cflrr.com. That is an email server in Central Florida (cfl) on the Road Runner (rr) cable modem network, which supplies high-speed Internet access to tens of thousands of households.

So who sent this message? That is very hard to say. As you might expect, there is no such address as zjjimwalker8467r21@lycos.com. The best way to determine who sent a spam message like this is to examine the content. Spam cannot reel in suckers

20 · 6 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

unless there is some way for the suckers to contact the spammer. Sometimes this is a phone number, but in this message it is a hyperlink to a Web page. However, clicking links in spam messages is a dangerous way to surf—a much safer technique to learn more about links in spam is message source inspection. Outlook Express provides a Message Source view, but this may only show the encoded content and not be readable ASCII. Some email clients (e.g., Outlook) allow one to set a default of conversion of all messages into plain text; if one wishes to see images, one can have them downloaded on a per-message basis. In addition, many email clients can display the underlying details of any hyperlink when one hovers the cursor over the label for the link.

One way to get at the content of such messages is to forward them to a different email client, for example, Qualcomm's Eudora, then open the mailbox file with a text editor such as TextPad. This reveals the http reference for the link that this spammer wants the recipient to click. In this case, the sucker who clicks on the link that says "To get your approved amount go here" is presented with a form that is not about mortgages, but about data gathering. To what use the data thus gathered will be put is impossible to say, but a little additional checking using the *ping* and *whois* commands reveals that the Web server collecting the data is in Beijing. The chances of finding out who set it up are slim. The standard operating procedure is to set up and take down a Website like this very quickly, gathering as much data as you can before someone starts to investigate. However, over the last 10 years, the resources devoted to investigating spammers have been minimal compared to the resources that have gone into sending spam. Even when lawmakers can agree on what spam is and how to declare it illegal, government funds are rarely allocated for spam fighting. There have been a few high-profile arrests and prosecutions, often driven by large companies, such as Microsoft and AOL, but spamming remains a relatively low risk form of computer abuse.

If one can identify a link in spam, the Better-Whois service (<http://betterwhois.com/>) may be able to provide details of who is officially registered as owners and administrators of the site—assuming they have not hidden themselves behind anonymizing companies such as GoDaddy.com, which can conceal the true owners while providing an anonymized email address through which to attempt to communicate with the owners.

20.3 3 SPAM DEFINED. The story of spam is a rags-to-riches saga of a mere nuisance that became a multibillion-dollar burden on the world's computing resources. For all the puns and jokes one can make about spam, it may be the largest single thief of computer and telecommunication resources since computers and telecommunications were invented.

Perhaps it is no surprise that spam has become a costly problem, because spam was the first large-scale computer threat to be purely profit-driven. The goal of most spam is to make money, and it cannot make money if people do not receive it. In fact, spam software will not send spam to a mail server that has a slow response time; it simply moves on to other targets that can receive email at the high message-per-minute rate needed for spam to generate income (based on 1 person in perhaps 100,000 actually responding to the spam message). If spam does not generate income, it becomes pointless because it takes money to send spam. You need access to servers and bandwidth (which you either have to pay for or steal). Ironically, a few simple changes to current email standards could put an end to most spam by more reliably identifying and authenticating email senders, a subject addressed later in this chapter.

20.3.1 Origins and Meaning of Spam (not SPAM®). SPAM® has been a trademark of Hormel Foods for over 70 years.⁵ For reasons that will be discussed in a moment, the world has settled on *spam* as a term to describe unwanted commercial email. However, uppercase SPAM® is still a trademark, and associating SPAM®, or pictures of SPAM®, with something other than the Hormel product could be a serious violation of trademark law. Security professionals should take note of this. The word *Spam* is acceptable at the start of a sentence about unsolicited commercial email, but SPAM can be used for spam only if the rest of the text around it is uppercase, as in “TIRED OF SPAM CLUTTERING YOUR INBOX?”

The use of the word “spam” in the context of electronic messages is widely thought to stem from a comedy sketch in the twenty-fifth episode of the BBC television series *Monty Python’s Flying Circus*.⁶ First aired in 1968, before email was invented, the sketch featured a restaurant in which SPAM® dominated the menu. When a character called Mr. Bun asks the waitress, “Have you got anything without SPAM® in it?” she replies: “Well, there’s SPAM®, egg, sausage and SPAM®, that’s not got much SPAM® in it.” The banter continues in this vein until Mr. Bun’s exasperated wife screams, “I don’t like SPAM®!” She is further exasperated by an incongruous group of Viking diners singing a song, the lyrics of which consist almost entirely of the word “SPAM®.” A similar feeling of exasperation at having someone foist on you something that you do not want and did not ask for clearly helped to make “spam” a fitting term for the sort of unsolicited commercial email that can clutter inboxes and clog email servers.

In fact, the first use of spam as a term for abuse of networks did not involve email. The gory details of spam were carefully researched in 2003 by Brad Templeton, former chairman of the board of the Electronic Frontier Foundation.⁷ According to Templeton, the origins lie in annoying and repetitive behavior observed in multiuser dungeons (also known by the acronym MUDs, an early term for a real-time, multiperson, shared environment). From there the term *spam* migrated to bulletin boards—where it was used to describe automated, repetitive message content—thence to USENET, where it was applied to messages that were posted to multiple newsgroups.

A history of USENET and its relationship to the history of spam is salutary for several reasons. First of all, spam pretty much killed USENET, which was once a great way to meet and communicate with other Internet users who shared common interests, whether those happened to be political humor or HTML coding. Newsgroups got clogged with spam to the point where users sought alternative channels of communication. In other words, a valuable and useful means of communication and an early form of social networking was forever tainted by the bad behavior of a few individuals who were prepared to flaunt the prevailing standards of conduct.

The second spam–USENET connection is that spam migrated from USENET to email through the *harvesting* of email addresses, a technique that spammers—the people who distribute spam—then applied to Web pages and other potential sources of target addresses. Spammers found that software could easily automate the process of reading thousands of newsgroup postings and extracting, or harvesting, any email addresses that appeared in them. It is important to remember that, although it might seem naive today, the practice of including one’s email address in a message posted to a newsgroup was common until the mid-1990s. After all, if you posted a message looking for an answer, then including your email address made it easy for people to reply. It may be hard for some computer users to imagine a time when email addresses were so freely shared, but that time is worth remembering because it shows how easily the abuse of a system by a few can erode its value to the many. Harvesting, which resulted in receiving spam at an email address provided in a newsgroup posting for

20 · 8 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

the purposes of legitimate communication, was an enormous advance in abuse of the Internet and a notable harbinger of things to come. Elaborate countermeasures had to be developed, all of which impeded the free flow of communication. Much of the role fulfilled by newsgroups migrated to closed forums, where increasingly elaborate measures are used to prevent abuse.

20.3.2 Digging into Spam. Around 1996, as early adopters of email began experiencing increasing amounts of unsolicited email, efforts were made to define exactly what kind of message constituted spam. This was no academic exercise, and the stakes were surprisingly high. We have already employed one definition: unsolicited commercial email (sometimes referred to as UCE). This definition seems simple enough, capturing as it does two essential points: Spam is email that people did not ask to receive, and spam is somehow commercial in nature.

However, while UCE eventually became the most widely used definition of spam, it did not satisfy everyone. Critics point out that it does not address unsolicited messages of a political or noncommercial nature (such as a politician seeking your vote or a charity seeking donations). Furthermore, the term “unsolicited” is open to a lot of interpretation, a fact exploited by early mass emailings by mainstream companies whose marketing departments used the slimmest of pretexts to justify sending people email. As the universe of Internet users expanded in the late 1990s, encompassing more and more office workers and consumers, three things about spam became increasingly obvious:

1. People did not like spam.
2. Spammers could make money.
3. Legitimate companies were tempted to send unsolicited email.

20.3.2.1 Get-Rich-Quick Factor. How much money could a spammer make? Consider the business plan of one Arizona company, C.P. Direct, that proved very profitable until it was shut down in 2002 by the U.S. Customs Service and the Arizona Department of Public Safety. Here are some of the assets that authorities seized:

- Nearly \$3 million in cash plus a large amount of expensive jewelry
- More than \$20 million in bank accounts
- Twelve luxury imported automobiles (including eight Mercedes, plus assorted models from Lamborghini, Rolls-Royce, Ferrari, and Bentley)
- One office building and assorted luxury real estate in Paradise Valley and Scottsdale

These profits were derived from the sale of \$74 million worth of pills that promised to increase the dimensions of various parts of the male and female anatomy. The company had used spam to sell these products, but in fact it was not shuttered for sending spam, the legal status of which remains ambiguous to this day, having been defined differently by different jurisdictions (not least of which was the U.S. Congress, which arguably made a hash of it in 2004).

C.P. Direct crossed several lines, not least of which was the making of false promises about its products (none of which it ever tested and all of which turned out to contain the same ingredients, regardless of which part of the human anatomy they were promised

to enhance). The company compounded its problems by refusing to issue refunds when the products did not work as claimed. However, rather than discourage spammers, this case proved that spam can make you rich, quick. Indeed, the hope of getting rich quick remains the main driver of spam. The fact that a handful of people were prosecuted for conducting a dubious enterprise by means of spam was not perceived as a serious deterrent.

20.3.2.2 Crime and Punishment. Spammers keep on spamming because risks are perceived to be small relative to both the potential gains and the other options for getting rich quick. The two people at the center of the C.P. Direct case, Michael Consoli and his nephew and partner, Vincent Passafiume, admitted their guilt in plea agreements signed in August 2003; but they were out of jail before May 2004, and they seemed to have suffered very little in the shame department. Two years after their release, the pair asked the state Court of Appeals to overturn the convictions and give back whatever was left of the seized assets.

Consider what has happened with Jeremy Jaynes, named as one of the world's top 10 spammers in 2003 by Spamhaus, a spam-fighting organization discussed later in Section 20.4.1 of this chapter. When he was prosecuted for spamming, Jaynes was thought to be sending out 10 million emails a day. How much did he earn from this? Prosecutors claimed it was about \$750,000 a month. In 2004, Jaynes was convicted of sending unsolicited emails with forged headers, in violation of Virginia law. He was sentenced to nine years in prison. However, in September 2008, Jaynes, who had not served any time and remained free on bail (set at less than two months' worth of his spam earnings) had his conviction overturned by the Virginia Supreme Court, which ruled that the state antispam law was unconstitutional⁸—a ruling attacked as ill-founded by some critics specializing in antispam legislation.⁹

Another notorious spammer was Sanford "Spamford" Wallace, founder of Cyber Promotions in the 1990s, which actively used spam as a commercial service. In October 2009, Facebook won a civil suit against him for sending fraudulent messages to its users.¹⁰ Wallace was ordered to pay a \$711 million fine—which he was unlikely to pay because he filed for bankruptcy in June 2009.

In August 2011, he was indicted in the federal court in San Jose on

... multiple counts of fraud and related activity in connection with electronic mail. Wallace was also charged with three counts of intentional damage to a protected computer and two counts of criminal contempt. According to the indictment, from approximately November 2008 through March 2009, Wallace executed a scheme to send spam messages to Facebook users. Those messages compromised approximately 500,000 legitimate Facebook accounts, and resulted in more than 27 million spam messages being sent through Facebook's servers. The indictment alleges that Wallace sent spam messages to Facebook users during three time periods: First, on or about Nov. 5, 2008, and continuing until approximately Nov. 6, 2008, Wallace accessed Facebook's computer network to initiate the transmission of a program that resulted in more than 125,000 spam messages being sent to Facebook users; Second, on Dec. 28, 2008, Wallace accessed Facebook's computer network to initiate the transmission of a program that resulted in nearly 300,000 spam messages being sent to Facebook users; Third, on Feb. 17, 2009, Wallace accessed Facebook's computer network to initiate the transmission of a program that resulted in more than 125,000 spam messages being sent to Facebook users.¹¹

At the time of writing (May 2013), *USA v. Sanford Wallace* was scheduled to open on Monday June 3, 2013, in the court of Judge Edward J. Davila in the San Jose Courthouse.¹²

20 · 10 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

20.3.2.3 A Wasteful Game. In many ways, spam is the heir to the classic sucker's game played out in classified advertisements that promise to teach you how to "get cash in your mailbox." The trick is to get people to send you money to learn how to get cash in their mailbox. If a spammer sends out 25 million email messages touting a product, she *may* sell enough products to make a profit, but there are real production costs associated with a real product. In contrast, if she sends out enough messages touting a list of 25 million proven email addresses for \$79.95, she may reel in enough suckers willing to buy that list and make a significant profit, because the list costs essentially nothing to generate. The fact that most addresses on such lists turn out to be useless does not seem to stop people from buying or selling them.

