Even so, firewalls are vulnerable to data- or code-driven attacks through offered services. These are sometimes called “allowed path” vulnerabilities. For instance, an attack through SMTP (mail) or HTTP (Web) will not be stopped by a firewall if the firewall is configured to let email and Web services through, as is necessary for e-commerce. Firewalls also will not stop OS exploits from insiders or from the trusted entities that are granted access to the platform. However, it is important to realize that firewalls, if properly configured, can close down exposure to a significant number of platform vulnerabilities simply by denying untrusted outsiders access to platform utilities and services. Exhibit 21.3 illustrates reasonable protection from network- and platform-based attacks but not from application and database attacks. The database

layer is shown separately in the diagram because of the importance of its role in e-commerce; however, database attacks usually can be considered as a type of application attack.

Application-based attacks represent a critical issue that is gaining more attention in recent years. There is no simple solution, but there is a growing sense that the security provided by a firewall, an SSL-enabled Website, and encryption, together with digital certificates and signatures, is not enough. These measures are necessary but not sufficient. Applications, above all, *are* the online business. The Payment Card Industry Data Security Standards (PCI DSS) puts any organization processing credit card transactions on notice that Web application vulnerability protection was required as of June 2008. The PCI DSS specifies either “having all custom application code reviewed for common vulnerabilities by an organization that specializes in application security” or “installing an application layer firewall in front of Web-facing applications.”⁵

Online applications are increasingly sophisticated, and the software that implements the application logic has become highly complex, requiring component-based and object-oriented paradigms such as Enterprise Java Beans, CORBA, and DCOM/COM services. Collectively, these are known as *application servers*. The key point, however, is that because the application logic is custom and complex, it is often rife with errors in implementation or logic that can be and often are exploited by hackers.

Application security must not be confused with marketing claims. A secure online application is one that is resistant to attacks. It is not simply one that authenticates end users, encrypts transaction data, provides nonrepudiation of transactions, and guarantees service. These are all matters of importance that address characteristics of the transaction, not properties of the software. The remainder of this chapter addresses the software problem in some detail. The next section provides a different view of e-commerce systems from the layered view discussed previously. It identifies vulnerabilities in the different software components and strategies for managing the risks.

21.6 COMPONENTS AND VULNERABILITIES IN E-COMMERCE SYSTEMS. Exhibit 21.4 shows a generic multitier architecture of an e-business, together with a summary of the types of vulnerabilities and risks to each of the major components. Using the Internet, Web clients (running on PCs or handheld devices) interface with a front-end Web server, a middleware layer of business application logic, back-end databases, an ERP system, supply-chain management software, and even some legacy systems that are now brought to the Internet.

21.6.1 Client-Side Risks. Most e-commerce is performed using standard Web browsers and mail clients. Increasingly, e-commerce is being performed on handheld mobile devices such as personal digital assistants (PDAs) and mobile phones. The security risks particular to wireless devices are covered in Chapter 33 of this *Handbook*. Client-side security risks are mainly from malicious mobile code such as Web scripts, ActiveX controls, and hostile Java applets.⁶ Another major risk in client-side software is loss of privacy.⁷ Each computer, with its related software, receives and transmits a great deal of personal identifying information (PII). For instance, browsers may convey information about the computers (name, IP address, browser type, version, company name) and sometimes about the users themselves, particularly if automatic form-filling features have been enabled. Browsers also are used to track movements through the Web. For instance, every Website the browser visits typically gets a record of the previous site from which the user entered. Banner ads in Web pages also track which sites have been visited in order to create a profile of Web usage, and cookies can be

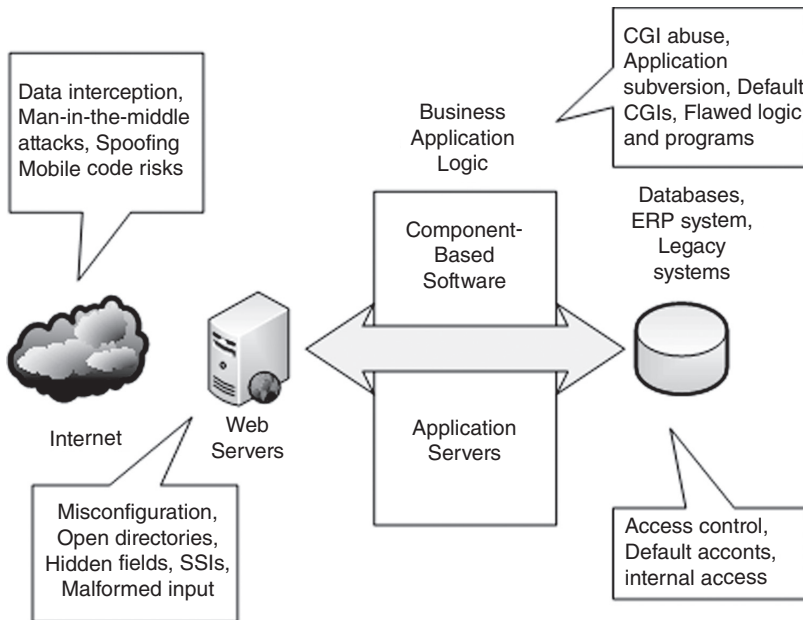

EXHIBIT 21.4 Multitier Architecture of an E-Business

placed on end-user systems for the purpose of tracking and at times re-creating user input.

A class of more insidious programs, known as *spyware*, can send information about computer usage out to specific sites, often without the user's knowledge or approval. One of the key risks with client-side software is that users simply do not know what the programs are revealing about themselves, or to whom. A simple principle is that a program should not be sending out any data that the user does not know about. An audit of the programs on any given machine probably would reveal that quite a few are in violation of that principle. Although most spyware programs are written to provide marketing data for software vendors or to redirect a user to predetermined sites, many manipulate and target users more effectively by spying on usage activity and even installing additional malicious code. For example, SpectorSoft markets a spyware tool known as eBlaster to people who suspect their spouses are engaging in illicit online affairs. This type of spyware program spies on user activity, from keystrokes to screen shots, and sends a log of the activity out over the network to a predetermined logging site. Spyware can be identified using diagnostic programs such as Ad-Aware from Lavasoft (www.lavasoft.com), but because of the dynamic nature of spyware technology, it may be difficult to identify all possibilities of infection.

A final client-side risk that businesses need to be especially concerned about is the risk of malicious executables that run on their user workstations. The desktop machine is like a petri dish for software: It is constantly changing and growing with new software executables—some of an unsavory nature. Malicious software, or *malware* as it is now known, finds many ways of infecting machines. For instance, one common way of disseminating malicious software is via email attachments. Another is by masquerading as legitimate software on a Web page available for download. Users often upload and download software to and from internal network file shares. In addition, USB “thumb drives” and even old-fashioned floppy disks are still a viable way of transmitting

malicious software. The Back Orifice “remote administration kit” is a well-known example of malicious software that, when installed, will allow anyone—including a hacker—to administer and control a machine remotely. Some malware products, running on an internal machine, may compromise the entire network because a remote hacker can control a trusted resource, possibly with enterprise administration rights. Data leakage and theft offered by the initial spyware infection can result in incidents that might undermine the integrity, authenticity, availability, or auditability of an entire data infrastructure. It is essential, therefore, that corporations carefully filter and closely monitor the application software that is downloaded and run (with or without the user’s knowledge) on all systems from the e-commerce perimeter to the individual internal hosts.

21.6.2 Network Protocol Risks. Network risks primarily arise from sending confidential data over the Internet—a public, packet-switching network. Many good protocols address the risks of sending confidential data over the Internet.⁸ In fact, a few years ago, the list included:

- SET
- SSL
- S/HTTP
- S/MIME
- CyberCash

Although some of these protocols are still around in one form or another, the industry has generally accepted SSL as the protocol of choice for secure Web browser transactions. The objective of most secure network protocols is to layer security properties on top of the TCP/IP network layers. Although TCP/IP provides reliable and robust delivery of datagrams over the Internet, it does not provide confidentiality, authentication, or strong message-integrity services. These are the properties that secure protocols provide. Some go even further. For instance, SET-compliant protocols leave the credit card number encrypted even at the merchant site. Since the merchant does not need to know the consumer’s credit card number, by hiding the number from the merchant, a significant portion of credit card fraud can be eliminated. Rather than decrypting the credit card number at the merchant site, it is passed in encrypted form from the merchant to the credit-issuing bank. There it is decrypted, and the merchant’s account is credited the amount of the purchase. The protocol details of SET, SSL, and other e-commerce protocols are described in Chapter 3 of this *Handbook*, in *E-Commerce Security: Weak Links, Best Defenses*, and in other books as well.⁹

Depending on the needs of an online business application, there is a requirement for more or less of the security properties afforded by secure protocols. For most Web browsing, a secure protocol is unnecessary; the standard Web protocol, HTTP, suffices. However, when customers send confidential or personal information to a site, a secure protocol that encrypts the data is preferable. The de facto secure protocol standard is SSL, now implemented in every standard Web browser. SSL will not only negotiate a secret session key between the Website and a client to encrypt the data, but it also will authenticate the Website. The Website must have a valid certificate endorsed by a Certificate Authority, which the users implicitly trust. Using a list of trusted Certificate Authorities maintained within the client browser, access can be prevented to other, untrusted sites. Once the connection is established, the user can verify that the Website

is, in fact, the one intended by examining the site certificate. Users rarely do this in practice, but the certificate is available and should be more widely utilized.

These secure properties—that is, encrypted sessions and host site authentication—serve the purpose for most online commerce applications. Some applications, though, may demand even stronger security services. For instance, banking and investment applications often transmit highly confidential information, with the possibility of huge financial losses through inadvertent error or intentional fraud. These types of transactions require not only confidentiality of the data, but also authentication of the client. A financial institution must never give access to account information or permit transactions without authenticating the user.

Common identification schemes on the Internet include simple user name and password authentication. A much more secure solution is to require strong client authentication using client certificates. SSL supports client certificates, although sites rarely use this capability because it involves requiring customers to obtain a certificate from a Certification Authority.

In the future, e-commerce protocols will need to be increasingly sophisticated if they are to meet the stringent security and privacy requirements of new Internet applications. For example, as criminal, medical, patent, and other important databases migrate to the Internet, the protocols developed for accessing them need to consider the security and privacy needs of the database owners and maintainers, as well as those of the client or requester. Today, the progress in genomics is producing much information about the likelihood of developing deadly disease based on a genetic DNA sequence. This knowledge raises moral and ethical questions as to how much information about potential diseases should be revealed to doctors and patients, and also raises the specter of such information getting into the wrong hands once it is accessible on the Internet.

Consider the case of a doctor querying an online genetic disease database with a patient's DNA sequence. The online application attempts to match the DNA sequence with diseases that might develop in the future. If the database were maintained by a commercial entity such as an insurance provider, the patient almost certainly would not want the company to know of any disease that might be returned as the result of a query, because that information could be used to deny both insurance and employment.