One form of spam that does not rely on selling a product is the *pump-and-dump* stock scam. Sending out millions of messages telling people how hot an obscure stock is about to become can create a self-fulfilling prophecy. Here is how it works:

- Buy a lot of shares on margin or a lot of shares in a company that is trading at a few pennies a share.
- Spam millions of people with a message talking up the stock you just bought.
- Wait for the price of the shares to go up, and then sell your shares for a lot more than you paid for them.

Such a scheme breaks a variety of laws but can prove profitable if you are not caught (you can hide your identity as a sender of spam); nevertheless, regulators still can review large buy and sell orders for shares referred to in stock spams.

The underlying reasons for the continuing rise in spam volume can be found in the economics of the medium. Sending out millions of email messages costs the sender very little. An ordinary personal computer (PC) connected to the Internet via a \$10-per-month dial-up modem connection can pump out hundreds of thousands of messages a day; a small network of PCs connected via a \$50-per-month cable modem or digital subscriber line (DSL) can churn out millions. Obviously, the economic barrier to entry into get-rich-quick spam schemes is very low. The risk of running into trouble with the authorities is also very low. The costs of spam are borne downstream, in a number of ways, by several unwilling accomplices:

Email Recipient

- Spends time separating junk email from legitimate email. Unlike snail mail, which typically is delivered and sorted once per day, email arrives throughout the day and night. Every time you check it, you face the time-wasting distraction of having to sort out spam.
- Pays to receive email. There are no free Internet connections. When you connect to the Internet, somebody pays. The typical consumer at home pays a flat rate every month, but the level of that rate is determined, in part, by the volume of data that the Internet service provider (ISP) handles, and spam inflates that volume, thus inflating cost.

Enterprise

- Loses productivity because employees, many of whom must check email for business purposes, are spending time weeding spam out of their company email

inbox. Companies that allow employees to access personal email at work also pay for time lost to personal spam weeding.

- Wastes resources because spam inflates bandwidth consumption, processing cycles, and storage space.

Internet Service Providers (ISPs) and Email Service Providers (ESPs)¹³

- Wastes resources on handling spam that inflates bandwidth consumption, processing cycles, and storage space.
- Have to spend money on spam filtering, block list administration, spam-related customer complaints, and filter/block-related complaints.
- Have to devote resources to policing their users to avoid getting block-listed. (There is more about filters and block lists in the next section.)

Two other economic factors are at work in the rise of spam: hard times and delivery rates. When times are tough, more people are willing to believe that get-rich-schemes like spamming are worth trying, so there are more spammers (tough times affect the receiving end as well, with recipients more willing to believe fraudulent promises of lotteries won and easy money to be made). When delivery rates for spam go down—due to the use of spam filters and other techniques that are discussed in Section 20.4.5—spammers compensate by sending even more spam.

20.3.2.4 How Big Is the Spam Problem? There is some controversy about the proportion of email classified as spam. By 2006, spam was said to be consuming over 90 percent of email resources worldwide.¹⁴ This was a staggering level of system abuse by any standard. However, when a handful of security professionals had claimed, a decade earlier, that spam was a computer-security threat, they were met with considerable skepticism and some suspicion, perhaps in part because of the anticlimax of Y2K; also, there was doubtless an element of the recurrent suspicion that security professionals trumpet new threats to drum up business—a strange notion, given the perennial abundance of opportunities for experts in a field that persistently reports near-zero levels of unemployment.

A useful historical perspective on spam's depressing impact on email is provided by the reports freely available at the MessageLabs Website. Its annual reports provide conservative estimates of the growth in spam; for example, the 2007 annual report¹⁵ showed total spam hovering around 85 percent of all emails from 2005 through 2007, with new varieties (those previously unidentified by type or source) keeping fairly steady at around 75 percent of all email.

Symantec reported about spam as over 90 percent of total email traffic in 2009¹⁶ and 2010,¹⁷ but the proportion began dropping over the next few years. In June 2011, Symantec reported a spam rate of about 73 percent of total email¹⁸; by December 2011, they reported a further drop to about 70 percent.¹⁹ According to Kaspersky Lab in early 2013, "... the share of spam in email traffic decreased steadily throughout 2012 to hit a five-year low. The average for the year stood at 72.1%—8.2 percentage points less than in 2011. Such a prolonged and substantial decrease in spam levels is unprecedented."²⁰ A different study in January 2013 suggested that only about 60 percent of all email was spam in 2012.²¹ Estimates by other experts suggested that only about 15 percent of the total spam was getting through all the spam filters at ISP and application levels.²²

20 · 12 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

Although most companies and consumers probably will concur that spam has grown from a mere annoyance to a huge burden, some people will say spam is not a big problem. These include:

- Consumers who have not been using email for very long
- Office users who do not see the spam addressed to them due to some form of antispam device or service deployed by their company

These perceptions obscure the fact, noted earlier, that spam consumes vast amounts of resources that could be put to better use. The consumer might get cheaper, better Internet service if spam was not consuming so much bandwidth, server capacity, storage, and manpower. In the author's experience working with a regional ISP, growth in spam volume is directly reflected in server costs. The ISP had to keep adding servers to handle email. By the time it got to four servers, 75 percent of all the email was determined to be spam. The ISP had incurred server costs four times greater than needed to handle legitimate email. Furthermore, even with four servers, spikes in spam volumes were causing servers to crash, incurring the added cost of service calls in the middle of the night, not to mention the loss of subscribers annoyed by outages.

Spam has a direct effect on infrastructure spending. Storage is one of the biggest hardware and maintenance costs incurred by email. If even 70 percent of all email is unsolicited junk, then companies that process email are spending much more on storage than they would if all email was legitimate. The productivity hit for companies whose employees waste time weeding spam out of their inboxes is also enormous. Beyond these costs, consider the possibility that spam actually acts as a brake on Internet growth rates, having a negative effective on economies, such as America's, that derive considerable strength from Internet-related goods and services.

Although the Internet appears to grow at a healthy clip, it may be a case of doing so well that it is hard to know how badly we are doing. Perhaps the only reason such an effect has not yet been felt is that spam's impact on new users is limited. As noted earlier, when new users first get email addresses, they typically do not get a lot of spam. According to some studies, it can take six to twelve months for spammers to find an email address, but when they do, the volume of spam to that address can increase very quickly. This leads some people to cut back on their use of email and the Internet.

In "The Economics of Spam," published in the Summer 2012 issue of the *Journal of Economic Perspectives*, Justin M. Rao (Microsoft) and David H. Reiley (Google), both formerly employees of Yahoo! Research, discuss the *externality* of spam—the use of victims' resources to support profit for the criminals. They write,

We estimate that American firms and consumers experience costs of almost \$20 billion annually due to spam. Our figure is more conservative than the \$50 billion figure often cited by other authors, and we also note that the figure would be much higher if it were not for private investment in anti-spam technology by firms... On the private-benefit side, based on the work of crafty computer scientists who have infiltrated and monitored spammers' activity... we estimate that spammers and spam-advertised merchants collect gross worldwide revenues on the order of \$200 million per year. Thus, the "externality ratio" of external costs to internal benefits for spam is around 100:1.²³

20.3.3 Spam's Two-Sided Threat. When mail servers slow down, falter, and finally crash under an onslaught of spam, the results include lost messages, service interruptions, and unanticipated helpdesk and tech support costs. Sales are missed.

Customers do not get the service they expect. The cost of keeping spam out of your inbox and your enterprise is one thing, the cost of preventing spam from impacting system availability and business operations is another; but there is another side of the spam threat, the temptation to become an abusive mass mailer, otherwise known as a spammer. This is something that spam has in common with competitive intelligence, otherwise known as industrial espionage. When done badly, mass mailings, like competitive intelligence, can tarnish a company's reputation.

Leaving aside the matter of the increasingly nasty payloads delivered with spam, things like Trojans and phishing attacks, even plain old male enhancement spam constitutes a threat to both network infrastructure and productivity. For a start, spam constitutes a theft of network resources. The inflationary effect on server budgets has already been mentioned. The negative impact on bandwidth may be less obvious but is definitely real. In 2002 and 2003, the author was involved in the beta testing of a prototype network-level antispam router. It was not unusual for a company installing this device to discover that spam had been consuming from two-thirds to three-quarters of its network bandwidth. Whether this impact was seen as performance degradation or cost inflation, very few companies were willing to remove this device once it had been installed. In other words, when companies see what their network performance and bandwidth cost is like when spam is taken out of the equation, they realize just what a negative impact spam has. This is something that might otherwise be hard to detect given that spam has risen in volume over time.

An even more dramatic illustration of the damage that spam can cause comes when a network is targeted by a really big spam cannon (a purpose-built configuration of MTA devices connected to a really big broadband connection; for example, a six-pack of optimized MTAs can fire off 3.6 million messages an hour). The effect can be to crash the receiving mail servers, with all of the attendant cost and risk that involves. One way to prevent this happening, besides deployment of something like an antispammer router, is to sign up for an antispam service, which intercepts all of your incoming email and screens out the spam. Such a solution addresses a number of email-related problems, but at considerable ongoing cost, which still constitutes a theft of resources by spammers.

The company Commtouch.com provides a spam cost calculator that produces some interesting numbers.²⁴ Consider these input values for a medium-size business:

Employees: 800

- Average annual salary: \$45,000
- Average number of daily emails per recipient: 75
- Average percentage of email that is spam: 80 percent

According to the calculator, total annual cost of spam to this organization, which is assumed to be deploying no antispam measures, is just over \$1 million. This is based on certain assumptions, such as the time taken to delete spam messages, but in general, it seems fairly realistic. Of course, the size of the productivity hit caused by the spam that makes it to an employee inbox has been hotly debated over the years, but it is clearly more than negligible and not the only hit. Even if antispam filtering is introduced, there will still be a need to review or adjust the decisions made by the filter to ensure that no important legitimate messages are erroneously quarantined or deleted. In other words, even if the company spends \$50,000 per year on antispam filtering, it will not reclaim all of the \$1 million wasted by spam.

20.3.3.1 Threat of Outbound Spam. Even as organizations like the Coalition Against Unsolicited Commercial Email (CAUCE) were trying to persuade companies that spamming was an ill-advised marketing technique that could backfire in the form of very annoyed recipients, and just as various government entities were trying to create rules outlawing spam, some companies were happy to stretch the rules and deluge consumers with email offers, whether those consumers had asked for them or not. This led some antispammers to condemn all companies in the same breath. The author's own experience, working with large companies that have respected brand names, was that none of them actually wanted to offend consumers. Big companies always struggle to rein in maverick marketing activities, and mass emailing is very tempting when a rogue employee or simply an uninformed one are under pressure to produce sales; but upper management is unlikely to condone anything that could be mistaken for spamming.

The motives for corporate responsibility in email are not purely altruistic. Smart companies can see that the perpetuation of disreputable email tactics only dilutes the tremendous potential of email as a business tool. Whatever one thinks of spam, there is no denying that, as a business tool, bulk email is powerful. It is also seductive. When one has a story to tell or a product to sell, and a big list of email addresses is just sitting there, bulk email can be very tempting. Naïve users can find themselves thinking “Where’s the harm?” and “Who’s going to object?” But unless they have documented permission to send their message to the people on that list, the smart business decision is to resist the temptation. Remember, it only takes one really ticked-off recipient of your unsolicited message to ruin your day.

20.3.3.2 Mass Email Precautions. One of the most basic business email precautions is this: Never send a message unless you are sure you know what it will look like to the person who receives it. This covers the formatting, the language you use, and, above all, the addressing. If you want to address the same message to more than one person at a time, you have three main options, each of which should be handled carefully:

1. Place the email addresses of all recipients in the To field or the Copy (Cc) field so all the recipients will be able to see the addresses of the other people to whom you sent the message. This is sometimes appropriate for communications within a small group of people.
2. If the number of people in the group exceeds about 20, or if you do not want everyone to know who is getting the message, move all but one of them to the Blind Copies (Bcc) field. The one address in the To field may be your own. If the disclosure of recipients is likely to cause any embarrassment whatsoever, do a test mailing first. Send a copy of the message to yourself and to at least one colleague outside the company, and then have the message looked at to make sure the Bcc entries were made correctly.
3. To handle large groups of recipients, or to personalize one message to many recipients, use a specialized application like Group Mail that can reliably build individual, customized messages to each person on a list. This neatly sidesteps errors related to the To and Cc fields. Group Mail stores email addresses in a database and builds messages on the fly using a merge feature like a word processor. You can insert database fields in the message. For example, a message can refer to the recipient by name. The program also offers extensive testing

of messages, so that you can see what recipients will see before you send any messages. And the program has the ability to send messages in small groups, spread over time, according to the capabilities of your Internet connection.