Likewise, the database maintainer probably would not want to know of the query or of its result, as such knowledge might put it at risk for lawsuits, should the information be leaked. Furthermore, the database maintainer would want the rest of the database to remain inaccessible except for specific results returned to an approved inquiry. Preventing access to any other information in the database would help to protect the commercial interests of the company, because then the database could not be duplicated easily. Nor could queries be made without a cost-tracking mechanism. To support this dual model of secure and private information access, e-commerce protocols need to be developed and commercialized that not only encrypt data in transmission but also consider the total security and privacy needs of both parties to the transaction.

Another e-commerce application area that will require better security and privacy protocols involves applications that accept e-cash or digital coin payments. Currently, most online payment schemes use either credit or debit cards, with payments made from the buyer's checking account at a bank. Payments are made either with online verification of funds or with off-line batch payments at the end of the day. A number of applications, particularly those involving payments of a few dollars or even pennies, are being created that cannot support the costs of a bank-based transaction.

Many commercial services and products, such as vending machines and parking meters, are coin activated and do not require customers to have an account or a line

21 · 12 WEB-BASED VULNERABILITIES

of credit. Although efforts are being made to convert such services to computerized devices, with micropayment capabilities, it will be many years before this is actually accomplished. In any case, there will always be customers who want to pay with cash or its electronic equivalent, so that the transaction cannot be tracked by a third party, such as a bank or a creditor.

Newer online applications for micropayments may include collecting fees for downloading music, data, weather reports, stock quotations, articles from magazines, and pages from books. Many of these applications are provided today without charge and supported by banner advertising, but a concern for profits is motivating most Websites to seek additional sources of income. Whatever the application, there is a need for cash-based alternatives to the current account-based system for making payments. The key security and privacy concerns are with ensuring that e-cash is properly spent and accounted for and that anonymity is preserved throughout. Several protocols have been developed with these goals in mind, but none has reached commercial success or adoption by the vendor community. As mobile e-commerce begins to drive more traditionally cash-based transactions (e.g., parking meters, vending machines, and ticket booths), wireless vendors may adopt these new digital cash-based protocols.

Regardless of the network protocol used in an e-commerce application, the key concern is for those attackers who will attempt to breach the easiest obstacle in their quest to obtain system privileges and unauthorized access to data. If the security provided by the network protocol is perceived to be strong, attackers will look for alternatives that bypass the network security. For instance, these types of standard attacks from the hacker's toolkit will bypass the security provided by most e-commerce protocols:

- **Man-in-the-middle attacks.** Capturing transmissions in transit for eavesdropping or forgery
- **DNS attacks.** Altering records in the worldwide Domain Name System to misdirect connections to the wrong addresses
- **War dialing.** Automated testing of every phone number in a block of numbers
- **Exploiting software vulnerabilities in network services.** Such as FTP, Bind, SMTP, and HTTP servers
- **Internal access.** Improper use of authorized access by an insider (employee, contractor)
- **Leveraging trusted hosts.** Attacking from another system that has a privileged relationship with the target system
- **Brute-force crypto attacks.** Automated testing of all possible decryption keys to decipher a ciphertext

In summary, it is important not only to select the appropriate network protocol for each online application but also to avoid a false sense of security that might arise from use of a “secure” network protocol. Good security engineering will consider vulnerabilities in other components of the system that are more attractive targets to determined hackers.

21.6.3 Business Application Logic. The business application logic pictured in Exhibit 21.4 represents one of the key areas of vulnerability in e-commerce systems. The program logic encodes what the online business is offering in terms of products,

services, and customer convenience. It also defines the look and feel of the Website and provides all of the interactive features, such as dynamic Web pages, personalized Web pages, and online transaction capabilities. Because each application is unique, the software that implements the logic must be, in many cases, custom-developed for each particular site.

In contrast, most of the other software components of a Website are commercial off-the-shelf (COTS) software. For instance, the Web server, back-end databases, and supply-chain logistics software are often purchased off the shelf from software vendors. With COTS software, the end user has no control over the code and therefore is not responsible for coding bug fixes. When software bugs in COTS software are discovered, the software vendor usually issues a patch or incorporates a bug fix in the next release version. Software vendors can fix discovered bugs, but they depend on customer sites to actually apply the patches or upgrades to the software. In practice, this occurs less often than desired and is a significant reason why many Internet-based systems are vulnerable.¹⁰ The most important task in securing COTS software systems is to make sure that: (1) they are properly configured for a secure installation according to the site's security policy, (2) the software is properly updated to the current version and patch level, and (3) administrators are aware of the risks associated with bugs in the software.

Because many business applications are custom-developed, either by an in-house staff or by outsourcing to an e-business developer, the programs represent a key risk for several reasons. The dynamic, interactive nature of e-businesses, coupled with increasingly sophisticated online services, requires a significant amount of development to code the logic. As a result, the application programs tend to be very complex pieces of software, likely to contain flaws, and susceptible to the kinds of attacks launched against Websites. In practice, errors in design and implementation of business application logic often compromise the security of an e-business.

Traditionally, the middle tier of software is implemented on Web servers using CGI and more recently PHP: Hypertext Processor (PHP). CGI and PHP scripts are programs that run on the Web server machine as separate processes from the Web server software. The Web server invokes these general-purpose programs in response to user requests. The CGI/PHP script's main function is to process user input and to perform some service, such as retrieving data or dynamically creating a Web page for the end user. Because CGI and PHP scripts process untrusted user input, the security risks associated with them and other forms of middle-tier software are extremely high. Many attacks against Web-based systems are implemented by exploited CGI/PHP scripts. And while CGI and PHP scripts can be written in any general-purpose programming language, they are written most often in Perl, C, Tcl, and Python.

More recently, component-based software (CBS) is making inroads in e-commerce applications as well as in standard Web applications. The purpose of CBS is to develop, purchase, and reuse proven software in order to implement application logic quickly, easily, and with high quality. Two of the more popular component frameworks for e-commerce applications are Enterprise JavaBeans (EJB) using XML and Java 2 Enterprise Edition (J2EE), which supports component-based Java. Other component models include the Object Management Group's (OMG) Common Object Request Broker Architecture (CORBA) and Microsoft's Common Object Model (COM) and Distributed COM (DCOM). These component frameworks are the glue that enables software components to use standard infrastructure services while hiding the details of the implementation by using well-defined interfaces.

Business application logic, when coded in CBS systems, usually runs on application servers with particular component models, such as EJB, CORBA, COM, and DCOM.

CBS also provides an interface to back-end services such as database management, enterprise resource planning (ERP), and legacy software systems.

In addition to supporting traditional CGI functions, component-based software is expected to enable distributed, business-to-business applications over the Internet. The component-based software paradigm also supports good software engineering, as described later. The Unified Modeling Language (UML) facilitates object-oriented analysis and design for component-based frameworks. In addition, as the market for component-based software expands, many standard business application components will be available for purchase off the shelf.

Although the benefits of component-based software are numerous, they pose security hazards similar to those of CGI scripts. Component-based software enables development in general-purpose programming languages such as Java, C, and C++, which can execute with all the rights and privileges of server processes. Like CGI, they process untrusted user input, and because component-based software can be used to build sophisticated, large-scale applications, the likelihood for errors may be even greater than for simple CGI scripts. Regardless of the implementation—CGI or application servers—the security risks of server-side software are great, and therefore server-side software must be designed and implemented carefully.

The key risks in the middleware layer of e-commerce sites are:

- Misconfiguration of the CGI
- Default and development CGI scripts being left on the production server
- CGI misuse
- Application subversion
- Flawed logic
- Programming errors

21.6.4 CGI Script Vulnerabilities. CGI scripts are frequent targets of attackers because they are often misconfigured and vulnerable to misuse.¹¹ When designing CGI scripts, it is prudent to expect the unexpected, particularly the malicious attack. Although the Web designer has control over the content of CGI scripts, there is no control over what end users are going to send to them. Also, often overlooked are vulnerabilities of CGI scripts that exist on the server as part of the distribution but that are not actually used in the application. Some CGI scripts, included as part of the Web server distribution, have well-known flaws that can be exploited to obtain unauthorized access to the server. Even if the default CGI scripts are not used as part of the Web server pages, anyone can access them by simply knowing the script names.

One of the most common—yet easily preventable—security hazards is misconfiguration of software, especially CGI scripts. One feature supported by many Web servers is the ability of individuals throughout an organization to write CGI scripts and have them execute from their own directories. Although useful for prettying up personal Web pages, this feature also can introduce system security hazards. In Web-based applications, the Web server should be configured to prevent CGI scripts from executing anywhere but in a single CGI directory under control of the system administrator.

The script-aliased CGI mode for Web servers ensures that CGI scripts will execute only from an explicitly named directory in the server configuration file. In addition, the CGI script path is not named in the Uniform Resource Locator (URL) to the CGI. Rather, the server “aliases” the explicit path to the CGI script to a chosen name, such

as *cgi-bin*. Thus, running the server in script-aliased CGI mode prevents rogue CGI scripts from executing while it also hides the explicit path to the CGI scripts.

The CGI script directories also should be properly configured using OS access controls. For instance, if CGI scripts are written in a compiled language such as C, the script sources should be excluded from the document root of the Web server, so that they cannot be accessed via the Web. They should be accessible to the system administrator or Web content development group only, and inaccessible to everyone else in the organization. If the script sources fall into the hands of malicious perpetrators, the source code can be inspected for flaws, making the perpetrator's job even easier. Access to the CGI executables directory, frequently called the *cgi-bin*, should be properly controlled as well. Only the Web server and administrator need access to this directory. Liberal access permissions to the CGI executables directory give those with malicious intent the opportunity to place their own scripts within the site.

Most CGI scripts are written in scripting languages such as Perl, JavaScript, and Python. Scripting languages are useful for rapidly prototyping systems, but they also let the developer write dangerous code very easily. For instance, it is easy to construct system commands with user input, a potentially dangerous situation. Writing the same system functionality requires several lines of programming code and knowledge of system libraries. The easy accessibility of scripting languages makes them appealing, but also threatening to security-critical applications. It is also important to prohibit access to interpreters from the Web server. For instance, system administrators may be tempted to include the Perl interpreter in CGI script directories; however, doing so provides direct Web access to interactively execute Perl commands—an extremely dangerous configuration.

Finally, administrators should account for every CGI program on the server in terms of its purpose, origin, and modifications. Remove CGI scripts that do not serve a business function, and view with suspicion CGI scripts that are distributed with operating systems and Web servers, downloaded from the Internet, or purchased commercially. These steps will eliminate most of the potentially dangerous CGI scripts. Once a stable set of CGI programs is established, make a digital hash of the program executables (e.g., using MD5 or SHA-1) to enable future integrity checks.

21.6.5 Application Subversion. Application subversion attacks are not discussed often in relation to e-businesses, but they represent a significant threat to most online applications. Application subversion is a form of program misuse. Unlike buffer overflow attacks, application subversion attacks exploit the program logic without violating program integrity, in order to elevate user privileges and gain unauthorized access to data. It is the very complexity of the target program that gives the attacker the means to gain unauthorized access. Application subversion attacks use programs in ways that the program's designers and developers did not anticipate. Typically, these attacks are not scripted, but rather developed from online interactive use and subsequent abuse.

Referring to Exhibit 21.1, an application subversion attack will attempt to discover ways of short-circuiting paths in the workflow. For instance, there may be a hidden path that lets the user gain access to account information without being authenticated to that account. Many such attacks work on the premise that access to confidential information is not properly authenticated.