Whether you use a program like Group Mail for your legitimate bulk email, or something even more powerful, depends on several factors, such as the size of your organization, the number of messages you need to send, and your privacy policy. Privacy comes into play because some software used to send email, such as Group Mail, allows the user of the program access to the database containing the addresses to which the mail is being sent. This is generally not a problem in smaller companies, or when the database consists solely of names and addresses without any special context; but it can be an issue when the database contains sensitive information or the context is sensitive. For example, a list of names and addresses can be sensitive if the person handling the list knows, or can infer, that they belong to patients undergoing a certain kind of medical treatment.

You may not want to allow system operators or even programmers to have access to sensitive data simply because they are charged with sending or programming messages. Fortunately, mailing programs can be written that allow an operator to compose mail and send it without seeing the names and addresses of the people to whom it is being sent. Test data can, and should, be used to proof the mailing before it is executed.

Another basic email precaution is never to send any message that might offend any of the recipients. In choosing your wording, your design, your message, know your audience. Use particular caution when it comes to humor, politics, religion, sex, or any other sensitive subject. When using email for business email, it is better to stand accused of a lack of humor rather than a lack of judgment.

Respect people's preferences, if you know them, for content. If people have expressed a preference for text-only messages, do not send them HTML and hope they decide to change their minds. Ask first because the forgiveness-later path is not cost effective when you have to deal with thousands of unhappy recipients calling your switchboard. When you do use HTML content, still try to keep size to a minimum, unless you have recipients who specifically requested large, media-rich messages.

Antispam measures deployed by many ISPs, companies, and consumers sometimes produce false positives, flagging legitimate email as spam, potentially preventing your email from reaching the intended recipients, even when they have asked to receive your email. If your company's email is deemed to be particularly egregious spam, the server through which it is sent is likely to be blocked. If this is your company's general email server, blocking could affect delivery of a lot more than just the spam. If the servers through which your large mailing is sent belong to a service provider, and its servers get blocked, that could be a problem for you too. And if you use a service provider to execute the mailing for you but fail to choose wisely, your mail may be branded as spam just because of the bad reputation of the servers through which it passes. Be aware that using spam to advertise your products could place you in a violation of the CAN-SPAM Act of 2003, even if you do not send the spam yourself. (See Section 20.4.9 for more on CAN-SPAM.)

What can be done to prevent messages that are not spam from falling victim to antispam measures? Adherence to responsible email practices is a good first step. Responsible management of the company's email servers will also help, as will selection of reputable service providers. You should also consider tasking someone with tracking antispam measures, to make sure that your email is designed to avoid, as much as

20 · 16 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

possible, any elements of content or presentation that are currently being flagged as spam.

To make sure your company is associated with responsible email practices, become familiar with the “Six Resolutions for Responsible E-Mailers.” These were created by the Council for Responsible Email (CRE), which was formed under the aegis of the Association for Interactive Marketing (AIM), a subsidiary of the Direct Market Association (DMA). Some of the country’s largest companies, and largest legitimate users of email, belong to these organizations, and they have a vested interest in making sure that email is not abused. Here are the six resolutions:

1. Marketers must not falsify the sender’s domain name or use a nonresponsive IP address without implied permission from the recipient or transferred permission from the marketer.
2. Marketers must not purposely falsify the content of the subject line or mislead readers from the content of the email message.
3. All bulk email marketing messages must include an option for the recipient to unsubscribe (be removed from the list) from receiving future messages from that sender, list owner, or list manager.
4. Marketers must inform the respondent at the time of online collection of the email address for what marketing purpose the respondent’s email address will be used.
5. Marketers must not harvest email addresses with the intent to send bulk unsolicited commercial email without consumers’ knowledge or consent. (Harvest is defined as compiling or stealing email addresses through anonymous collection procedures such as via a Web spider, through chat rooms, or other publicly displayed areas listing personal or business email addresses.)
6. The CRE opposes sending bulk unsolicited commercial email to an email address without a prior business or personal relationship. (Business or personal relationship is defined as any previous recipient-initiated correspondence, transaction activity, customer service activity, third-party permission use, or proven off-line contact.)

These six resolutions may be considered a reasonable middle ground between antispam extremists and marketing-at-all-costs executives. If everyone abided by these resolutions, there would be no spam, at least according to most people’s definition of spam. After all, if nobody received more than one or two messages per week that were unwanted and irrelevant, antispam sentiment would cool significantly.

20.3.3.3 Appending and Permission Issues. Some privacy advocates have objected to the sixth resolution because it permits email *appending*. This is the practice of finding an email address for a customer who has not yet provided one. Companies such as Yesmail and AcquireNow will do this for a fee. For example, if you are a bank, you probably have physical addresses for all your customers, but you may not have email addresses for all of them. You can hire a firm to find email addresses for customers who have not provided one. However, these customers may not have given explicit permission for the bank to contact them via email, so some people would say that sending email messages to them is spamming.

Whether you agree with that assessment or not, several factors need to be assessed carefully if your company is considering using an email append service. First of all,

make sure that nothing in your privacy policy forbids it. Next, think hard about the possible reaction from customers, bearing in mind that email appending is not a perfect science. For more on how appending works, enter “email append” as a search term in Google—you will find a lot of companies offering to explain how they do it, matching data pulled from many different sources using complex algorithms.

Another concern that must be considered is that some messages will go to people who are not customers. For that reason, you probably want to make your first contact a tentative one, such as a polite request to make further contact. Then you can formulate the responses to build a genuine opt-in list. As you might expect, you can outsource this entire process to the append service, which will have its own, often automated, methods of dealing with bounced messages, complaints, and so on.

Do not include any sensitive personal information in the initial contact, since you have no guarantee that bob.jones@majorfreemail.net is the Robert Jones you have on your customer list. When Citibank did an append mailing in the summer of 2002, encouraging existing customers to use the bank’s online account services, it came in for some serious criticism. Although the bank was not providing immediate online access to appended customers, the mere perception of this, combined with a number of mistaken email identities, produced negative publicity. Here is what Citibank said in the message it sent to people it believed to be customers, even though these people had not provided their email address directly to the bank:

Citibank would like to send you email updates to keep you informed about your Citi Card, as well as special services and benefits... With the help of an email service provider, we have located an email address that we believe belongs to you.

Although this message is certainly polite, it clearly raised questions in the minds of recipients. Two questions could undermine appending as a business practice: Where exactly is this service provider looking for these email addresses? Why doesn’t the company that wants my email address just write and ask for it? The fact is, conversion rates from email contact are higher than from snail mail, so the argument for append services is that companies that use them move more quickly to the cheaper and better medium of email than those that do not. The counterpoint is that too many people will be offended in the process.

Consider to what lengths you are stretching the prior business relationship principle cited in the sixth responsible email resolution. A bank probably has a stronger case for appending email addresses to its account holder list than does a mail order company that wants to append a list of people who requested last year’s catalog. The extent to which privacy advocates accept or decry the concept of prior business relationship is largely dependent on how reasonable companies are in their interpretation of it.

Marketing to addresses that were not supplied with a clear understanding that they would be used for such purposes is not advisable. Depending on your privacy statement, it could be a violation of your company’s privacy policy. Going ahead with such a violation could not only annoy customers, but also draw the attention of industry regulators, such as the Federal Trade Commission (FTC). Of course, you will have to decide for yourself if it is your job or responsibility to point this out to management. And be sure to provide a simple way for recipients to opt out of any further mailings. (A link to a Web form is best for this. Avoid asking the recipient to reply to the message. If the email address to which you mailed the message is no longer their primary address, they may have trouble opting out.)

20.4 FIGHTING SPAM. The fight against incoming spam can be addressed both specifically, as in “What can I do to protect my systems from spam?”, and in general, “What can be done to prevent spam in general?” Of course, if the activity of spamming were to be eliminated, everyone would have one less threat to worry about.

20.4.1 Enter the Spam Fighters. In the five-year period from 1997 to 2002, a diverse grouping of interests and organizations fought to make the world aware of the problem of spam, and to encourage counter-measures. The efforts of CAUCE, which continue to this day, spurred lawmakers into passing antispam legislation and helped bring order to the blacklisting process by which spam-sending servers are identified. In 1998, the *Spamhaus Project*, a volunteer effort founded by Steve Linford, began tracking spammers and spam-related activity. (The name comes from a pseudo-German expression, coined by Linford, to describe any ISP or other firm that sends spam or willingly provides services to spammers.)

The Anti-Phishing Working Group (APWG) was founded in 2003 and is one of the most active and productive anti-phishing organizations today:

The APWG is a worldwide coalition unifying the global response to cybercrime across industry, government and law-enforcement sectors. APWG’s membership of more than 2000 institutions worldwide is as global as its outlook, with its directors, managers and research fellows advising: national governments; global governance bodies like ICANN; hemispheric and global trade groups; and multilateral treaty organizations such as the European Commission, Council of Europe’s Convention on Cybercrime, United Nations Office of Drugs and Crime, Organization for Security and Cooperation in Europe and the Organization of American States. Membership is open to financial institutions, retailers, solutions providers, ISPs, telcos, defense contractors, law enforcement agencies, trade groups, treaty organizations and government agencies. APWG member benefits include: clearinghouses of cybercrime event data; cybercrime response utilities for professionals from the private, public, and NGO sectors who combat cybercrime; community-building conferences for cybercrime management professionals; public education utilities for cybercrime prevention; standards development for cybercrime data exchange and programs for promotion of cybercrime research.²⁵

Commercial antispam products started to appear in the late 1990s, starting with spam filters that could be used by individuals. Filtering supplied as a service to enterprises appeared in the form of Brightmail, founded in 1998 and now owned by Symantec, and Postini, founded in 1999 and now owned by Google. A host of other solutions, some free and open source, others commercial, attempted to tackle spam from several different directions. Nevertheless, despite the concerted efforts of volunteers, lawmakers, and entrepreneurs, spam has continued to sap network resources while evolving into part of a subculture of system abuse that includes delivering payloads that do far worse things than spark moral outrage.

20.4.2 A Good Reputation? Since spam is created by humans, it is notoriously difficult, if not impossible, for computers to identify spam with 100 percent reliability. This fact led some spam fighters to consider an alternative approach: reliably identifying legitimate email. If an email recipient or a Mail Transfer Agent could verify that certain incoming messages originated from legitimate sources, all other email could be ignored. One form of this approach is the challenge-response system, perhaps the largest deployment being the one that Earthlink rolled out in 2003. When you send a message to someone at Earthlink who is using this system, and who has not received a message from you before, your message is not immediately delivered. Instead, Earthlink sends an email asking you to confirm your identity, in a way that

would be difficult for a machine to fake. The recipient is then informed of your message and decides whether to accept it or not. Unfortunately, this approach can be problematic if the user does a lot of e-commerce involving email coming from many sources that are essentially automated responders (which cannot pass the challenge). Manually building the whitelist of allowed respondents can be tiresome, and failure to do so may mean some messages do not get through (e.g., if the sender is a machine that does not know how to handle the challenge). One solution to this problem is to compile an independent whitelist of legitimate emailers whose messages are allowed through without question. This is the reputational approach to spam fighting, and it works like this:

- Bank of America pledges never to spam its customers and send them only email they sign up for (be it online statement notification or occasional news of new bank services).
- Bank of America email is always fast-tracked through ISPs and not blocked as spam.
- Bank of America remains true to its pledge because its reputation as a legitimate mailer enables it to conduct email activities with greater efficiency.

There are considerable financial and logistical obstacles to making such a system work, and it tends to work better with bigger mailers. Adoption also faced skepticism from some privacy and antispam advocates who suspected that the goal of such systems was merely to legitimize mass mailings by companies that still did not understand the need to conduct permission-only mailings. The relentless assault of spam on the world's email systems eventually may lead all legitimate companies to forswear unsolicited email and thus make a reputational system universally feasible. Tough economic times, though, may tempt formerly clean companies to turn to spam in a desperate effort to boost flagging sales.