Another common attack sends malformed input to a program. Many Web pages use forms extensively to drive the application, while the data input on the form is checked using client-side scripting. An attacker can take advantage of the fact that many online

application developers assume that the client is going to use the form properly and that the scripts will check all input sent to the site. The attacker can examine the data stream sent by the form and then, rather than using the form, send a modified data stream via URL within the browser or incorporating it into a custom command of the attacker's choosing. An attacker may be able to obtain access to the application by placing system commands in the input stream. If the input stream is subsequently used in a *system()* call by the online application, the end user may force the execution of system commands on the attacker's behalf.

Some application developers rely heavily on hidden fields in the HTML document. Hidden fields allow the Web developer to include information on the page that is not displayed, although the end user can see the hidden field data simply by viewing the HTML source. The mistake application developers make is, first, in believing that the end user cannot see the hidden fields, and, second, in relying on the integrity of the hidden field data for making online decisions. Some online merchants have made the mistake of including pricing information for items in the hidden fields and using those prices to determine the cost of the online transaction. The end user can simply change the pricing in the hidden fields and send lower prices back to the merchants, for a discounted purchase.

Another misuse of hidden fields is to redirect application output. For instance, some Websites include file system path information in hidden fields on their Web pages. This information is used by a server-side script to determine where to read or write transaction information. Attackers, simply by changing the hidden field, can overwrite files or read files to which they should not have access. In some cases, it may be possible to store a program entered in a form field to be used later as a means of running a privileged shell on the remote system.

In summary, rigorous software quality assurance is necessary throughout the design and development of all Web-enabled and e-business applications, including front-end Web pages, application middleware, and operating systems. Once the software is believed to be immune to application misuse and subversion attacks, the system administrator must perform other activities to ensure the security of the e-business middleware:

- All unnecessary scripts or application server programs must be eliminated from the production server.
- Source code of application middleware must be carefully guarded against download or unauthorized access.
- Proper configuration of the CGI and application middleware is necessary to ensure executable access only to the correct application middleware, with the lowest practical privilege level. Sanity checking of inputs to application middleware must be done to ensure that only well-formed input is accepted.
- Testing of application code with the use of programs such as WebInspect by SPI Dynamics (www.spidynamics.com) that are specifically designed to discover flaws within Web-based applications.

21.6.6 Web Server Exploits. Web server security has been written about and covered in detail, including in *E-Commerce Security: Weak Links, Best Defenses*¹² and *The Web Security Source Book*,¹³ among other titles. Here we highlight some of the common exploits of Web servers used against many e-businesses.

21.6.6.1 Configuration. The key to Web server security is its configuration. Like other complex pieces of software, Web servers are highly configurable to meet the needs of any given site. By default, most software vendors configure the software application for maximum functionality but minimum security. Thus, by default, when the server is first started, it is likely to be more permissive than any given company's security policy would like. The principal premise for configurability is in the variations that exist among sites.

A correctly configured Web server is the result of a policy that defines what access is allowed, to which individuals, for each resource. This policy, in turn, is used to configure routers, firewalls, and all public servers, such as the Web server. Configuring the Web server, while necessary, is by no means sufficient to secure the system. The discussion of application server exploits in Section 21.6.5 demonstrates this principle.

21.6.6.2 HTML Coding and Server-Side Includes. Once the Web server is configured as securely as possible, it is important to ensure that the Web pages themselves do not open holes in the security. Many Web page developers fall into some common pitfalls that may compromise the site's security. The preceding section mentioned the problem of relying on hidden fields in HTML for security or business-critical data. Users can abuse the hidden field data to subvert an application.

HTML offers other potential vulnerabilities. One that is most often criticized is *Server Side Includes* (SSI). The SSI configuration option, if enabled, allows directives to be embedded in HTML that the server will execute. For instance, if the next statement were embedded in an HTML document, it would direct the server to display the contents of the system password file:

```
<!--#exec /bin/cat /etc/passwd -->
```

Certainly, Web pages should not be written with SSIs without a compelling reason. Although access to the HTML code is normally under control of the site, there are many ways an attacker might get an SSI into an HTML page. First, the attacker may have found another way into the system (e.g., by a CGI script exploit) but may want to provide either an easier backdoor or a redundant backdoor in case the CGI script vulnerability is found and closed. Once the CGI script is exploited, the attacker may implant an SSI directive within one of the site's HTML pages. Another way for an attacker to gain access is to have the server generate a Web page with the SSI of choice embedded in the HTML. How can an attacker do this? One approach exploits a server that generates dynamic HTML depending on the end user's data, preferences, or history. If the Web server ends up using some of the attacker's data to generate the HTML page, the attacker may be able to insert an SSI directive in the HTML. In summary, a better solution than continuously monitoring the HTML pages is simply to disable the SSI. In that event, even if SSIs were embedded, the server would not execute them. This is a configuration option, and like all system configuration files, the Web server configuration file should be protected by both file permission protection and file integrity checks, to ensure that it cannot be tampered with.

Although SSIs are often highlighted, a more common risk results from keeping documents or files in a publicly accessible portion of the Web server. The accessible portion of the Web server is called the *document root*. This root specifies the portion of the file system that the Web server can read and display to a Web client if requested. The document root can be a superset of the Web pages that are actually displayed when the user clicks through a Website. There may be other documents in the document root

that are not linked to or from Web pages. This does not mean they are not accessible, however. Simply giving the correct address for any document will result in either displaying or downloading the document to any Web client. Therein lies the problem.

It is worth noting that HTML content is no longer found only in files served by the Web. On the local hard disk, Microsoft Windows applications often install Help documents comprised of CHM (“chum”) files and binaries. An attacker could exploit this vulnerability, leading to elevated privileges to the Windows XP “My computer” zone; unfortunately, local files are often overlooked and considered “trusted” during penetration tests.¹⁴ Recognizing these risks, Microsoft Corp. began use of Microsoft Assistance Markup Language with the Windows Vista OS.

21.6.6.3 Private Documents in Public Directories. Private documents inadvertently placed in a public directory can result in a compromise of confidential information and loss of privacy. For example, if a database file of credit card numbers (say, *cardnumbers.mdb*) were stored in the document root of the Web server for a fictitious company, *mycompany.com*, this URL address typed in a Web browser could download the file: www.mycompany.com/cardnumbers.mdb

This risk is even greater if *directory browsing*, another configurable feature, is enabled. Directory browsing allows an end user to view the contents of the file system at a given directory level if a Web page does not exist with the same name. Directory browsing is really a way to explore the file system of another site using a Web browser. Users may view this feature if they go back one level from a given Web page by deleting the right-hand section of a page’s URL and viewing its higher-level directory (e.g., in <http://a.b.com/d/e.htm>, one would remove the “e.htm” thus attempting to browse <http://a.b.com/d/>). Attackers can learn a lot of valuable information from viewing the contents of a directory including private files. Furthermore, the browser itself provides for clicking on a file name in the directory structure, which causes the file to be downloaded. Again, directory browsing, if enabled, is an open vulnerability and an unfortunately easy way to download private or confidential information.

21.6.6.4 Cookies and Other Client-Side Risks. Another potential vulnerability for an e-business is the use of *cookies*. Because HTTP is a *stateless protocol*, each new Web page that is visited has no memory of the last Web page that was visited by that user. Cookies are used to “keep state” between different Web pages visited in a given session. Cookies can make an e-business transaction appear to be seamless, sequential, and coordinated.

Most people, when discussing the risks of cookies, focus on the client-side privacy risks. Although these certainly exist, cookies also pose risks to the businesses that employ them. If the information contained in cookies is trusted, much the same way that the content in hidden fields is trusted, then the e-business may be vulnerable to cookie exploits called *cookie poisoning*. Some Websites use cookies to carry authentication information for a given user who traverses its pages. Once users have authenticated themselves, their token of authentication may be carried with them via cookies from one Web page to all subsequent pages at that site. Using cookies is a fairly weak form of authentication. The cookie can be stolen easily by someone snooping a user’s local area network or the Internet and then, with the information gained, to access the user’s personal pages on the Website. Secure protocols such as SSL should be employed to mitigate this risk.

Cookies also are used for other purposes that can introduce new vulnerabilities into critical transactions. Because cookies are under the control of end users, they can be

changed in whatever manner a user chooses. If cookies are designed to instruct a Web server where to write a customer-specific file, by changing the cookie data, an end user might overwrite other customer files or even replace critical system files. Similarly, if cookies are used for carrying order information, as is common in electronic shopping carts, then changing the contents of the cookies would corrupt the transaction. This could result in an unauthorized deep discount to the customer. This example and other cross-site scripting vulnerabilities are quite prevalent on today's Web. Browser exploits, HTTP header injection, cross-site request forgeries (CSRFs), and numerous flavors of phishing are all examples of Web client/user attack.

Regardless of the technology used, it is important to examine the features and functions of Web servers from a security-critical viewpoint. Dependence on a specific technology for critical transactions demands that the technology be trustworthy, so that it does not provide vulnerable points of attack.

21.6.6.5 Embedded Identifiers in URLs. Sometimes registration or unsubscribe messages include personalized URLs; for example, "To unsubscribe, click on <http://www.some-company.com/unusbscribe/? = 12345>" The problem is that the identifying code (12345 in the example) can be replaced by any other number—and some of the generated numbers will unsubscribe other subscribers. Another unfortunate use of such a technique occurs in email messages for participation in Webinars; sometimes the coded URL in the email goes directly to a registration page with information filled in—information such as the precise name, email address, and employer information drawn from the database of previous contacts.

In general, it is poor practice to provide such short identifiers that a user or a simple program or batch file could be used to delete valid records in a database or to harvest confidential data from a Website. For example, a simple html file in Adobe Acrobat can be used to force the program to access every URL in the file; if a malefactor has created, say, 20,000 unique identifiers and all or most of them are affiliated with real people, the malefactor could easily affect the accounts or collect the information shown on the customer-specific pages.

To avoid such problems, either create an address space with far more possible identifier values than a 1:1 mapping of real accounts to identifiers; e.g., for a 100,000-person list, use-generated values using a string of 20 positions with 94 values per position available in uppercase, lowercase, numbers, and special characters, resulting in $94^{20} = 10^{39}$ key-space, far beyond anything manageable by an amateur.

21.6.7 Database Security. Databases traditionally have represented an important intellectual property of information-based companies. As a result, they have almost always been company proprietary and unavailable to public access. In the new model of business, however, many of these proprietary databases are made available on the Internet, often without careful consideration of the risks involved. The Web browser becomes the database query interface, often to unknown and untrusted entities.

Although there has been much research in database security over the last two decades, the commercial sector has adopted only two key tenets: authenticating and authorizing principals to certain objects. Access to databases thus is controlled by properly authenticating the credentials of the requesting principal and then verifying which objects the authenticated principal is authorized to access. Any online database application must perform these two functions rigorously to protect the most valuable assets of e-business as well as customer privacy.

Although many vendors claim secure channel access from the Web server to the database, there are many pitfalls. To start with, the fundamental reason why databases are vulnerable is that Web interfaces are commonly appended to what once may have been a closed and proprietary interface, without concern for overall security. Second, unsecured middleware programs such as CGI scripts or application servers usually mediate access from the Web server to the database. Web servers can provide client authentication from simple user name and password entry to strong certificated authentication. The needs of the business and the size of the accessing community will dictate which solution is feasible.

Despite obvious security advantages, most users do not store encrypted information in their databases, primarily for performance reasons. Encrypting and decrypting information on the fly during search, retrieve, and store operations can be too slow for real-time transactions. Also, even encrypting the data in a storage unit would not provide complete protection, as the online application must be able to read from and write to the database in clear text. Application-based attacks would still be able to get at the data while it was in plain, unencrypted text format.

Another key vulnerability of online databases also arises from application-based attacks. As described earlier, attacks that exploit vulnerabilities in the business-application logic often can provide unrestricted access to a database.

Attacks that exploit a buffer-overflow vulnerability in an application server program usually will be able to get command shell access on the remote server. From there, the attacker usually is able to find source code for the application server programs, such as Perl scripts or even C code, that are used to access the database. Because these programs *need* access to the database, they also must know the passwords used to access the various data partitions. If the programmers have foolishly *hard-coded* the passwords, then simply reviewing the source code may be enough to discover these passwords. With passwords in hand, the attacker can use the application server program via the Web interface to gain unauthorized access to the database. More directly, with a password it is possible to query a database from the command shell, using SQL commands or commands from the database language of choice.

Finally, like the other complex programs that run e-businesses, databases must be securely configured. Basic steps that the database administrator (DBA) needs to take include:

- Enforcing Web client authentication to the database
- Enforcing Web client authorization for access to database records
- Eliminating default database and database platform accounts
- Ensuring that passwords are read from encrypted files, not stored in program code
- Changing easily guessed passwords
- Configuring and maintaining internal access controls
- Auditing log files for suspicious activity

Account maintenance can be a key vulnerability in database management. Often the database software vendor will create a DBA account with an easily guessed password. Worse, DBAs may use the default account and password distributed with the database installation. This permits an attacker who has knowledge of the default passwords to gain access to all portions of the database by assuming the identity of the database administrator.

21.6.8 Platform Security. One area alluded to earlier in this chapter concerns the platforms that host components of an e-business. The platform, or operating system, represents the foundation of the e-business, but it is a potentially weak link in security. If there are cracks in the foundation, there is very little that even strong application software can do to keep the business secure. Therefore, it is imperative that system administrators properly patch platform vulnerabilities and maintain the security of the platform itself. As mentioned earlier, firewalls can go a long way toward blocking access to platform vulnerabilities by unauthorized outsiders. However, authorized but unprivileged users within the firewall can exploit known platform vulnerabilities to yield root privileges on a business-critical machine. Outsiders able to gain user privileges on the platform through any means also may be able to penetrate platform holes into severe security breaches.

Some key steps necessary to maintain platform security include:

- Eliminating default accounts generally installed with the operating system
- Prohibiting easily guessed passwords
- Enforcing password expiration
- Deactivating any unnecessary services that may be running by default
- Regularly applying security patches to the operating system
- Updating the operating system to its most recent release
- Ensuring that file access permissions are properly enforced, so as to prevent unnecessary access to critical files
- Enabling audit logging with intrusion monitoring
- Running system file integrity checks regularly

Some administrators believe that deploying a firewall is an acceptable substitute for configuring their platforms securely. Furthermore, with the plethora of different platforms running their enterprises, many system administrators give up on installing the latest OS patches and on securely configuring their platforms. They mistakenly assume that firewalls will protect them from all threats, even without maintenance. Unfortunately, relaxing host security can make the job of hackers easy. By hopping from machine to machine, they usually can find the valuable information they are looking for, or if that is their goal, they can wreak maximum damage.

An increasingly important platform for considerations of Website security is smart phones. By the end of 2012, there were 2.1 billion mobile Web users in the world at the end of 2012.

According to estimates by The ITU (June 2012), there were 2.1 billion active mobile-broadband subscriptions in the world. That is 29.5 percent of the global population.

- Mobile-broadband subscriptions have grown 40 percent annually over the last three years.
- Mobile-broadband subscription outnumber fixed broadband subscriptions 3:1.
- In developed countries mobile-broadband users often also have access to a fixed-broadband connection, but in developing countries mobile broadband is often the only access method available to people.

21 · 22 WEB-BASED VULNERABILITIES

- Ericsson (November 2012) forecasts that global mobile broadband subscriptions will reach 1.5 billion at the end of 2012, and 6.5 billion in 2018. The mobile phone will continue to be the dominant mobile broadband access device.¹⁵

Tablets also have their own versions of browsers. Web designers are increasingly having to cope with significant differences among platforms accessing their code.

Craig Smith included the following points in a January 2013 article entitled “Optimizing Ecommerce for Tablets and Smartphones”:

- **Improving navigation and usability:** Users should be able to select options easily and correctly; avoid drop-down menus and buttons that are close together.
- **Leveraging responsive design:** Determine how to present the Website according to what kind of device is accessing it.
- **Determining the purpose of the access:** Distinguish between the types of queries that are most common—and different—across platforms. Optimize design for the most common types for each platform.¹⁶

Another question is whether e-commerce sites should depend on Web access or develop applications (*apps*) specifically for smartphone and tablet operating systems.¹⁷ A major advantage of apps is that they can be programmed to avoid the vulnerabilities common to mobile devices in these early years of widespread adoption.

21.7 SUMMARY. This chapter has provided an overview of the weakest links in Web applications, including Web clients, network protocols, front-end Web servers, back-end databases, application servers, and the platforms on which they run. Secure network protocols are necessary but certainly not sufficient for securing e-commerce. The vulnerabilities described here are largely based on software flaws that exist in the application layer of e-commerce transactions.

Perhaps the most common vulnerability in e-commerce systems is misconfiguration of software. Because the responsibility for software configuration lies with the user, a security policy must be implemented and enforced. Once a system is configured, it is important to subject it to third-party validation and testing. A third-party audit can ensure that the configured system, including routers, firewalls, servers, and databases, meets the specifications of the security policy. The system also should be tested periodically against well-known, common attacks as well as against newer threats as they arise.

Like any software system, commercial off-the-shelf software has flaws, many of which are security-critical. It is imperative that system administrators stay current with vendor Websites, with hacker sites, with newsgroups, and with wherever threats and patches to their software are released. Both the security and hacker communities are constantly at work finding flaws in COTS that software vendors and security firms generally correct quickly. Software consumers—those who buy and use the software—must do their part by applying all relevant patches to their vulnerable software.

For custom-developed software, which includes front-end Web pages, application servers, CGI scripts, and mobile content such as ActiveX or Java, developers must do everything possible to ensure that their software is not vulnerable to attack and that it does not infringe on users’ privacy.

22 · 2 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

22.1 INTRODUCTION. This chapter describes the wide array of possible physical threats that can affect information systems (IS) infrastructure. A *threat* is any credible situation—whether actual, imminent, predicted, or possible—with the potential for causing harm, damage, or disruption. The terms *threat* and *hazard* are used synonymously in this chapter and have the same meaning. *Risk* refers to the probability of occurrence of a threat. For a structured terminology for discussing threats and risks, see Chapter 8 in this *Handbook*.

The infrastructure affected can be any component of a computer system or communications network; any of the cables, wiring, or devices that transfer power or data; or any of the support services or utilities needed to sustain full IS performance. In addition, this chapter considers threats against employees as a significant component of physical security.

The speed and accuracy of any system is dependent on the performance of a long chain of physical components as well as on the productivity of all of the people who utilize or maintain each component. Anything less than full system-wide performance can be costly.

A physical threat is any event that can degrade the performance of an information system—whether such an event is actually occurring or imminent, or credibly likely or possible, or completely unexpected and without warning. The list of possible threats is a long one, beginning with natural and man-made external events that can degrade IS performance. Many other possible threats are internal, resulting from accidents or misuse or deliberate attack. Internal threats also include reliability failures, installation or maintenance issues, or lack of proper testing. Threats can also be caused by situations within the facility, building, or complex, or as a consequence of local or regional events, or, increasingly, events worldwide and even from outer space. Threats happen and can come from almost anywhere, so it is prudent and far less costly to try to anticipate all likely and significant threats.

Although in this chapter the terminology often refers to “all possible threats,” readers must understand the implicit assumption that they are considering only reasonable categories of threat. Planning to cope with the results of a world-destroying impact with a continent-sized asteroid is useless; trying to define a strategy for responding to an attack by extraterrestrial invaders armed with ray-guns is impossible and useless.

This chapter begins a threat-assessment process, which starts by identifying all reasonably defined threat situations. This process must be comprehensive and rigorous and involve all stakeholders. It is not enough simply to assign likelihood and an impact for the usual or the obvious threat situations. There must be a full risk analysis, so that risk, vulnerability, and response and recovery costs can be quantified, as explained in Chapter 23 in this *Handbook*. Otherwise, the whole process is valueless. Absent comprehensive planning, security becomes an irrational selection of vendors and solutions, which can only add cost and increase liability risks. Alternatively, a strategic risk-management process can maximize future profits and add value, protect morale and productivity, enhance goodwill, and improve relations with customers and communities.

The events of September 11, 2001, sounded a shattering wake-up call that unexpected threats can actually happen and that even the best security practices, products, and services are of little value without proper planning, implementation, and support. Hurricane Katrina, four years later in 2005, demonstrated again that both business and government are still unprepared, even though such an event was predicted many times.

This chapter suggests a comprehensive perspective on physical security that can add value and help avert disaster. Chapter 23 in this *Handbook* goes on to suggest physical

security implementation and management that can protect people and property while optimizing morale, productivity, and profitability.

22.2 BACKGROUND AND PERSPECTIVE. Historic data and statistics are of limited value in predicting future threats. For a discussion of the unreliability of computer-crime statistics, see Chapter 10 in this *Handbook*. The past is no longer prologue because many new threats are emerging and many types of incidents are increasingly severe, widespread, complex, damaging, and costly. Proliferating and increasingly dispersed infrastructure system components are often vulnerable and hard to protect. And hybrid configurations of new and legacy systems vastly complicate the protection process.

There are few threat statistics that can reliably predict the infrastructure future. Computer-crime reports mostly cover logical security, while general crime statistics often do not relate directly to computer security. Historic information is further flawed because many incidents are never detected and far more are not reported for fear of embarrassment, liability, or loss of business. Many security incidents are masked as quality-control problems for the same reasons, or are misdiagnosed because no one had time to determine the true cause(s). Lacking reliable precedents, predicting future threats is especially difficult—yet increasingly necessary. Chapter 10 discusses computer crime statistics in more detail; Chapter 58 and Chapter 62 discuss risk-management methodologies.

Most incidents happen suddenly, without warning, and often where least expected. Many threats once thought to be unlikely now occur widely and strike with surprising intensity and devastation. Other contributing factors include poor risk management due to inexperience, denial, or complacency that can quickly turn routine threats into costly incidents. Businesses with good security preparedness can usually survive, while many others will not.