Another and more universal method of excluding spam would be for ISPs to deliver, and consumers to accept, only those emails that were stamped with a verifiable cryptographic seal of some kind. A relatively simple automated system to accomplish this was developed in 2001 by a company called ePrivacy Group, and it proved very successful in real-world trials conducted by MSN and several other companies. If adopted universally, such a system could render spamming obsolete, but that goal proved to be unattainable. The success of this approach depended on widespread deployment, and the project ultimately was doomed by infighting between the larger ISPs, despite ePrivacy Group's willingness to release the underlying technology to the public domain.

The ultimate in reputation-based approaches to solving the spam problem may well be something that information security experts have urged for years: widespread use of email encryption. If something like Secure/Multipurpose Internet Mail Extensions (S/MIME) was universally implemented, everyone could ignore messages that were not signed by people from whom they were happy to receive email. Of course, the fact that email encryption can be made to work reliably is not proof that it always will, and the encryption approach does not, in itself, solve the fundamental barrier to any universal effort at outlawing spam: the willingness of everyone to participate. One of the qualities that led email to become the most widely used application on the Internet, the lack of central control, is a weakness when it comes to effecting any major change to the way it operates.

20.4.3 Relaying Trouble When considering the problem of spam in general, the question is why ISPs allow people to send spam. The fact is, many do not. Spamming is a violation of just about every ISP's terms of service. Accounts used for spamming are frequently closed. However, there are some exceptions. As you might imagine, a few ISPs allow spam as a way to get business (albeit business that few others want). Some of these ISPs use facilities in fringe countries to avoid regulatory oversight. Furthermore, some spammers find it easier, and cheaper, to steal service and use unauthorized access to other people's servers to send their messages. A phenomenon of email is mail relaying. According to Janusz Lukasiak of the University of Manchester, mail relaying occurs "when a mail server processes a mail message from an unauthorized external source with neither the sender nor the recipient being a local user. The mail server is an entirely unrelated third party to this transaction and the message should not be passed via the server."²⁶ The problem with unauthenticated third parties is that they can hide their identity.

In the early days of the Internet, many servers were left *open* so that people could conveniently relay their email through them at any time. It was quite acceptable for individuals to send their email through just about any mail server, since the impact on resources was minimal. Abuses by spammers, whose mass emailings *do* impact resources, led to ISPs instituting restrictions. Some ISPs require the use of port 587 for SMTP authentication. Others require logging in to the POP server to collect incoming mail before sending any out. Since that requires a user name and password, it prevents strangers from sending email through the server.

Open relays are now frowned on. However, relaying continues to occur, partly because configuring servers to prevent it requires effort. Also, spammers keep finding new ways to exploit resources that are not totally protected. For example, port 25 filtering, instituted to reduce spamming, can be bypassed with tricks like asynchronous routing and proxies. A relatively recent development is the use of botnets, groups of compromised computers, to deliver spam. (For more about botnets see Chapters 15, 16, 17, 30, 32, and 41 in this *Handbook*.)

A war is continually being waged between spammers and ISPs, and that war extends to the ISPs' ISP—most Internet service providers actually get their service from an even larger service provider, companies like AT&T, MCI, and Sprint, which are the backbone of the Internet. How much trouble do these companies have with spam? As far back as 2002, network abuse (spam) generated 350,000 trouble tickets each month at a single carrier. These companies are working hard to prevent things like mail relaying and to defeat the latest tricks that spammers have devised to get around their preventive measures.

20.4.4 Black Holes and Block Lists Black hole lists, or block lists, catalog server IP addresses from ISPs whose customers are deemed responsible for spam and from ISPs whose servers are hijacked for spam relaying. ISPs and organizations subscribe to these lists to find out which sending IP addresses should be blocked. The receiving end, such as the consumer recipient's ISP, checks the list for the connecting IP address. If the IP address matches one on the list, then the connection gets dropped before accepting any traffic. Other ISPs choose simply to ignore, or black hole, IP packets at their routers. Among the better known block lists are RBL, otherwise known as MAPS Realtime Blackhole List, Spamcop, and Spamhaus.²⁷

How does an entity's IP address get on these lists? If an ISP openly permits spam, or does not adequately protect its resources against abuse by spammers, it will likely be reported to the list by one or more recipients of such spam. Reports are filed by people

who take the time to examine the spam's header, identify the culpable ISP, and make a nomination to a block list. Different block lists have different standards for verifying nominations. Some test the nominated server; others take into account the number of nominations. If an ISP, organization, or individual operating a mail server finds itself on the list by mistake, it can request to be removed, which usually involves a test by the organization operating the block list.

Note that none of this block-list policing of spam is official. All block lists are self-appointed and self-regulated. They set, and enforce, their own standards. The only recourse for entities that feel they have been unfairly blocked—and there have been plenty of these over the years—is legal action. Some block lists are operated outside of the United States, but if an overseas organization block-lists a server located in the United States, it probably can be sued in a U.S. court. However, it is important to note that the blocking is not done by the operator of the block list, it is done by ISPs that subscribe to, and are guided by, the lists.

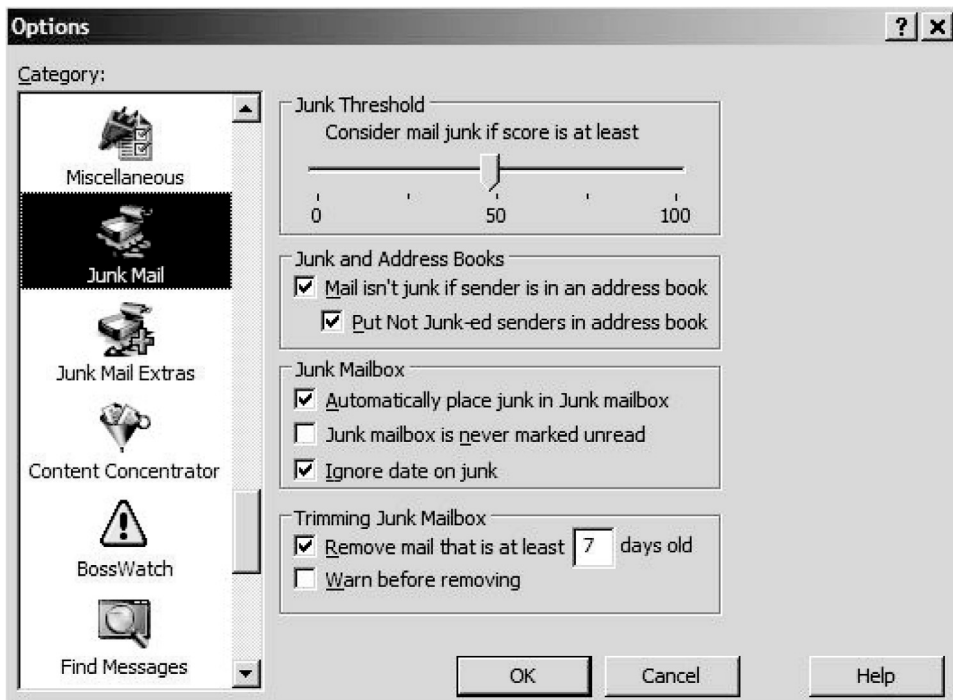

20.4.5 Spam Filters Block-list systems filter out messages from certain domains or IP addresses, or a range of IP addresses; they do not examine the content of messages. Filtering out spam based on content can be done at several levels.

20.4.5.1 End User Filters Spam filtering probably began at the client level, and even today many email users perform manual negative filtering for spam, identifying spam by a process of elimination. This is easy to do with any email application that allows user-defined filters or rules to direct messages to different inboxes or folders. Many people have separate mailboxes into which they filter all of the messages they get from their usual correspondents, friends, family, colleagues, subscribed newsletters, and so on. This means that whatever is left in the in basket is likely to be spam, with the notable exception of messages from new correspondents for whom a separate mailbox and filter has not yet been created.

To perform a filter that positively identifies spam, elements common to spam messages need to be identified. Many products do this, and they usually come with a default set of filters that look for things like From addresses that contain a lot of numbers and Subject text that contains a lot of punctuation characters—spammers often add these in an attempt to defeat filters based on specific text, so the Subject line “You’re Approved” might be randomly concatenated with special characters and spaces like this: “**You~re Ap proved!**”

In fact, the tricks and tweaks used by spammers in crafting messages designed to bypass filters are practically endless. Nevertheless, even the spam filtering built into some basic email programs offers a useful line of defense. For example, in Exhibit 20.3 you can see the control panel for spam filtering in the Eudora email application, which places mail in a Junk folder based on a score derived from common spam indicators, giving users control over how high they want to set the bar.

Unfortunately, some of the language found in spam also appears in legitimate messages, such as “You are receiving this message because you subscribed to this list” or “To unsubscribe, click here.” This means that the default setting in a spam filter is likely to block some messages that you want to get. The answer is to either weaken the filtering or create a whitelist of legitimate From addresses so that the spam filter will allow through anything from these addresses. Most personal spam filters, like the one shown in Exhibit 20.3, can read your address book, and add all of the entries to your personal whitelist. New correspondents can be added over time.

**EXHIBIT 20.3** Junk Mail Filter Controls

Most personal spam filters direct the messages they identify as spam into a special folder or in basket where they can be reviewed by the user, a process sometimes referred to as quarantining. To avoid wasting hard drive space, the filtering software can be programmed to empty the quarantine folder at set intervals or simply to delete suspected spam older than a set number of days. This quarantine approach gives the user time to review and reclaim wrongly suspected spam.

20.4.5.2 ISP Filtering Faced with customer complaints about increased levels of spam around the turn of the century, ISPs began to institute spam filtering. However, they were hesitant to conduct content-based spam filtering, fearing that it might be construed as reading other people's email and lead to claims of privacy invasion. Yet ISPs must be able to read headers to route email, so filtering on the From address and Subject field was introduced (hence the increasingly inventive attempts by spammers to randomly vary Subject text). Some ISPs found that distaste for spam reached a level at which some users were prepared to accept revised terms of agreement, to allow machine reading of email content to perform more effective spam filtering. Sticky legal issues still exist for ISPs, however, especially since there is no generally accepted definition of spam and no consensus on the extent to which freedom of speech applies to email. For example, do political candidates have a right to send unsolicited email to constituents? Do ISPs have a right to block it? These are questions on which the courts of law and public opinion have yet to render a conclusive verdict.

One place where content-based spam filters are being deployed with little or no concern for legal challenges is the corporate network. Based on the fact that the company network belongs to the company, the right to control how it is used trumps

concerns over privacy. Employees do not have the right to receive, at work, whatever kind of email they want to receive. And most companies would argue that there is virtually no corporate obligation to deliver email to employees. For more details of email policies, see Chapter 48 in this *Handbook*.

20.4.5.3 Filtering Services Companies like Brightmail and Postini arose in the late 1990s to offer filtering services at the enterprise level. Brightmail developed filters that sit at the gateway to the enterprise network and filter based on continuously updated rules derived from real-time research about the latest spam outbreaks. Postini actually directs all of a company's incoming email to its servers and filters it before sending it on. With specialization, filtering services can utilize a wide range of spam fighting techniques, including:

- Block lists
- Header analysis
- Content analysis
- Filtering against a database of known spam
- Heuristic filtering for spamlike attributes
- Whitelisting through reputational schemes

Because these systems constantly deal with huge amounts of spam, they are able to refine their filters, both positive and negative, quickly and relatively effectively. And they catch a lot of spam that would otherwise reach consumers. For example, by 2008, nine of the top 12 ISPs were using Brightmail, which claims a very low false positive rate and 95 percent catch rate. Unfortunately, that still means that some spam gets through, and when spammers can direct millions of messages an hour at a network, the volume of what gets through still can pose a threat.

Another approach uses the collective intelligence of subscribers to identify spam quickly and spread the word via network connections. Cloudmark, for example, had several million subscribers at the time of writing (April 2008) paying about \$40 per year to receive nearly instantaneous updates, from servers that receive and categorize reports from members on any spam that gets through. A member's credibility score rises with every correct identification of spam and sinks with incorrect labeling of legitimate email as spam (e.g., newsletters the member has forgotten subscribing to). The reliability of reporters helps the system screen false information from spammers that might try to game the system by claiming that their own junk email was legitimate.

20.4.5.4 Collateral Damage There are two major drawbacks to spam filters. First, they allow spammers to continue spamming. In other words, because they must decide, on a message-by-message basis, which messages are spam and which are not, filters consume a lot of resources, in some cases more than if all the spam was allowed through. When block lists and whitelists work well, they can substantially reduce the amount of spam that reaches the filtering stage, but eventually all filters are serial, and thus resource constrained and resource intensive.

Second, filters sometimes err, in one of two ways. They sometimes produce a false positive, flagging a legitimate message as spam, preventing a much-needed message from getting to the recipient in a timely manner. And they sometimes produce false

20 · 24 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

negatives, allowing spam messages into the inbox. False negatives and false positives impose a drag on productivity.

20.4.5.5 Snowshoe Spamming It was inevitable that spammers would adapt to the filtering measures described above. By late 2012, an increasing number of spammers were distributing their spam among a large number of compromised servers, leading to the term *snowshoe* spamming. McAfee Labs summarized the problem as follows:

Snowshoe spamming is now one of the biggest spam problems. The issue has exploded over the past two years and will continue to increase sharply due to lack of exposure by law enforcement authorities and threats of lawsuits by companies using the illegal email lists.

The phenomenon is characterized by the following:

- Spammers blast out millions and millions of blatantly illegal spam messages every day from newly rented hosts until they get evicted from their subnetworks or move on.
- Recipients have their inboxes bombarded with these spam messages and are unable to opt out of them because they are not sent from a legitimate source.
- The result of snowshoe spamming is permanently blacklisted addresses and sometimes subnetworks.
- Because spamming is seen as simply annoying rather than malicious, authorities have largely ignored this problem, despite the growing volumes of unwanted email originating from these sources. Companies using these shady marketers have threatened to file defamation lawsuits when researchers have tried to expose this activity.²⁸

20.4.6 Network Devices The rapid rise of spam volumes in the late 1990s occurred at a time of massive email-enabled computer virus and worm attacks, arising from the classic malware motivation of bragging rights. Analysis of these problems, according to the classic factors of means, motive, and opportunity, revealed that spammers differed quite significantly from virus writers. Spammers are mostly motivated by money, not bragging rights. This insight opened up a new line of defense against spam, removing that motivation.²⁹

All that remained was to understand how spammers make money, that is, the economics of spam, then to find a way to disrupt those economics. The classic spam model is to send out a vast number of emails offering a product or service, relying on the fact that at least some of these offers will reach real people, at least some of whom will make a purchase. If enough sales are made to create a profit over and above the cost of doing business, the spammer will continue to operate. Although a good public education and awareness program can reduce the number of people who buy the spammers' offers, it is unlikely to reduce that number enough. Because filtering spam out of the message stream reduces the spammer's return on investment, it tends to make spammers more inventive in their attempts to beat filters and to send even more spam in the hopes that enough will get through. In fact, spammers were able to find companies willing to sell them bandwidth on a massive scale, including dedicated point-to-point T3 digital phone line connections.

Another way to attack the economics of spam is by following the money. Every deal has to be closed, typically via a Website. Is it possible to shut down the spammer's Websites? This line of inquiry led the author to an interesting finding: Spam goes stale very quickly. An examination of spam archives showed that most links in old spam were dead, sometimes because the Website was shut down by the hosting company,

sometimes because the spammer did not want to risk being identified. Thus, the key to the economics of spam was revealed: time. If you slow spam down, spammers cannot generate enough responses before response sites are taken down.

Shortly after this realization, network security expert David Brussin devised a means of slowing down spam through TCP/IP traffic shaping. This became the technology at the heart of the antispam router. Instead of looking at each message in turn to determine if it is spam, the antispam router samples message traffic in real time and slows that traffic down if the sample suggests the traffic contains spam. To spammers, or rather the spamming software used by spammers, a network protected with an antispam router behaves as if it is on a 300-baud modem. In other words, the connection is too slow to deliver enough messages quickly enough for that one-in-a-million hit that the spam scheme needs in order to make money before the Website is shut down. The spamming software quickly drops the connection; no messages have been lost and no messages have been falsely labeled as spam. Delivery of legitimate email has not been affected. One or two spam messages have been delivered, but a lot less than are allowed through by the 95 percent catch rate of a typical spam filter.

There are two main tricks to this technology. One is tuning the TCP/IP traffic shaping, the other is tuning the sampling process. The latter needs regular updates about what spam looks like currently, so that it can identify a spammy connection as quickly as possible. These updates can be derived from services that constantly identify new spam. An application control panel is used to handle the tuning of the traffic shaping. Network administrators have found that a properly tuned antispam router can reduce bandwidth requirements by as much as 75 percent. Unfortunately, an antispam router works best on a high-volume connection, protecting MTAs at ISPs, larger companies, schools, and government agencies. There is no desktop version. Still, the technology has become a valuable part of the antispam arsenal, although the scourge of spam still continues.

20.4.7 Email Authentication On a technical level, what allows spam to continue to proliferate is the lack of sender authentication in the SMTP protocol. Several initiatives have sought to change this situation, either by changing the SMTP protocol or by adding another layer to it. One obvious way to authenticate email is via the sender's domain name, and numerous schemes to accomplish this have been proposed:

- **Sender Policy Framework (SPF).** An extension to SMTP that allows software to identify and reject forged addresses in the SMTP MAIL FROM (Return-Path) that are typically indicative of spam. SPF is defined in Experimental RFC 4408.³⁰
- **Certified Server Validation (CSV).** A technical method of email authentication that focuses on the SMTP HELO-identity of MTAs.
- **SenderID.** An antispooofing proposal from the former MARID IETF working group that joined Sender Policy Framework and Caller ID. Sender ID is defined primarily in Experimental RFC 4406.³¹
- **DomainKeys.** A method for email authentication that provides end-to-end integrity from a signing MTA to a verifying MTA acting on behalf of the recipient. It uses a signature header verified by retrieving and validating the sender's public key through the Domain Name System (DNS).
- **DomainKeys Identified Mail (DKIM).** A specification that merges DomainKeys and Identified Internet Mail, an email authentication scheme supported by Cisco, to create an enhanced implementation.

20 · 26 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

When properly implemented, all of these methods can be effective in stopping the kind of forgery that has enabled spam to dominate email. Each has varying pros and cons and requirements. SPF, CSV, and SenderID authenticate just a domain name. SPF and CSV can reject forgeries before message data is transferred. DomainKeys and DKIM use a digital signature to authenticate a domain name and the integrity of message content. In order for SenderID and DomainKeys to work, they must process the headers, and so the message must be transmitted.

Obviously a scheme like DomainKeys makes email more complex than SMTP. Additional data and processing effort are required. DNS records have to be expanded and maintained. However, the effort may be worth it. Although something like DomainKeys does not prevent email abuse, it does make abuse of email on protected domains easier to detect and track, and this is a deterrent to spamming now that several stiff sentences for spamming have been handed down.³² Since 2004, the email services of both Yahoo and Google have signed outgoing email with DomainKeys, but it is not yet clear if any one of the described schemes, or some derivative thereof, will become the standard for all email. And therein lies the rub. Spam could be effectively sidelined *if* all legitimate email was reliably authenticated; recipients could simply ignore all unauthenticated messages. However, that is a large *if*.

20.4.8 Industry Initiatives Back in 2002, at the urging of consumer advocates, government agencies, and many large corporate users of email, the major email service providers started to hold meetings to discuss a unified approach to improving email and eliminating spam. There were high hopes that the problem of spam would be solved by this group, which was known in the business as AMEY, for AOL, Microsoft, Earthlink, and Yahoo!. There was certainly plenty of encouragement. Early in 2003, the FTC, America's main consumer protection agency, convened a conference on spam, and the commissioners made it clear they wanted action. Indeed, by the end of 2003, Congress had passed the first federal antispam legislation (see Section 20.4.9).

In January 2004, then Microsoft chairman and chief executive Bill Gates announced to the World Economic Forum, "Two years from now, spam will be solved." Two months later, the AMEY companies filed lawsuits against persons alleged to be major spammers, claiming that spam cost businesses in North America \$10 billion each year in lost productivity, network upgrades, and destroyed or lost data. However, by January 2006, spam constituted more than three-quarters of all email. What went wrong? Repeated efforts to get the AMEY companies to adopt a new, open, royalty-free standard have run aground on concerns over intellectual property rights. Both Microsoft and Yahoo! have asserted ownership over parts of the various mechanisms put forward to authenticate email and thus solve the spam problem. Ironically, a lack of trust between the large ISPs has resulted in a lack of trust of the email they deliver.

20.4.9 Legal Remedies Laws against spam have been passed by many countries, including the United States. The CAN-SPAM Act of 2003 (Controlling the Assault of Non-Solicited Pornography And Marketing Act, effective January 1, 2004) established certain requirements for anyone sending commercial email. The law also provides penalties for spammers and for companies whose products are advertised in spam. The law addresses "email whose primary purpose is advertising or promoting a commercial product or service, including content on a Website."³³

Enforcement of the CAN-SPAM Act is primarily the job of the FTC, but the act also gives the Department of Justice authority to enforce the act's criminal sanctions. Other federal and state agencies can enforce the law against organizations under their

jurisdiction, and ISPs can also sue CAN-SPAM violators. Here are the law's main provisions, as stated by the FTC:

- **Bans false or misleading header information.** The From, To, and routing information of your email—including the originating domain name and email address—must be accurate and identify the person who initiated the email.
- **Prohibits deceptive subject lines.** The subject line cannot mislead the recipient about the contents or subject matter of the message.
- **Requires that your email give recipients an opt-out method.** You must provide a return email address or another Internet-based response mechanism that allows a recipient to ask you not to send future email messages to that email address, and you must honor the requests. You may create a menu of choices to allow a recipient to opt out of certain types of messages, but you must include the option to end any commercial messages from the sender.

Any opt-out mechanism you offer must be able to process opt-out requests for at least 30 days after you send your commercial email. When you receive an opt-out request, the law gives you 10 business days to stop sending email to the requestor's email address. You cannot help another entity send email to that address or have another entity send email on your behalf to that address. Finally, it is illegal for you to sell or transfer the email addresses of people who choose not to receive your email, even in the form of a mailing list, unless you transfer the addresses so another entity can comply with the law.

- **Requires that commercial email be identified as an advertisement and include the sender's valid physical postal address.** Your message must contain clear and conspicuous notice that the message is an advertisement or solicitation and that the recipient can opt out of receiving more commercial email from you. It also must include your valid physical postal address.

Note that messages which are transactional or relationship based—that is, email that “facilitates an agreed-upon transaction or updates a customer in an existing business relationship”—are also covered in the sense that these messages may not contain false or misleading routing information.

Readers will find extensive discussion about whether CAN-SPAM has been—and could ever be—effective by searching the Web with any search engine. For a critique of the law published in February 2004, see “Can CAN-SPAM can spam?”³⁴

20.5 PHISHING. Phishing is the use of unsolicited commercial email to obtain—electronically fish for—information about you, information that you would not normally disclose to a stranger, such as your bank account number, personal identification number (PIN), and other personal identifiers such as Social Security number. There was virtually no phishing activity before 2002 and relatively little in 2003, but by 2004 phishing had become an everyday threat and has continued unabated ever since. This is one category of threat that could have been squelched, along with the rest of spam, if industry leaders had chosen to cooperate rather than to compete for customers based on promising “better antispam than the other guys.”

20.5.1 What Phish Look Like. Most of us first became aware of *phishing* when we received an email about a problem with an account, typically a bank account, but possibly an eBay, PayPal, Amazon, or other online account. A typical phishing

20 · 28 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

message is designed to look as if it had been sent by a large enterprise, such as the Bank of America, complete with accurate copies of the company logo, typeface, and terminology. At first glance, such messages can be quite convincing. If you receive a message like this that references an institution at which you *do* have an account, you might be tempted to read it. You might even be tempted to follow the instructions, and these are likely to lead you to a Website that asks for confidential information. Consider the text of a typical phishing message:

You are receiving this message, due to you protection, Our Online Technical Security Service Foreign IP Spy recently detected that your online account was recently logged on from am 77.32.11.84 without am International Access Code (I.A.C) and from an unregistered computer, which was not verified by the Our Online Service Department.

If you last logged in you online account on Monday May 5th 2007, by the time 6:45 pm from an Foreign Ip their is no need for you to panic, but if you did log in your account on the above Date and Time, kindly take 2-3 minute of your online banking experience to verify and register your computer now to avoid identity theft, your protection is our future medal.

What looks, at first glance, to be a very official and technical message, turns out to be full of errors. The best thing to do with these messages is delete them. The worst thing to do is respond to them. Until there is a major overhaul of email security, no reputable institution will be using email to request changes or updates to confidential account information.