22.2.1 Today's Risks Are Greater. Today's threats are increasingly sophisticated, unpredictable, potentially serious, and increasingly commonplace as well. Disruptive incidents can result from mistakes or accidents, snoopers or hacking, vandalism, disgruntled or disruptive persons, labor disputes, demonstrations, civil unrest, extremists of many stripes, and, increasingly, both domestic and international terrorism. Although violent-crime incidence has decreased in recent years in some parts of the world, these data may be misleading because they rarely include workplace-related events. Violence in the workplace is now common and often without warning. Incidents can include harassment, bomb scares, robbery, hostage situations, shooting, or arson. And each and every one of these threats can seriously affect IS performance.

Physical threats can extend beyond direct attacks. Many scares do not result in actual violence, and disruptive incidents can occur outside of the workplace. However and wherever they happen, violence-related incidents are increasingly commonplace, disruptive, and costly.¹

Those who threaten the IS infrastructure must at least gain access to some physical part of it, but often this can be done inconspicuously, by trickery, deception, or simply forced entry. A physical attack may be the best way to compromise an information system—much more effective and less likely to be detected than a logical attack. Often, many vital system components are vulnerable, exposed, or easily accessible. These components include wiring and cable runs, connection and junction points, system and network equipment, and the utilities that support them. Attacks or spying by physical means are often easy, fast, safe, and sure.

22 · 4 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

22.2.2 Likely Targets. Businesses and organizations are increasingly likely to be the targets of hackers, disgruntled employees, competitors, disturbed persons, demonstrators, hate groups, extremists, and even terrorists. Motives may include a conspicuous, tempting, or challenging target, rage or revenge, an opportunity to cause reputational damage or at least adverse publicity, to make a political statement, for extortion or blackmail, or for personal gain or profit. Often, there are no discernable motives. And beyond being likely targets, most businesses are convenient, easy, and safe targets as well, because most are unaware and unprepared for today's threats, much less for future ones. Although government facilities remain preferred targets, many are now better protected than most businesses, thanks to new procedures that are covered in Chapter 23 in this *Handbook*.

Another likely threat arises from the need of extremists and terrorists to finance their activities. Many groups and all independent, self-directed cells are dependent on crime to finance their operations. Today's crimes can include robbery and holdups, counterfeit currency and credit cards, Internet phishing and scams, theft, extortion, blackmail, and selling pirated software and other knock-offs. In addition, many foreign governments, businesses, and criminal organizations are actively engaged in spying. Although these are mainly corporate security and logical security problems, they also represent potential physical threats that must be deterred.

22.2.3 Productivity Issues. Good security can be directly correlated with high productivity, which, in turn, can improve performance, customer satisfaction, and goodwill. Good security is measurable and can strategically enhance each of these factors to add both value and profit. Anything less than good security invites wasted time and money.

People who do not feel safe will not be productive. This applies to employees, visitors, vendors, and others on premises, as well as to customers, vendors, stockholders, and other stakeholders at remote locations. Everyone using any information system must be comfortable that physical safety and privacy are insured and that the system is uninterruptible, secure, and operating at full performance. Everyone concerned must be involved in the planning process, generally understand the threats, and support the security procedures. Otherwise, performance inevitably suffers.

Whenever a security incident occurs, morale and productivity are likely to plummet and can remain low for many weeks, or even months. Whether the infrastructure is actually affected or not, significant disruption of operations is likely. Even when there is no injury or damage, the perception of a potential event can be costly; it can disrupt productivity, lose business and customers, and jeopardize goodwill.

No one knows how often productivity-related events occur. Businesses generally do not report them, and neither do the media. But these things do happen and probably with considerable frequency. Yet all threats can be mitigated to some extent and many more prevented at far less cost than the consequences by effective technical preparations, adequate employee awareness and training, and well-planned and well-rehearsed responses.

22.2.4 Terrorism and Violence Are Now Serious Threats. Acts of terrorism and violence are now a reality that can occur anywhere in the world. September 11, 2001, and the events that followed have brought home the stark reality that violence can happen anywhere and can cause massive damage and disruption. And most major disasters can disrupt information systems far removed from the actual incidents.

Workplace violence is also happening with increasing frequency and often at facilities assumed to be safe.² Bomb and biological or chemical scares, personal threats, harassment, hostage situations, and shootings are all happening with increasing frequency. Whether actual violence occurs or not, the threats alone, the many rumors generated, and the imagined proximity to danger are all productivity-related events that can seriously disrupt the performance of information systems for a long time. Therefore, these become infrastructure security issues that require special planning and should not be left to premises security personnel to prevent.

There are other serious threats from foreign intelligence, terrorists, and domestic groups generally unknown to the public. Some of these are explained well in the Project Megiddo report published by the Federal Bureau of Investigation (FBI) in 1999 in anticipation of the millennium. The report provides “an FBI strategic assessment of the potential for domestic terrorism in the United States undertaken in anticipation of or response to the arrival of the new millennium.”³ The threats cited then are basically unchanged today, except that more previously unknown threats have since been added. There are consultants with FBI contacts who can offer valuable advice.

Attempted violence is now a serious threat to all IS infrastructures. However, thorough security planning can do much to avoid trouble and needless expenses.

22.2.5 Costs of Damaged IS Infrastructure. Direct costs of system downtime can exceed many thousands of dollars per hour. The losses include the slack-time costs of people who cannot use the systems, costs of support and maintenance people diverted to restoring operations, recovery expenses, overtime, and often lodging, food, and travel expenses during recovery. Usually, many outside resources are needed for response and recovery. Everything quickly becomes expensive. Often, to further compound the costs, needed resources are just not available immediately.

Indirect costs can also be significant. Reestablishing and keeping good public relations can be expensive. Often, public announcements, news releases, and briefings to the news and financial media and to stockholders are needed to neutralize public embarrassment and control rumors. Key customers must be contacted and reassured, and pending orders rescheduled. Still more costs include lost business or market share and dropping stock prices. Competitors often will take as much advantage as they can, which necessitates further costs defending brands and reputation.

Any number of such costs can devastate an enterprise unless strong security measures are deployed effectively and quickly. Ad-libbed responses are often disastrous. In reality, an infrastructure outage of more than a few hours is often fatal, and the enterprise can never fully recover. Good security usually can prevent disastrous costs.

22.2.6 Who Must Be Involved. Many threats to information systems also involve corporate or premises security personnel, whose role is to protect people and property within and surrounding the workplace. The CEO and the CFO are also involved, because they must now comply with the applicable laws and regulations. Compliance requires that events that might materially affect financial performance must be included within an organization’s financial filings and statements. Major security incidents are clearly such events whose impact must now be predicted—as described in this chapter.

Premises security often includes little more than guards, access control, and some surveillance. Their understanding of the IS infrastructure’s special security needs is often minimal, lumped in with overall physical security procedures, and rarely extends much beyond the immediate premises. Yet, IS security requires additional knowledge,

22 · 6 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

experience, protection, and support. Good security must be strong, fast-acting, focused on specific targets, and closely monitored. Effective early warning systems are necessary in order to prevent threats from happening. In reality, each security function will have its own needs and priorities and use its own resources. During a serious incident, security for the premises, occupants, information systems, and the infrastructure must all coordinate efficiently and effectively. They must also work smoothly with local fire and police departments, with other emergency responders, and with many outside resources.

Who, then, should manage the process of determining the threats to the IS infrastructure? And who are the stakeholders who should be involved in this process?

The best person to manage the physical security of information systems is one who knows a great deal about possible threats and about the IS infrastructure. The office manager, facilities manager, or corporate security director or their staffs are usually ill-equipped to determine or manage IS security. Often, too, the chief information officer (CIO), chief information security officer (CISO), and IS security officers (ISSOs) deal with protecting data and data processing, and are not the best persons to understand IS physical security, especially in a large installation. Therefore, the best person is a trusted individual with the right knowledge and experience and with enough time to manage the process well. Planning and managing infrastructure security, implementing and testing it, training and security awareness, monitoring, and periodic updating of the system and procedures are a full-time job in most organizations, and require a support staff in larger organizations.

Chapter 65 in this *Handbook* discusses the role of the CISO in detail.

Another consideration is that no one person should know all the secrets, which is a rule that has become especially important in dealing with the IS infrastructure. When trouble comes, many experts must mobilize very quickly, efficiently, and effectively. To do this, the responders must be familiar with all the information systems and have fast access to the infrastructure. No matter how well trusted, no one person should know everything about the physical and logical defenses. (If need be, such information should be safely stored with strong access controls.) It is wise to divide the secrets so that no one group knows or has access to them all. Having done this, multiple persons can then share each portion of the secrets and observe each other, so that no one person is indispensable. Chapter 45 in this *Handbook* presents details of employee management and security.

But only the security vulnerabilities and defensive implementations should be secrets. There is no point in letting others know about the defenses and where the organization is vulnerable. However, the process of determining the underlying threats should be common knowledge among all the stakeholders involved. By identifying a large number of threats that have been assessed—but keeping the likelihood, vulnerability, and impact information secret—we can discourage would-be troublemakers by at least providing some idea of the *number* of threats that have been considered. With any luck, they will attack less-prepared sites.

22.2.7 Liability Issues. Aside from the need for efficient emergency response, another issue that is becoming increasingly important, is potentially very costly, and is often overlooked. This is the issue of liability. Every organization has a legal and fiduciary duty to protect the people and property within and surrounding its premises. If any injury or damage occurs in or around a workplace—even long afterward—allegations of negligence will likely follow. The motive is often that damages awarded by the courts can be very large and lawyers often take on these cases on speculation, in hopes of

receiving very large fees. And whether the organization was actually at fault or not, the resultant legal fees, the time and costs needed to defend the organization, bad publicity and possible loss of business, and the eventual fines and awards can be devastating.

If negligence is alleged, the issue is whether the organization was properly prepared for the emergency and whether its response was effective. The question is simply: Did management perform its duty to protect the organization? An affirmative answer would require at least:

- Evidence of a thorough threat assessment process
- Good security plans, policies, and procedures that have actually been implemented
- Proper training and current security awareness
- Periodic drills, exercises, security reviews, and feedback from known events
- Periodic updates to assure that security remains effective

If it can be demonstrated that all these measures were not taken, or that there were deviations from generally accepted standards, the result could be punitive as well as compensatory damage awards. Gross negligence will probably be alleged as well, in which case insurance may not defend the accused organization or individuals, who would then be personally liable. Even with insurance in effect, it may not be sufficient to cover the very large penalties that juries commonly award.

Chapter 60 in this *Handbook* discusses insurance for responding to damages in IS.

Even when all the correct answers are given, the accused often find they are considered to be guilty until they can prove themselves innocent. And this can be a long, painful, and costly process.

However, a nearly iron-clad defense against liability is that federal procedures were followed. The most comprehensive of these are from the Department of Homeland Security (DHS) and its Federal Emergency Management Agency (FEMA) Directorate.⁴ Of all of the other security planning and management procedures, which are many and varied, only the DHS/FEMA methodology is likely to become generally accepted. The procedures are already well known, uniform, and comprehensive, and they consider all threat possibilities and all response resources. It is unlikely that a plaintiff's attorney will ever allege that these procedures are deficient or ever bring a case once it appears that an organization is compliant. This is not to remove all liability, merely to reduce the scope to situations usually covered by insurance. Chapter 23 in this *Handbook* outlines how to plan, implement, and manage the DHS/FEMA procedures.

22.2.8 Definitions and Terms. Information infrastructure security is simply a means of IS performance assurance. Good security precludes any IS disruption that might degrade performance in any way. Any slowdown or loss of productivity, loss of data, breach of privacy, or disruption of the systems, networks, and utilities that support any information system diminishes performance. Good security assures that all systems remain fully operational, robust, and accurate, and that all their data remain private and cannot be compromised.

There are three elements of information systems security. Each element must be especially designed and maintained to protect against different threats of varying scope and intensity. The three elements include:

1. **Logical security**, which is also known as information systems security, protects only the integrity of data and of information processing.

22 · 8 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

2. **Physical security**, which is also called infrastructure security, protects the rest of the information systems and all of the people who use, operate, and maintain the systems. Physical security also must prevent any type of physical access or intrusion that can compromise logical security.
3. **Premises security**, which is also known as corporate or facilities security, protects the people and property within an entire area, facility, or building(s), and is usually required by codes, regulations, and fiduciary obligations. Premises security protects broad areas. It often provides perimeter security, access control, smoke and fire detection, fire suppression, some environmental protection, and usually surveillance systems, alarms, watchmen, and guards. Premises security is often an extension of law enforcement.

Clearly, there is much overlap between each element, and a threat to one is often a threat to the others as well. However, each element is likely to perceive and handle each threat differently. Although the remainder of this chapter deals with physical security, some threats that are usually considered the realm of logical or premises security must also be covered.

22.2.9 Uniform, Comprehensive Planning Process. The threat assessment process can go by a number of names, which are all functionally similar. Among the terms are emergency, disaster, operations, contingency and crisis-response planning, and damage control. Some processes are proprietary and do not share a common language or standardized procedures that can be understood by everyone involved. Many regulated industries must develop emergency response plans using terms and formats dictated by the regulating agency, which makes these terms and formats proprietary as well. There are many diverse examples of regulated industries that use hazardous or nuclear materials or operate dams.

Many organizations that are involved in emergency response—such as hospitals and emergency medical services, schools, the American Red Cross, and many volunteer agencies, National Guard and military units—may still use other terms and models. Government agencies at the local, state, and federal levels still use a wide variety of security plans and procedures, even though there is now one standard methodology required, as explained in Chapter 23. Most of these procedures are not uniform or comprehensive. And they can be incompatible, present major communications barriers, and cause unnecessary misunderstandings, delays, and wasted resources. In turn, most private organizations are not aware of the government procedures in place or of the many resources that can assist them.

Every organization experiences essentially the same threats and has limited response capabilities and resources. Almost every organization is likely to be overwhelmed in a major emergency, and everyone can benefit enormously from outside resources. Yet, each venue tends to use dissimilar models, terms, and procedures that are often unintelligible to the others. In many cases, their models become file-and-forget plans and procedures that no one understands or accepts.

If only as prudent risk-management strategy to avoid liability issues, a single, uniform, and comprehensive standard for processes, procedures, and language is needed. The best way to do this is to adopt the DHS/FEMA methodology, which encompasses all hazards, coordinates all resources efficiently, and is clear, concise, understood, and accepted by everyone involved. Details are given in Chapter 23. This is now required for all federal government departments and agencies, and for state and local jurisdictions as well, if they wish to continue receiving federal grants and assistance.

A useful public/private standard for evaluating disaster/emergency preparedness is published by the Emergency Management Assessment Program⁵ (EMAP), which is a nonprofit professional organization. The EMAP standard covers all the current DHS/FEMA methodology and provides a clear and concise method to determine compliance, as well as a self-auditing process. EMAP also provides an independent, outside security audit of any government organization to ascertain that its emergency management program complies with the federal requirements; it may soon be able to audit private organizations also. The audit is done at the applicant's facility by professional, well-trained volunteers. The whole security-audit process is both rigorous and inexpensive. The EMAP is therefore a suggested alternative to a CPA-provided security audit as well as to the audit procedures of other professional organizations that generally do not include either infrastructure security or compliance with federal procedures.

Security preparedness that is compliant with these standards may become a requisite for the private sector to obtain insurance, to avoid liability and excessive costs, to establish innocence, or to use capital markets for risk management. Knowing these standards will help the threat assessment process and, later, can provide better protection.

22.3 THREAT ASSESSMENT PROCESS. Effective security planning begins with a thorough threat assessment. This process begins by establishing an ad hoc organization, obtaining budget approval and the sponsorship of senior management, and formation of a steering committee that represents all the stakeholders.

The first four tasks are to:

1. Identify all potential threat situations.
2. Determine the likelihood and estimate the direct and indirect costs of each threat.
3. Evaluate and prioritize each threat.
4. Prepare and present a final report that each committee member signs.

This report becomes evidence of due diligence to avoid liability, and becomes the basis for protecting the infrastructure, which is described in Chapter 23.

The way *not* to go through the planning process is for a few people to decide on the threats and risks and then write the security plan. This is the opposite approach to good and effective planning. And it will not work. Very few of the key personnel will accept or even understand the plan, and it will probably be ignored or overlooked when the next emergency arises. Good examples of failed planning are the emergency management plans for New Orleans and Baton Rouge areas that were put in place before Hurricane Katrina in 2005. Apparently, both were good plans. But few officials understood the plans or remembered to use them.

The threat assessment planning process *must* be done thoroughly and completely. For additional perspectives on risk assessment and risk management, see Chapters 62 and 63 of this *Handbook*.

22.3.1 Set Up a Steering Committee. The security planning process is not effective unless all of the stakeholders are represented, and the best way to do this is to establish a steering committee. The committee will help identify and evaluate potential threats, and help develop a comprehensive protection plan.

22 · 10 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

The committee should represent all stakeholders and include as much experience, knowledge, and perspective as possible. Stakeholders should include users, administrators, management, key partners, customers, vendors, and service providers (such as maintenance, repair, and cleaning personnel). A project manager should participate, as should legal, financial, and human resources representatives. Independent experts and facilitators are recommended as well. The best committee chair is usually an outside facilitator who is immune from political or cultural bias, loyalties, or product preferences. It is also wise to seek input from stockholders, lenders, insurers, and community and government officials.

This can be a virtual committee that rarely needs to meet in full session. Communications by email or phone should be sufficient, and an in-house staff can gather data, issue reports, and work with individual committee members. Confidentiality is not an issue at this point. The committee's purpose is to identify threats and to assist in planning. No member need have full knowledge of the actual vulnerabilities or the resulting security systems and protections. Each member, however, should sign off on the committee's final report.

Once its initial mission is completed, it is best for this committee to convene at least annually to review new and changing threats and to assess how well the security systems have performed. This committee not only represents all concerned stakeholders, but it can provide oversight so that management does not neglect to exercise, review, and update the security plan. In effect, the committee provides due diligence that management has fulfilled its fiduciary responsibilities.

22.3.2 Identify All Possible Threats. The first step is to identify all possible threat situations that might affect the information infrastructure. This is not to say that each threat will someday happen but that, conceivably, it might, nearby or even at a distance. The causal connection could be tenuous at best and the event most unlikely, but it could someday happen. It is far better to think objectively about such things and to plan effectively than to simply write them off as events that could “never happen here” or to claim that, if such a disaster does happen here, “there is nothing we can do to mitigate it.” Both statements are patently false and potentially very costly.

The threat list can be very long. The format should tabulate each specific threat with a one-line description to clarify what is meant. For example, “flooding” is too general a term to meaningfully assess its risk. Instead, one might list “riverine flooding,” which could be the result of heavy rains, snowmelt, or a breached dam or levee; “local flooding,” such as a water-main break, severe storm, or a major fire nearby; or “premises flooding,” due perhaps to leaking pipes, drains, or leaking windows, roofs, building setbacks, a burst water tank or cooling tower, or fire suppression. The purpose is to have a long list of specific threat situations that can be individually assessed. There can easily be 100 or more threats listed. As the project proceeds, those involved will surely add still more threats and fine-tune the definitions. The threat list should include threats that are direct as well as indirect and threats affecting the general area, the region, or the whole country. It is best to list all threats, including those that are deemed unlikely to occur, as a precaution against inadvertently omitting some that might have more importance than is apparent at first glance.

Unfortunately, threats tend to cascade: One threat situation can create others, and these, in turn, can create more threat situations. For example, severe flooding can close roadways and keep people away from work, impede delivery of supplies necessary to operate (such as food or water or fuel for an emergency generator), disrupt communications, cause mud slides, ignite fires, trigger looting, or cause civil unrest. As

another example, during a fire there will likely be loss of electrical power for equipment cooling, ventilation, or communications, and released water or chemicals that must be contained. Each of these conditions is a separate threat with its own risk. In reality, few hazards occur in isolation, and many of the cascading events may be unexpected and unpredictable, and can themselves trigger still more events.

Therefore, the tabulation of each threat should also include two other columns: (1) events that could trigger the threat, and (2) cascading threats that could result from the threat. This is easily done by numbering each threat and referencing the numbers that may interconnect the various threats. The information is needed to evaluate the impact of each threat. It can only be a general indication for planning purposes of what might happen. The actual cascading will probably be different, but the analysis of the threats will still be valid.

Do not rely on force majeure—for example, a major earthquake—as an excuse that a particular threat may be unavoidable. Force majeure does not limit liability because such events can be anticipated and some steps taken to minimize injury and damage. Nor may acts of war serve as an excuse, for the same reasons.

Finally, the threat list should be divided into major categories such as natural events, man-made events, vandalism, attacks, support system failures, and so on. The remainder of this chapter builds on the threat list and establishes categories best suited to particular needs.

22.3.3 Sources of Information and Assistance. The next step is a compilation of past events: historical records and details as to what happened, when, and how, what injury and damage resulted, was there warning, how fast was the onset? The compilation should include events in both near and distant areas that could possibly cause damage and disruption, either directly or indirectly. Perhaps the 2005 subway and bus bombings in London or the earlier commuter-train bombings in Madrid could affect American workers who commute and become concerned about their own safety.

As the threat list gets bigger, it is necessary for everyone involved to think out of the box and to look for scenarios that past trends suggest could eventually happen. This thinking can be productive when it examines possible scenarios objectively. The author, as a security consultant in New York, worked with tenants in the World Trade Center and tried to suggest disaster planning but was overruled by the landlord who assured everyone that this was “the safest place on earth.”

Information sources to investigate include the weather bureau, libraries, local fire and police departments, state and county officials, utility companies, newspaper files, and local knowledge of past events within the region. Power and communications utility companies can provide outage reports, but their terminology must be clearly understood. For example, an electrical “outage” may only include interruptions lasting more than five minutes. Regional and state regulatory authorities, public utility commissions, industry and professional organizations, and business development groups may also provide useful information, once their perspective and terminology are clarified.