If you received an email like the one discussed above but did not have a Bank of America account, you might have been confused. The fact is, the people sending these phishing messages usually have no idea whether the recipients have accounts at the institution named in the message. Indeed, this type of mismatch is the easiest way to spot some phishing messages. However, if the phisher, who has likely sent out millions of copies of the same email, gets lucky and you do happen to have an account at the named institution, or if the email is generic, then things get a little trickier. You are more likely to open a message that appears, often quite convincingly, to come from your bank. If you cannot resist looking at email about an account problem, here are some of the clues that the message is bogus. (Note that we are not implying that messages lacking these clues are therefore legitimate.)

- **Deceptive link.** Most phishing messages make an effort to look like they are legitimate, for example, by using logos and graphics stolen from the Website of the targeted institution. All phishing messages we have seen also include a link to a Website, where you are asked to provide the data the phisher is trying to steal. However, this link typically is disguised. For example, the link might be long and complicated and include the name of the bank but actually not take you to the bank's Website. Alternatively, the link may appear to be plain and simple text but in fact it is HTML-coded to go somewhere else. Some email programs, such as Eudora, will warn you of this deception and show you the real link when you place your mouse over the link text prior to clicking.

The design of the link in a phishing scheme can be critical to its success. An increasing number of users are appropriately wary of long, complex, or merely numerical IP address links in email (e.g., "Click <http://123.212.192.68>"). By the use of HTML coding, messages typically obscure the destination address. However, the link is also relevant in the next stage of the attack, when the victim clicks the link. If the URL of the phishing site appears as a numerical address in the

URL field of the browser, the victim may become suspicious. Various techniques are used to make this address look plausible.

- **Change PIN/Password.** Emails that ask you to change your account access credentials are highly suspect. Legitimate companies do not make such requests via email precisely because email is so unreliable. No security update to a reputable banking Website is going to ask that you log in to your account to reset it or to prevent its being suspended. And why would a legitimate message ask you to use a password *that has supposedly been compromised*? No government agency is going to ask for your credentials or personal information via email. And no lottery on Earth uses email to notify winners. Ignore these messages, or report them as spam, and move on.
- **Bad spelling, grammar, and logic.** Whoever thought those tedious grammar lessons could be so useful? Bad grammar, spelling, and even faulty logic can be the fastest way to spot bogus email. Consider this example: “Therefore, if you are the rightful holder of the account please fill in the form below so that we can check your identity.[sic]” There is a telling typo here (*identity* for *identity*), and the logic is hopeless. Think about it: Why would a bank send an email to someone if it was not sure the person was the rightful holder of the account? Again, this is not how real companies do business today, so just move on.
- **Generic phish.** Generic account warnings are particularly nasty. They are one way that phishing attacks try to get around the problem of not knowing where the victim (you) has an account. For example, all bank accounts in America are insured by an institution called the Federal Deposit Insurance Corporation (FDIC). In 2004 someone created a particularly nasty attack that preyed on this fact, potentially snagging anyone with a bank account. This was one of the first phishing attacks to fake the linked URL using a vulnerability in Microsoft Internet Explorer to mask the actual URL. If you clicked the link in the message, the site you went to really looked as if it were www.fdic.gov but actually led to the phisher’s site.

20.5.2 Growth and Extent of Phishing. Any new form of computer abuse can be said to have arrived when a toolkit facilitating the abuse becomes available. Phishing toolkits first appeared in 2006, offering scripts that enabled attackers to automatically set up phishing Websites spoofing the legitimate Websites of different brands (including the illegal appropriation of images and logos that consumers associate with those brands). These scripts helpfully generate corresponding phishing email messages. Criminals continue the evolution of their tools without respite; a January 2013 report found that spear phishers have applied a new tool called Bouncer that adapts their URLs to include unique identifiers for their intended victims; attempting to access the criminals’ pages without a valid identifier in the URL results in a 404 (no such page) error, thus interfering with researchers’ analysis of the phishing pages.³⁵

In February 2013, analysts found that “When security experts looked into some of the highest profile hacks in recent years—one particular criminal group kept on coming to their attention. The Comment Group, which industry insiders say is based in China, offer hacking for hire—be it for individuals, corporations or governments...” They research individual companies or organizations to locate detailed information that allows highly specific topics and even content in the phishing messages. For example, a Coca-Cola executive reportedly opened a phishing email supposedly from his own boss; the link he clicked on downloaded spyware into his computer and allowed Chinese

20 · 30 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

industrial spies to extract information which stymied the acquisition of China's largest soft-drinks company.³⁶

In April 2013, the U.S. Department of Homeland Security (DHS) warned "organizations that post a lot of business and personal information on public web pages and social media sites" not to do so. In October 2012, phishers harvested detailed information about employees from a public posting by an energy company listing attendees at a conference. In addition to spear-phishing attacks on named individuals, "Malicious emails that appeared to be from one of the attendees were sent to others on the list informing them of a change in the sender's email address. Recipients were politely asked to click on an attached link that promptly took them to a site containing malware."³⁷

The APWG is a valuable repository of statistical information about phishing.³⁸ Their report on phishing during the fourth quarter of 2013 includes the following findings (these are direct quotations formatted as bullet points with page references removed):

- Phishing attacks against online game players saw a massive increase, from 2.7 percent of all phishing attacks in Q3 to 14.7 percent in Q4.
- Financial services continued to be the most targeted industry sector in the fourth quarter of 2012, with payment services close behind.
- Online gaming credentials are valuable to certain criminals, who sell them on the black market. In-game items held in those accounts can also be sold by phishers for real-world cash. Victims can even have their real-life identities stolen.
- Attacks against social media doubled to 6 percent, up from 3 percent in the third quarter.
- During Q4, about 30 percent of personal computers worldwide were infected with malware.
- More than 57 percent of PCs in China may have been infected, while PCs in European nations were infected least often.
- Except for October 2012, the number of phishing sites declined every month from April 2012 through December 2012.
- April 2012 saw 63,253 unique phishing sites detected, falling to 45,628 in December 2012.
- The APWG received reports of 28,195 unique phishing sites in December. December's total was 31 percent lower than the high of 40,621 reports in August 2009.
- Use of crimeware dipped slightly in this quarter from the previous, as did the use of data-stealing malware.
- The use of other malware has increased by a statistically significant amount from the previous quarter.³⁹

20.5.3 Where Is the Threat? Phishing appears at first to be a personal problem, a matter of consumer computer security rather than enterprise information security. Indeed, the federal agency charged with consumer protection, the FTC, has been active in educating consumers about the problem and the ways to avoid getting scammed by these messages.⁴⁰ However, phishing is also a computer-based threat to the information and welfare of companies as well as a threat to e-commerce in general.

Phishing attacks collect usernames and passwords. Many people use the same credentials for work-related systems as they do for personal systems (including the head of a highly secret government facility who was found to be using her bank ATM PIN as her top-secret network password). Criminal hackers are known to have penetrated systems by harvesting personal credentials and applying them to the target's business login. So a company computer security awareness program would do well to include warnings about phishing attacks.

Beyond the penetration threat, phishing can undermine consumer trust in a company. Although it hardly seems fair for consumers to resent Bank of America because a criminal has attempted to defraud them by abusing the bank's identity, such resentments do exist, and they need to be understood in a business context. Automation improves the profitability of banking, which is why banks encourage customers to use online services and offer incentives to drop paper statements and notifications. However, if banks are perceived as providing automation on the cheap, with insufficient safeguards built in to protect customer privacy and account access, some consumers will object, slowing down the pace of automation and jeopardizing productivity increases, potentially impacting the bottom line.

20.5.4 Fighting Phishing Some clever technological defenses specific to phishing have been put forward, such as methods for enabling browsers to verify URLs, but the best defense is a twofold approach that is entirely obvious. The first step is education, at the consumer and corporate level, teaching people how to spot phishing attacks and avoid falling victim to them. The second step is fixing the fundamentals of email in the ways outlined earlier with respect to spam. From a technical perspective, we already have the technology to do this. All that is missing is a willingness on the part of the leading service providers to take concerted action. Perhaps they could be encouraged to do so by the banks and other institutions that stand to gain a great deal if email is made more secure.

Failure to act on email security has already cost billions of dollars in wasted resources and lost productivity, but the effects go further than that, as evidenced by the emerging relationship among phishing, spamming, criminal hacking, Trojan code, personal data harvesting, and account compromise. The application of skills such as virus and worm writing to commercial ends has been enabled by the willingness of spammers to pay for compromised hosts with which to launch attacks and collect dollars and/or data. Spamming techniques have enabled the growth of phishing, which in turn has solidified the black market in compromised hosts and purloined personal data. New types of attack are constantly emerging from this unholy alliance between coders and criminals. Email addresses harvested by spam may be used for spear phishing attacks, where a specific company is targeted through emails sent to known customers or employees (the Department of Defense faced a rash of spear-phishing attacks in 2006). Trojan code distributed by spam methods has been used to corrupt local domain name servers and produce the same effect as a phishing message: Users are misdirected to malicious Websites simply by clicking on an apparently valid URL. (DNS attacks of this type are referred to as pharming.)

20.6 TROJAN CODE. Like the original Trojan horse, deployed by the Greeks to defeat the Trojans who were protected by the impregnable walls of the city of Troy, a computer Trojan is a bad thing disguised as a good thing (where Troy is your computer and the Greeks are the people who would like to gain unauthorized access). The technology has come a long way from the "steed of monstrous height" described

EXHIBIT 20.4 Screensaver Trojan

in Virgil's *Aeneid*, but the goal of Trojan code is the same as that of the original Trojan horse: Fool the defender of a protected place into granting access to outsiders. (See Section 15.3.2.17 for more on the origins of the name.)

Almost as soon as the Internet provided a way to distribute executable code, either as download links or email attachments, some people decided to exploit this ability to distribute their code without explicit permission. In other words, an innocent party might be tempted to download an apparently innocuous executable, which was actually something else. The person doing the downloading does so intentionally but is ignorant of the intentions of the person who crafted the Trojan code within the executable.

20.6.1 Classic and Recent Trojans. Despite the fact that the screens of today's computers do not need saving, screensavers continue to be a source of Trojan code. Some users apparently find the promise of animated waterfalls and fish tanks hard to resist. This leads users to download screensavers that they encounter on Websites or open screensaver files that they receive in email. In Exhibit 20.4 you can see an example of one screensaver.

The creator of this Trojan screensaver, discovered in February 2007, was apparently unhappy with a file-sharing network popular in Japan and named Winny. When this screensaver is opened, the Trojan displays an image warning the computer operator not to use Winny. This tactic is reminiscent of some of the very earliest viruses, which sought to spread relatively innocuous messages rather than cause damage. In fact, code does not have to have a malicious intent to be considered a Trojan—it merely needs the intent to get installed without permission. Unfortunately, in this particular case, the Trojan does go on to destroy data by overwriting certain files (e.g., those with .txt and .jpg extensions).

Another example of a screensaver Trojan is the one reported to be circulating as an email attachment called bsaver.zip in July 2007. When the file within the ZIP attachment is opened, the system is infected with the Agent-FZB Trojan horse, which then drops two rootkits to evade detection by security software and to make the system accessible to unauthorized users. (See Chapter 15 in this *Handbook* for more on rootkits.) This

screensaver was distributed by a spam campaign with message subject lines such as *Life is beautiful*, *Life will be better*, *Good summer*, and *help you*. The message text included phrases like “Good morning/evening, man! Really [sic] cool screensaver in your attachment!”