All local, regional, and state emergency management agencies should now have an all-hazard mitigation plan that lists all threats that have occurred throughout their jurisdiction. There should also be dates, descriptions, and map locations in their plan; this information may go back historically for a century or more. And each agency should have a local emergency operations plan that lists all potential threat situations within their jurisdiction. Look particularly at the appendices and annexes that discuss particular types of threats. In addition to what is in their plans, each agency should be of considerable assistance describing possible major threats that are man-made, involve

22 · 12 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

hazardous materials, or are major health risks. The threats they identify are probably your threats as well.

Also, work with each stakeholder for advice on threats they know about or perceive. Ask each person to reach out to their customers, vendors and suppliers, service providers, business neighbors, and consultants and academics as well. There will be much expertise, perspective, and good advice gleaned from these sources. The time seeking it will be well spent.

At the end of this chapter is a list of some reference books that can be helpful. Although some of the procedures are outdated, there is still much useful source data.

22.3.4 Determine the Likelihood of Each Threat. The steering committee should consider the likelihood that each threat may happen. The best way to estimate likelihood is as an annual probability on a relative scale (for example) from 0 (none) to 5 (very likely). A perceived likelihood of once every 100 years (which equals a 1 percent annual probability) could be rated a 1. A 5 percent annual probability might be rated a 2, while an annual probability of 20 percent or more had best be rated as a 5. Threats from severe weather should be rated higher than historical data suggests in order to account for the world's changing weather patterns. Threats with a likelihood of 0 should also be included, as this value can be used later to show the relative vulnerability of each and every threat.

The steering committee can adjust each rating as it deliberates so that the final results are useful and meaningful.

22.3.5 Approximate the Impact Costs. Once all the possible threats are determined and the likelihood of each is estimated, the next step is for the steering committee to deliberate the impact of each threat. Impact considers the potential losses and costs associated with each threat. (Do not consider cascading threats at this point.) Here also, a relative scale of 1 (very low) to 5 (very high) is suggested. A 0 impact rating is probably not relevant, because, in reality, some response and recovery costs will occur.

There may well be individual factors needed to clarify the importance of the overall impact. Such factors might include the likelihood of injury or death, the amount of property damage, the relative response and recovery costs, and, especially for a private organization, the costs of loss of business. The parameters of each factor and the scope of each rating can be adjusted as the planning proceeds, so that the results are realistic and meaningful. The purpose now is to show which threats are potentially the most dangerous or costly if they occur.

Threat assessment planning is best done using a worst-case scenario because this is what tends to happen in reality. Even then, actual costs incurred can be much higher than anticipated. Although the steering committee has only limited knowledge of possible costs, with some discussion the committee should reach consensus as to which rating to apply to each listed threat. Their findings will be reviewed later by others better able to predict potential costs and in a better position to realize that the impact of some threats is much more costly than others.

The impact costs are both direct and consequential. The direct expenses can include costs to locate the trouble(s), stabilize the systems, repair and install replacement infrastructure, reboot, restore databases, and thoroughly test both the data and the systems. Other direct costs that can result from each event include loss of productivity of system users, overtime needed to regain production schedules, temporary contracted services, and interim facilities, or materials and supplies needed immediately.

Add to these potential indirect or consequential costs such as food, sanitation, and lodging; loss of business, customers, or market share, falling stock price, and the costs of public relations efforts to control rumors and adverse news reports. Costs will continue to accumulate during the response phase, throughout the recovery period, and possibly long after. The totals can far exceed expectations.

22.3.6 Costs of Cascading Events. The possibilities and indeed the likelihood of cascading events have been described. Each event adds to the impact costs, but determining how likely is the cascading, and how much the extra cost, is at best an educated guess. If the causative events for each threat are shown on the threat list and the potential cascading events are there also, the impact costs of each individual event should be estimated. However, cascading may invalidate the likelihood factors. If one threat is already occurring, others may be imminent, regardless of the likelihood shown.

The total impact cost will probably be somewhat less than the sum of the parts. There may be some economies of scale during multiple events, as the response activity for one event can take care of another event for little extra cost. Here is where the experience and perspective of the steering committee, security professionals, and management become valuable. However, the combined costs must still be realistic, or the cost-value analysis described in Chapter 23 will be flawed.

22.3.7 Determine the Vulnerability to Each Threat. Deciding which threats are the most important can be subjective and controversial and based on unproven assumptions. The approach suggested here yields quantifiable data that are realistic and will clearly indicate which threats are the most important and why. Individual opinions will vary considerably. The steering committee reports can yield approximations that are statistically valid—if the rules are followed and everything is done carefully. The committee’s deliberations should be reviewed by experts and senior management, using calculations to be described, followed by the cost-value analyses described in Chapter 23.

One other common alternative is a matrix showing likelihood vertically and impact horizontally, rating both factors as high, medium, or low. This yields nine levels of vulnerability for each threat ranging from high-high to low-low. Such an arrangement is neither useful nor realistic. Since allowance need to be made for those impact factors that are potentially more costly than others.

Once everyone settles on the likelihood and impact of each threat, the current vulnerability of each threat can be calculated. Fundamentally, vulnerability is a calculation combining the likelihood of an event with how much damage it might cause. The method suggested yields six levels of vulnerability, from 0 (none) to 5 (very high). The next two steps are oversimplified but can be adapted to most needs. Simply multiplying the likelihood times the impact will yield vulnerability values from 0 to 25, which would not reflect the relative impact costs of most threats. Neither does simple addition, as some models suggest.

1. It is best to use several impact cost factors, as described earlier, and then combine each factor using constant multipliers for each, so that the relative importance of each impact cost is preserved. Combination by averaging each cost factor may not yield useful results. Combining the mean value of each factor (or sometimes the highest value) can yield more realistic data.
2. Finally, convert vulnerability calculations to a 0-to-5-point relative scale by choosing a range of results for each scale value.

22 · 14 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

Working through this procedure for all threats will show that the formulas, multipliers, and ranges of scale values may need to be adjusted slightly to yield meaningful results. As already mentioned, simple multiplication and/or addition or otherwise linear formulae will not yield realistic results.

The importance of calculating vulnerability is that it can be done in real time, and the multipliers can also be adjusted in real time as threat levels change. For example, this can be reflected in the National Terrorism Advisory System (NTADS)⁶ by locale or by possible target types. It can also input warnings from local police and intelligence sources. (Some threat information is probably classified, but the multiplier it can provide is not restricted or even sensitive information.) All the data can be displayed on a spreadsheet, even to the point of color-coding each vulnerability level. Everyone involved in security or emergency management can have real-time access to the same screens, which will update continually as conditions change.

It is well to provide a choice of display screens summarized or in detail by regions and threat categories, or prioritized by vulnerability.

Finally, the complete vulnerability data should be restricted and available only to those with a need to know. This information is highly sensitive; it shows potential wrongdoers where the IS infrastructure is well defended and where it is *not*.

22.3.8 Completing the Threat Assessment Report. Once the detailed threat assessment is completed, a general report should be prepared for circulation to all stakeholders. The report is mostly textual and does not suggest weak spots or what the security defenses may be. Each steering committee member should sign off on this report, and so should the senior management and security staff. The purposes of this report are to develop security awareness, for use in training, and as evidence of due diligence that a thorough threat assessment was indeed performed.

More on how to evaluate and manage the vulnerabilities is described in Chapter 23 of this *Handbook*.

22.4 GENERAL THREATS. A wide array of threat situations can affect the IS infrastructure, degrade productivity, and cause anxiety that will reduce performance and morale. The list suggested earlier begins to identify some of these threats. Some other possible situations that are not generally associated with the IS infrastructure are listed in this section. However, the various threats suggested in this chapter are far from a complete list. Therefore, expert advice, local knowledge, and analysis of current events should all be utilized to customize the threat list to the particular needs of each jurisdiction and then to review and revise the list periodically.

As mentioned before, specific threats are usually divided into broad categories that can easily be summarized to provide situational awareness. Generally, threats are categorized as natural hazards, technical and man-made threats, civil unrest, vandalism, and attacks. Other less likely but potentially more serious possibilities include bombs, hazardous materials release, a pandemic, and threats relating to weapons of mass destruction. A final grouping could be local events that are specific to the sites being protected. The groupings themselves are not important as long as all possible scenarios are covered. Some allocations will be arbitrary, as some threats could be put into any of several categories. (But never list any specific threat more than once.) There is as yet no single, uniform, comprehensive threat list format. As the planning process continues, the best threat groupings will likely evolve.

22.4.1 Natural Hazards. Natural hazard events are becoming ever more frequent, damaging, and widespread, as their patterns seem to be changing. Increasingly recent events include major flooding, severe thunderstorms; hurricanes and tornadoes; blizzards, heavy snowfall, and ice storms; wildfires and heavy smoke; contamination of air, water, buildings, or soil; and the increasing threats of disease. Although earthquakes tend to occur in cycles, these too seem more prevalent currently. Any of these can disrupt business in any number of direct and consequential ways—many unanticipated—depending on the locations of information systems, networks, terminals, data storage, cables, and utilities. Natural hazard events cannot be prevented, but their impact can be mitigated. A closer look at each category follows.

- **Atmospheric hazards.** These can include severe weather events, such as tropical cyclones and hurricanes; severe thunderstorms with hurricane winds, strong lightning, and large hailstones; tornadoes; windstorms; blizzards and heavy snows; ice storms; air pollution and high ozone levels; nuclear fallout (which is always occurring, but at low levels); extreme cold weather; and extreme hot weather.
- **Geologic hazards.** These are mainly landslides and mudslides, land subsidence (sinkholes), and expansive soils due to water.
- **Hydrologic hazards.** These hazards include riverine flooding and flooding of low-lying areas due to heavy or prolonged rains; rapid ice or snowmelt; ice jams or debris obstructions in waterways; coastal damage due to storm surge; erosion of streams; and collapse of roadways, bridges, and buildings. Hydrologic events can cascade to disrupt water and sewage systems, cause food and fuel shortages, and even trigger fires or explosions.

A dam or levee failure is a major hazard that must be carefully considered and then reviewed with experts. Most dams are well maintained and protected from natural hazards but not from vandalism or terrorist attack. Nor are most reservoirs well protected from chemical attack. The consequences of such events can be far more devastating than imagined. The 2005 failure of levees in New Orleans caused by Hurricane Katrina produced catastrophic results over wide areas.

A prolonged drought can be particularly disruptive. There may be many fires and heavy smoke that require evacuation. Potable and cooling water may be in short supply. Both people and equipment must be protected from dust or smoke that cannot be done effectively within many facilities. Hydroelectric power may be rationed and rolling blackouts imposed.

- **Seismic hazards.** Such hazards include earthquakes and tsunamis. Many areas of the United States are at moderate or even high risk of a large earthquake. There were major events in these areas hundreds of years ago, and it is believed the time is nearing for a recurrence. For example, the Ossipee Fault in central New Hampshire produced a “San Francisco–size” earthquake about 300 years ago and may occur yet again, which would cause significant damage to Boston and its suburbs. At the least it would topple equipment cabinets, break cables and wires, and probably disrupt cooling and ventilation to IS systems.

Tsunamis, which are caused by undersea earthquakes, could at some time hit U.S. shores, based on historic events. And like Hurricane Katrina, a major seismic event anywhere in North America could impact businesses throughout a wide area.