More recent reports about Trojans include the following cases and studies:

- The BackDoor.Wirenet.1 Trojan was identified in August 2012; the malware “is the first Trojan Horse program that works on the Mac OS X and Linux platforms that is ‘designed to steal passwords stored by a number of popular Internet applications.’”⁴¹
- The “PandaLabs Q1 Report” for 2013 found that “Trojans set a new record, causing nearly 80 percent of all computer infections worldwide. Despite their inability to replicate, Trojans are capable of triggering massive infections through compromised Web sites that exploit vulnerabilities in browser plug-ins like Java, Adobe Reader, etc. This attack method allows hackers to infect thousands of computers in just a few minutes with the same Trojan or different ones, as attackers have the ability to change the Trojan they use based on multiple parameters such as the victim’s location, the operating system used, etc.”⁴²
- In March 2013, Kaspersky Labs reported that a new spyware attack on Tibetan freedom activists used a Trojan designed for the Android mobile-phone operating system.⁴³
- The Flashback Trojan had infected more than 600,000 Macintosh computers by early April 2013 by exploiting a flaw in Java.⁴⁴
- In April 2013, criminals sent out invitations to watch video footage of the Boston Marathon bombings. A remote-access Trojan was installed as a “WinPcap Packet Driver (NPF)” to evade notice.⁴⁵
- In May 2013, Graham Cluley of Sophos reported on a Trojan (Mal/BredoZp-B) circulated in an email supposedly from Tiffany & Co. that claimed to include details of an export license and a payment invoice.⁴⁶

A Trojan tries to look useful or interesting so that users will install it, but buried within is unauthorized, undocumented code for unauthorized functions, just some of which are listed here:

- Deleting files or folders or entire drives
- Changing data, in subtle or dramatic ways
- Encrypting data (possibly for purposes of extortion)
- Copying data to other computers (possibly for purposes of industrial espionage)
- Downloading files without user consent (possibly for purposes of illicit e-commerce, illegal file sharing, pornography site hosting, cheap storage)
- Corrupting browser software and network files to redirect user from legitimate Websites to fake, bogus, malicious sites
- Enabling remote access to the compromised system (sometimes referred to as a RAT, for Remote Access Trojan), often used to turn computers into zombies that can be aggregated into botnets (for the purposes of spamming, phishing, and executing denial-of-service attacks)
- Aiding the spread of viruses using dropper code to cause infections

20 · 34 SPAM, PHISHING, AND TROJANS: ATTACKS MEANT TO FOOL

- Disabling antivirus and firewall programs
- Disabling competing forms of malware
- Logging keystrokes to obtain data such as passwords and credit card numbers
- Reporting browsing activity (enabling spyware)
- Harvesting email addresses for the purpose of spamming and other activities such as phishing

The motives behind Trojan code typically fall into one or more of three categories: malice, bragging rights, and financial gain. The gains can be realized in several ways. Purloined data can be sold. Access to compromised machines can be sold. Encrypted or stolen data can be ransomed. Denial-of-service threats can be used for extortion. Some companies have even used Trojans to try to increase the sales and installed base of their software.

20.6.2 Basic Anti-Trojan Tactics. Unfortunately, Trojans can be tough to combat. The first line of defense is well-educated users who know better than to execute code of dubious origin. Warnings to this effect should be part of any computer security awareness program, and a computer security awareness program should be part of every enterprise security model. Technical measures can be used to combat Trojans, but because none of these is perfect, it makes no sense to rely on them to the neglect of end user education. In fact, thinking of end users as *computer operators* rather than *computer users* might be a good place to start, given that the role of user implies a relatively passive role in maintaining the integrity and health of a computer, whereas operator reflects more accurately the level of responsibility required of anyone employing a computer in either work or recreation. (A computer user might be likened to someone who merely drives a car and never checks the oil or the tires; an operator is closer to a commercial driver who knows that getting safely and reliably from A to B takes a lot more than just holding the steering wheel and pressing the correct pedal.)

Technical measures against Trojans start with keeping all operating system and application patches up to date, universal use of memory-resident antivirus software that scans incoming files, and regular scanning of the entire system against a regularly updated virus database. At the same time, it helps to run memory-resident antibot software, such as Norton AntiBot, designed to recognize and thwart activity indicative of botnets. This software does not directly prevent Trojans from getting onto a computer, but it minimizes the damage that a Trojan can cause.

A good antispam solution is also necessary because spam is a major vector for Trojan attacks. If Jim in accounting never gets that message about the cool screensaver, he will not ever be tempted to open the attached file. It is not just screensavers that can be tempting. In April 2007, spam techniques were used to distribute, on a massive scale, messages with subject headings like “Worm Alert!” and “Worm Detected.” The messages came with a ZIP file attachment that posed as a patch that would prevent the bogus attack. When recipients, alarmed into action, went to open the ZIP file, they found that it was password protected, and some took that as a sign it was genuine. (The password was included in the message.) Proceeding with installation led to a rootkit, disabling of security software, theft of confidential information from the affected machine, and enrollment in a botnet of compromised computers. In one 24-hour period, Postini counted nearly 5 million copies of this Trojan spam directed at users of its antispam service. The company calculated that this one spam accounted for 87 percent of all malware being spread through email during that time.

20.6.3 Lockdown and Quarantine. More drastic anti-Trojan measures include preventing unauthorized changes or additions to executables and preventing systems from connecting to networks until they have been vetted. The idea of defeating malicious executables by freezing the operating system, and authorized applications in a known good state, goes back a long way, at least to the early days of antivirus efforts. However, the complexity of most operating systems and application code to-day makes such an approach challenging at best. Consider the emergence of Patch Tuesday as a standard means of maintaining the world’s most widely used operating system. Indeed, for many years now, a lot of software development has been predicated on the assumption that patches and updates can always be pushed out if needed, arguably leading to far less rigor in coding practices than when production code was burned to disk, at considerable expense, and changes required further shipments of disks.

The idea of quarantining computers when they attempt to connect to a network, using some form of network access control, offers a slightly different approach to the idea of locking down machines so that unauthorized code cannot be installed. Some enterprise network security managers have pursued this approach because it is increasingly difficult to control some network end points, such as the company laptop that travels with the employee to client sites and conferences, hotels, and WiFi hot spots, even spending time in the employee’s car and home. Laptops used in this manner face any number of attack vectors. Traditional defense mechanisms can be applied to these end points, including password protection, biometric authentication, disk encryption, and antivirus programs. However, these may not be enough, as many enterprises have discovered to their cost. So why not prevent these machines from connecting to the enterprise network until they have been scanned for unauthorized executables, like a routine health check? This approach holds promise but is not easy to implement. Furthermore, it leaves machines open to attack while they are away from the corporate network. A spam-distributed phishing exercise or screensaver Trojan could still lobotomize an end point between checkups and compromise confidential personal or corporate data. As you can see from Exhibit 20.5, a table compiled by Symantec in 2011 to show prices paid for various forms of data in the underground economy in 2009 and 2010, the financial incentives for such activities are real.

EXHIBIT 20.5 Table of Prices Paid for Data Traded in the Underground Economy⁴⁷

20.7 CONCLUDING REMARKS. The threats addressed in this chapter are still evolving, as are the countermeasures discussed here, although some of those mentioned may be rendered obsolete by new developments. If there is one lesson security professionals can learn from studying the threats discussed herein, it is that continued failure to improve the underlying security of Internet email will prolong the onslaught of spam, phishing attacks, and Trojans. The second lesson is that we must continue to educate computer users in order to prevent them falling prey to the deceptions of computer abusers. A third lesson might well be that more effective prosecution of computer criminals is needed, along with stiffer sentences.

21.1 INTRODUCTION. This chapter systematically reviews the primary software components that make up Web applications, with a primary focus on e-commerce, and provides an overview of the risks to each of these components.¹ The goal of this chapter is to point out that every system will have risks to its security and privacy that need to be systematically analyzed and ultimately addressed.

21.2 BREAKING E-COMMERCE SYSTEMS. To make a system more secure, it may be advisable to break it. Finding the vulnerabilities in a system is necessary in order to strengthen it, but breaking an e-commerce system requires a different mind-set from that of the programmers who developed it. Instead of thinking about developing within a specification, a criminal or hacker looks outside the specifications.

Hackers believe that rules exist only to be broken, and they always use a system in unexpected ways. In doing so, they usually follow the path of least resistance. Those areas perceived to provide the strongest security, or the most resistance to hacking, will likely be ignored. For example, if a system uses Secure Sockets Layer (SSL) to encrypt Web sessions between Web clients and the Web server, a hacker will not try to

21 · 2 WEB-BASED VULNERABILITIES

break the encryption stream but instead will look for an easier way to get at the data after they are decrypted and stored in the clear.

Hackers go where the money is—sometimes literally, sometimes not. They typically try to hack into a site only if there is some reward for their effort. Sometimes hackers are motivated by money, but as often the motivation is the lure of fame, notoriety, or acceptance by a peer group. The level of protection should be commensurate with the value of the resource being protected. For instance, a Website that publishes the menus for local restaurants may not be seen as a target for a denial of service or any other type attack. Such a Website simply is not as attractive a target as a bank's online Website, where a hacker can certainly gain in notoriety and even profit financially. Similarly, most people do not bother encrypting email messages due to lack of security awareness, and because most potential snoopers are not interested in ordinary personal email. Sensitive email from a high-profile organization should be encrypted, however, in order to protect valuable intellectual capital.

It is important to remember that the e-commerce system is a chain that is only as strong as its weakest link.² Hackers naturally attempt to attack that point of least resistance. This explains why a site may deliberately set up a honeypot (a sacrificial system) with appealingly vulnerable services in order to track and monitor potential hackers. In e-commerce, or any systems with a Web presence, cryptography often is perceived to provide the strongest level of protection; thus, hackers generally attack host-side services and client-side content.

Maintaining strong host security, both inside and outside the perimeters, is critically important. One unfortunate side effect of corporate perimeters is that system administrators tend to overlook host-based security, which may leave the host completely vulnerable. The result is that once hackers make it through or around perimeter devices and policies (e.g., firewalls, routers, or even receptionists), they can leverage the internal trust relationships to compromise many resources, including workstations, servers, and phone systems. The prudent administrator will exercise equal concern both at the entry to systems and within those systems.

21.3 CASE STUDY OF BREAKING AN E-BUSINESS. Consider an online investing e-business application and how a hacker might go about disassembling its security for malicious or financial gain. Online investing is very popular for several reasons. Rather than waiting for quarterly statements in the mail or dealing with a phone menu, customers can quickly view the status, balances, and current value of investment holdings by visiting the Web pages of their portfolio managers. If they wish to buy and sell equity shares on demand, they can establish online Web-enabled brokerage accounts. Exhibit 21.1 shows a simplified workflow diagram of an online investing application that enables users with established accounts to view portfolio holdings and cash balances, to update the stocks tracked, and to conduct online trades.

To see how this application can be broken, it is helpful to look at a sample network architecture that implements the online application. Exhibit 21.2 shows the network architecture of the system that implements the online investing application, along with example exploits. The system consists of the end users' client machines, the Internet, routers, firewall, front-end Web and email servers, application servers, databases, and workstations.

There are many ways a hacker could break this online application. Exhibit 21.2 shows one possible scenario. In step 1 of the attack, the hacker uses the Internet and a Web browser to misuse one of the Common Gateway Interface (CGI) scripts that invoke the application on a server. The CGI script could be a development CGI script

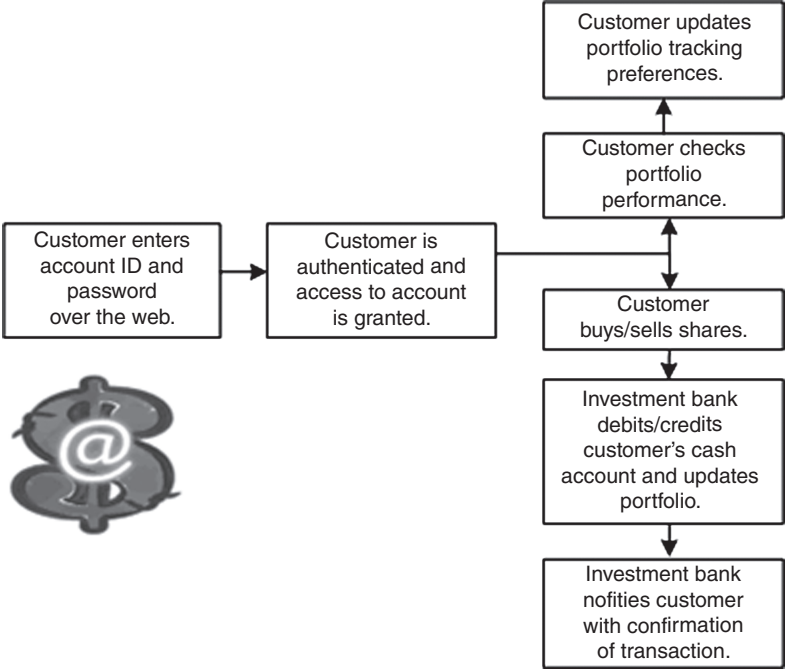

EXHIBIT 21.1 Online Investing Application

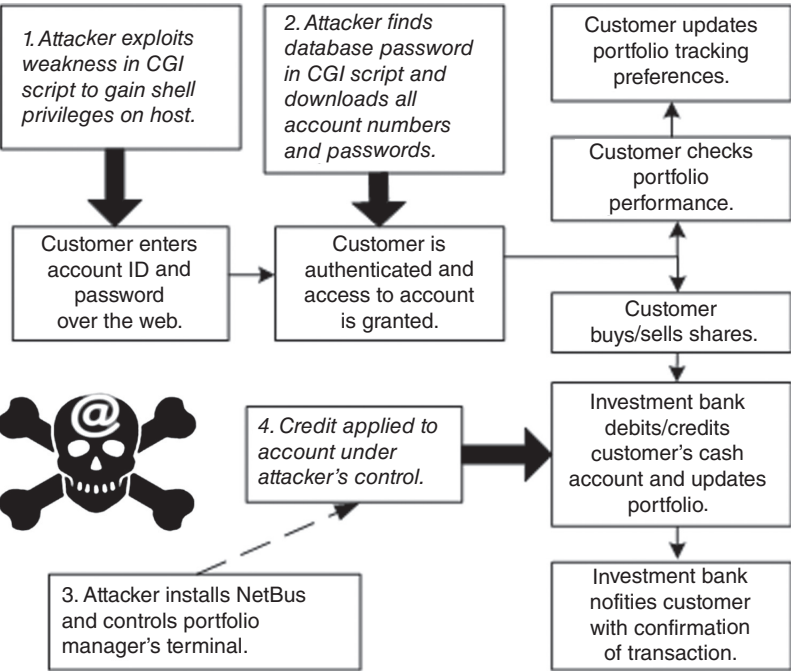

EXHIBIT 21.2 Breaking an E-Business

21 · 4 WEB-BASED VULNERABILITIES

inadvertently left on the server before going into production, a default CGI script from an application server distribution, or a script that implements flawed logic in the online investment application. Exploiting CGI scripts via cross-site scripting or other common exploit methods allow hackers to gain shell access to Web servers. CGI script vulnerabilities are discussed later in this chapter.

The vulnerability need not be in a CGI script. Application servers can be implemented in Java, C, C++, Perl, or Python in various application server frameworks. The difficulty lies not in which language the business application logic is developed; more important are the vulnerabilities introduced by the complex logic at this middleware layer. One of the key problems in the development of application middleware is poor input sanity checking; that is, the developers fail to impose limits on acceptable input. The hacker can exploit the lack of input sanity checking to feed the application server unexpected input used in system commands. This technique can gain shell privileges on the machine.

Although application server misuse is a common way of breaking into systems, there are many other ways to gain the initial access in step 1 of the attack. For instance, the Web and mail servers may be running any of several network services, such as *FTP* and *BIND/DNS*, which may be misconfigured and thus “poisoned.” The Web and mail server software themselves may be vulnerable to attack. Many popular commercial Web and mail servers have been vulnerable to buffer overflow attacks that often permit full system root privileges on the host.³ Once attackers gain system privileges on an internal host, they can exploit the inherent internal trust often woven among machines through network policies in order to gain access to other systems on the network. This strategy is precisely what the attacker follows in step 2 of the attack illustrated in Exhibit 21.2

Once attackers have access to the various file systems on the application server, they can view source code of CGI scripts or other application middleware to discover customer account numbers, passwords, and even database administrator passwords for accessing the back-end databases. From there, they can download important and confidential client information stored in the database. In step 3 of the attack, the attacker leverages the internal privileges gained to plant backdoors into the system unnoticed. A suite of software, commonly known as a rootkit and available to hackers, allows them not only to get into a system unnoticed but also to erase their tracks in audit logs. In the example shown, the hacker installs a rogue remote administration program known as Back Orifice, which provides the ability to remotely administer the host and network with the same privileges and power as an authentic system administrator.

At this point in the attack, the hacker has assumed total control of the systems and any Web-facing or commerce-related processes, with many options including:

- Stealing customer or company information for the purpose of financial gain
- Defacing the Web pages for notoriety or to publicize an agenda
- Working in a stealthy manner to uncover proprietary business information and other confidential intellectual capital (espionage)
- Blackmailing the business with threats of discrediting it
- Subverting the application for any other personal gain

Step 4 of the attack illustrates the last case, where the attacker credits a personal cash account. The hacker must move quickly enough to withdraw these funds before traditional back-end auditing discovers the discrepancy. There have been many defaced

Web pages of government agencies, and other important sites, and many reported instances of the other cases. Of course, some companies are understandably reluctant to publicize events that might lessen customer confidence, yet in many cases, legislation now requires the disclosure of a breach.

Unfortunately, it takes only a single flawed, unpatched computer, or overlooked vulnerability, for a hacker to compromise a system as a whole. Although *defense-in-depth* (using multiple forms of security, such as firewalls on the perimeter and intrusion detection inside the network) is a popular strategy, often multiple layers of defense fall like a house of cards when a single hole is exploited. For example, an attacker who gains *root* capability can disable all other security measures. The problem is known as an *asymmetric* attack because it is much more difficult and costly to defend against such an attack than to launch one. Although a committed hacker may be capable of spending as much time as is needed to break into a system, a company cannot spend as much money as needed to defend itself against all possibilities.

The number of flaws that can be exploited is staggering, considering all the different platforms and devices that make up current information technology (IT) infrastructures. Compounding the problem is the fact that a hacker can work in relative anonymity using a \$500 computer and modem to launch attacks. Even worse, hackers can work from any number of Internet kiosks available in airports, malls, cafés, and even laundries. As hackers get more sophisticated, and as more easily utilized scripts become available, attacks will be launched from mobile devices that can roam in and out of different geographic zones and then be discarded—making tracking of the attacker next to impossible.

21.4 WEB APPLICATION SYSTEM SECURITY. In spite of the fairly bleak picture painted here, organizations can effectively manage their risk from hackers. As in many other security domains, the security posture or stance assumed by the organization is critical for deterring and thwarting hackers. To use a physical-world analogy, consider burglars who intend to break into homes in a nice neighborhood. As the burglars scope out potential targets, they will notice some houses with burglar alarms—complete with conspicuous signs of the alarm systems—and some without. In all likelihood, the burglars will bypass the houses with the burglar alarms and move on to the other, less well-protected targets. Thus, the security stance assumed by the owner plays an important role.

Every organization must first determine its desired security stance as documented in its security policy. System administrators use the security policy to configure the systems, routers, firewalls, and remote access solutions. Without an explicit security policy, there is no way to determine what the security stance of the organization is, how to configure its systems, or even if a nonobvious security breach has occurred. Once the security policy is developed, the actual security implementation must be assessed. That is, the system must be tested and evaluated to determine how well it meets its security policy. Usually there is a difference between the desired stance and the actual stance. This difference is the security gap between where the organization would like to be (secure against particular threats) and where it actually is in practice.

The process of developing a security policy and evaluating the organization's systems against that policy will identify not only the gaps between the actual security stance and the desired posture but also weaknesses in the security policy itself. It is important to have an independent party, preferably an outside party, evaluate the security stance of the organization. A third party can fairly assess whether the organization's system upholds the security policy. If the group that develops the security policy or the system

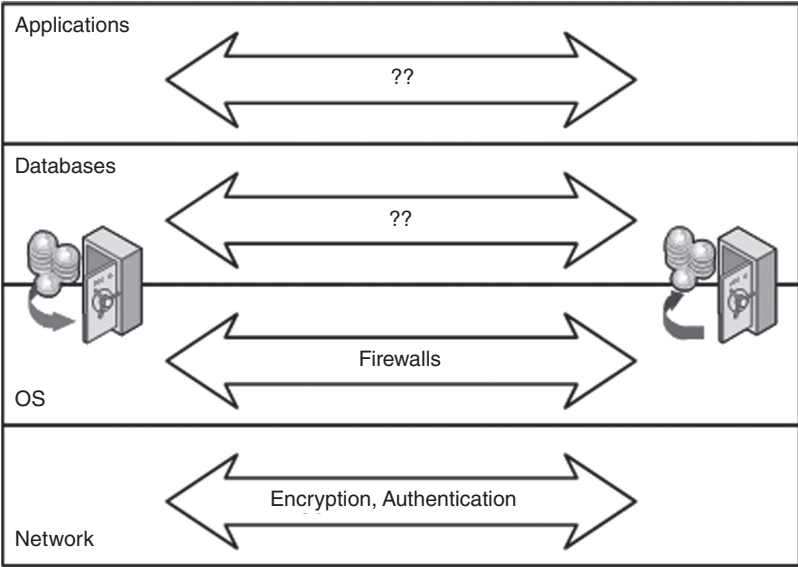

EXHIBIT 21.3 Layered View of an E-Business Application

configuration is also responsible for evaluating it, the evaluation may be biased, and potential vulnerabilities may be overlooked. This may occur not through ill will or dishonesty but rather because of the difficulty of being objective about one's own work.

21.5 PROTECTING WEB APPLICATIONS. Web application security can be understood from different views. First, consider the view of e-businesses in Exhibit 21.3. The diagram shows two e-businesses communicating over the Internet, perhaps performing business-to-business types of transactions.

In this view, the lowest layer of the e-business is the *networking layer*. At the networking layer, there are concerns about the reliability, integrity, and confidentiality of the data that runs over the communications channel. This layer is of particular concern because the Internet is a public switched network, meaning that any number of third parties may have access to the data that traverses the nodes of the Internet on the way from the data source to its destination. Also, the Internet Protocol (IP) is a connectionless protocol, which means there is no dedicated circuit between source and destination. As a result, packets sent during a given session may take different routes to their destination, depending on traffic congestion and routing algorithms. Because IP is an unreliable datagram protocol (i.e., IP uses independent packets forwarded from node to node, but there is no guarantee of successful transmission), the networking layer includes a connection-oriented reliable transmission layer such as Transmission Control Protocol (TCP) that ensures that dropped or lost packets are retransmitted and that bit flips that may have occurred during transmission (e.g., over wireless networks) are corrected.

Although TCP/IP provides for more reliable delivery of Internet packets, IP version 4 does not provide *secure* connection services. Typically, this means that there is no *guarantee* of confidentiality, identification, or even delivery of packets sent from one Internet host to another. Because packets often traverse several Internet nodes from source to destination, packet contents can be intercepted by third parties, copied, sub-

stituted, or even destroyed. This is the risk that most people citing risks of e-commerce have decried; they have overlooked the more substantive risks of e-commerce dealing with server- and client-side security and privacy. IPv6 holds promise to bring many security improvements to the network layer, but it has not been deployed widely in the United States. Fortunately, even in IPv4, we have good solutions to the data confidentiality problem. Cryptographic techniques can provide strong guarantees for data confidentiality, authentication of parties, and integrity of data sent during the transmission. Furthermore, digital signatures can be used to sign received mail in a “return receipt” application that provides guarantees of delivery of email. Thus, as shown in Exhibit 21.3, we can use encryption services to protect data transmitted over the network.

The operating system (OS), or *platform*, that hosts the Web applications lives on the networking layer. In a layered model, the services of one layer use the services of the lower layer and provide services to upper layers. The network layer often is thought of as a core portion of the operating system; however, from a layered services point of view, the OS software runs on top of the network layer.

Operating systems are notoriously rife with software flaws that affect system security. Operating systems are vulnerable because commercial OSs today are immensely complex; for instance, the Windows Vista operating system is purported to have more than 50 million lines of source code. It is impossible to catch all software design and programming errors that may have security consequences in a platform this complex. Even though UNIX operating systems have been in use for the better part of 30 years, new flaws in OS utilities are found on a weekly basis across all the different UNIX platform variants.⁴

Security holes in the platform are critical by nature. That is, if the OS itself is vulnerable to exploitation, security provided by the application can be compromised by holes in the platform. The OS is always the foundation on which applications are built, so cracks in the foundation make for weak security at the application layer. As Exhibit 21.3 suggests, firewalls provide protection against some operating system flaws. One of the key roles of firewalls is their ability to shut down services offered to *logical domain addresses*.

Using Internet domain addresses, the firewall administrator can partition Internet addresses into *trusted* and *untrusted* domain ranges. For instance, any Internet address outside the company’s domain can be considered untrusted. As a result, all OS services, such as remote logins, can be shut down to everyone outside of the company’s domain. Even within a company, the domains can be partitioned so that certain *subdomains* are trusted for access to certain machines, but others are not. The key benefit then of firewalls is their ability to restrict access to the platform through *offered services* (i.e., specific functions that pass data through the firewall). As a result, firewalls can make it easy to hide OS flaws from untrusted entities.