22.4.2 Other Natural Hazards

- **Major volcanic eruptions.** Volcanic eruptions can spread atmospheric dust worldwide, which can affect weather and cause severe storms, damage cooling systems, disrupt radio and satellite transmissions, and restrict air travel.
- **Wildfire.** Fire can close transportation routes, disrupt utilities and support systems over a wide area, require evacuations, and create heavy smoke that is dangerous to people and equipment.
- **Blight or infestation.** Caused by disease, weather, or insects, blight or infestation can create health problems and disrupt food supplies, which can indirectly impact business.
- **Sunspot activity.** The approximately 11-year cycle of solar magnetic storms that cause sunspots may cause waves of electromagnetic radiation that can disrupt communications and even the electrical power grid.

22.4.3 Health Threats. Of increasing concern is the possibility of health emergencies, such as a SARS or an anthrax outbreak, or West Nile virus in relatively small areas. Such outbreaks can probably be contained with antiviral medicines and vaccines. However, business disruptions will surely result. Of greater concern is the threat of another pandemic that could quickly spread through large populated areas. As yet, there are no effective means to prevent either the onset or the spread of a pandemic, other than isolation and quarantine, which includes closing businesses and schools and perhaps many municipal offices as well. As mentioned earlier as a possible worst-case scenario, personnel refusing or unable to report to work during a major health emergency might total as much as 40 percent of the workforce, and they might remain away from the workplace for as long as 14 months. Consult local health officials how to access detailed information about these threats.

22.4.4 Man-Made Threats. *Accidents* cause most security problems. Accidents, sloppiness, and blunders are the consequences of bad design, poor quality control, improper installation, failure to update, and poor maintenance. Disruption often occurs during maintenance. Deliberate actions such as snooping, pranks, vandalism, and spying are all increasingly prevalent and sophisticated but are still overshadowed by accidental, unintended events.

Moving furniture or equipment (unless done by trained professionals) can damage wiring, connectors, and other equipment sufficiently to crash systems. And while it rarely happens, substantial “accidental” damage can occur during a labor dispute or when nonunion personnel are brought on site.

Construction work, alterations, repairs, and wiring changes often cause damage to information systems. Crews often drape drop cloths over workstations and equipment to keep off dust and debris. But no one thinks to shut down the equipment first, so it becomes overheated and probably fails either immediately or soon after. Crews also plug in power tools, floor waxing machines, or vacuum cleaners in whatever electrical outlets are handy. If these happen to be dedicated circuits for systems equipment, damage may well result. In like manner, workstation users often plug time stamps, electric staplers, refrigerators, fans, and immersion heaters into outlets intended only for information systems. Such mistakes can cause intermittent problems that are difficult to locate.

Wiring runs and exposed wire can also create threats. Wiring and cabling are vulnerable in many ways—and are becoming increasingly more so. Data cables tend to be fragile and easily damaged by accident, moving furniture, cleaning and maintenance, improper connections (such as unauthorized equipment), rage, or deliberate attack. Metal wires are also vulnerable to electrical and magnetic interference from nearby light fixtures, motors, transformers, or RF emitters, as will be explained. Lightning is attracted to, and electrical power surges may be induced onto, any metal wires.

Fiber-optic wiring, which is fast replacing metal connections high-speed communications, is especially fragile. Any unusual pressure or a sharp bend in any fiber cable can alter its transmission characteristics and may cause failure. However, fiber is not affected by any electrical or RF inference.

Cables, patch panels, cords, and connectors are often exposed to accidental damage during routine premises maintenance and cleaning. Vacuum cleaners and shampooing and waxing machines can easily damage both signal and power wiring. Carpet shampooing can soak connections and flood underfloor wiring. The casters on chairs and equipment or the moving of furniture often damages cables and connectors.

Intrusions are a major threat. There are many ways to gain access to the infrastructure of information systems. Once an intrusion is successful, repeated disruptions may follow due to accidents, mistakes, snooping, hacking, spying, vandalism, extortion, or deliberate attack. Intrusion is not usually prevented by premises access control. The infrastructure's vulnerability points are different, and early detection is necessary to prevent trouble before it happens.

Intrusions via wiring and cabling are covered in the prior section. Here the emphasis is on preventing access to hardware, distribution and termination panels, patch panels, or any of the utilities that support them. Assessing the possible threats first involves inspecting the existing infrastructure and the defenses already in place. It is also necessary to determine what physical threats and vulnerability points are not sufficiently covered by premises and logical security.

Unauthorized persons should not be allowed access to any type of equipment room, rack, or closet. Everyone granted access, including visitors, should be logged in and out. And as a second layer of protection for critical areas, a gatekeeper should be at hand to observe everyone who enters and leaves, to authenticate each person's identity, and to know why access is needed. Gatekeepers may include guards, receptionists, supervisors, or managers. Except where high security is required, the gatekeeping functions can be performed remotely using surveillance and access control systems, and monitored by motion and proximity detectors.

Workstations located outside of equipment rooms are generally protected logically—using login procedures, tokens such as smart cards, and biometric devices—depending on the sensitivity of the data the system handles. Theft of equipment, components, or removable media is possible, especially during nonbusiness hours. Substitution, rather than theft, is a much more serious threat. The only safe defense is that all data must always be fully encrypted. Should a theft occur, spare units should be immediately available from nearby secure storage. To save time, thieves often cut signal cables rather than disconnect them. It is therefore wise to keep spare cables in a nearby secure storage.

There are various theft-deterrent devices to clamp or tether equipment to nearby partitions or furniture. These devices can be cumbersome and intrusive, may hinder maintenance or repairs, and most are quickly defeated with bolt cutters or a pry bar. Intrusion alarms are more effective but only detect an attempted intrusion rather than deter theft. Intrusion alarms are usually silent and triggered whenever a case or cabinet

is opened. Software can trigger alarms also when a cable is disconnected or broken, or when equipment is removed or fails. Good, sturdy equipment and cabinet locks are more effective and can dissuade theft, provided the equipment and cabinets themselves are not easily removed.

22.4.5 Wiretaps. Wiretaps are another means of intrusion whose purpose is to copy data and sometimes also to change it surreptitiously. Most taps can be placed quickly and inconspicuously even in occupied office spaces. And most wiretaps are very hard to detect—if not impossible—except by close visual inspection of all possible entry points, which is time consuming and cumbersome, and must be repeated periodically. Very often, wiretaps are simply not noticed.

Taps are used for surveillance and spying, changing or erasing data, stealing software, theft of service, injecting worms or viruses, or planting decoys to trick responders into thinking they have found the true cause of an incident. Any physical access to the interconnect points, cable runs, servers, clients, or network equipment is a major vulnerability. An experienced person can place a tap within a couple of minutes, unobtrusively, even when under escort and closely watched.

A wiretap is basically a monitoring device. It may be a small box connected directly into a circuit to tap off and record its data. The data can then be retrieved manually or be transmitted by wire or radio signal to a remote location where the information can be permanently stored and analyzed. The monitoring device may be a splitter that can tap off some of the signals traveling through the circuit and reroute them to a removed location or to a small transmitter that is close by and well concealed. The better tapping equipment uses system power, not batteries, so its service life is unlimited. Monitoring the data obtained can occur within the building or outside, via the Internet, from a nearby vehicle, or via a telephone connection to anywhere in the world.

Wiretaps have long been illegal in the United States without a court order. Years ago, an illicit phone tap in New York City, for example, was patched to a leased telephone line to Mexico where the actual surveillance could take place legally. The patch connection was made by someone at a telephone company central office and was not likely to be discovered. But if it eventually was found, the network could be traced and disconnected. This procedure suggests the lengths and expense that a determined adversary will go to, and it also suggests the high value of the information that could be gleaned. This was years ago, long before today's easy access to the Internet, cheap long-distance calls, Wi-Fi, microwave, satellites, and other broadband systems.

Fiber optic circuits are difficult and expensive to tap and sometimes impossible without breaking the circuit or changing their parameters, which can be detected quickly. There is new high-tech gear available for optical taps. But even with this, good results are problematic.

The first method is to create a sharp bend in the cable and detect some of the light rays that may leak from the outside of the bend. The signal is at best very weak. Cable can be constructed to prevent this. Or cables can be run through metal conduit to make access and then creating a sharp bend very difficult, even at junction boxes. Last, a sharp bend will change the optical impedance of the cable run and will slightly degrade its performance, perhaps enough to effectively crash the circuit. The change in optical impedance can be measured, including the approximate location of the anomaly. The cable-bending method may work, but it is hard to accomplish, detectable, and readily observed by inspection. This method can monitor data, but it cannot inject data.

The only direct method to tap a fiber cable is to open a connection, quickly interpose an interface device, and then reconnect the circuit. Alarms should be triggered

immediately when a circuit breaks or otherwise fails, and these may also give some idea where the problem occurred. But with a good interface device and by working quickly, the tap can be inserted and conditions restored to look normal before anyone can respond. If this method succeeds, the intercept quality will be excellent, and data can be injected into the tapped line as well.

Spying on what is carried by fiber circuits may be possible from within equipment rooms or at other points where the optical data are converted to electronic form or to radio waves. The equipment to do this and its capabilities are highly classified and generally unknown to most security experts.

Wireless transmissions do not need to be tapped, but the process still applies. All that is needed is a very sensitive radio and a high-gain antenna, often situated in an outside vehicle. Chapter 33 in this *Handbook* discusses wireless-network security in detail.

Metal wires are relatively easy to tap into undetectably. Small, inconspicuous induction coils placed next to a wire can easily pick up the signals without penetrating the insulation. Sometimes the taps are done with tiny probes that reach around the circumference of a wire. Induction taps are generally undetectable, except visually. However, induction taps are difficult when multiconductor, twisted-pair cables are used, especially those where each pair is shielded and the entire cable is metal clad, as are some aerial telephone cables to protect them from radio-frequency interference.

When induction is not practical, bridged taps easily placed within an accessible junction box, cross-connect or patch panel, test box, or termination strip. Bridged taps can employ a physical connection. On long cable runs, usually one or more inline terminal strips interconnect two cables. These are good locations for taps, especially where there may be unused wire pairs within the cable itself that can be used to route the tapped data to a safer location. Bridged wiretaps can also be inserted anywhere along a wire by penetrating the insulation with a needle or cutting away a tiny piece of the cladding and insulation in order to splice in a tap wire. Bridged taps are usually very high impedance, so they do not alter the circuit; therefore, like induction taps, they are undetectable, except visually. However, skill is required to place them to avoid damaging the tapped wires. As with fiber wiretaps, there are also high-tech methods of monitoring what metal wires carry, the details of which are classified.

Today, the biggest threat from wiretaps is that they are usually done by foreign intelligence, organized crime, or terrorist groups that are very well equipped, highly trained and experienced, and have almost unlimited funding to carry out their work. It is high likely that most of their surveillance is not detected, located, or removed until long afterward—if ever.

22.4.6 High-Energy Radio-Frequency Threats. A controversial area of research involves high-energy radio-frequency (HERF) weapons, which some experts claim pose a serious threat to disrupt, damage, or destroy electrical and electronic systems and equipment over a very wide area. There are several scenarios.

A prototype HERF weapon demonstration at security conferences some years ago showed that a bulky apparatus constructed from easily obtained components can cause personal computers to malfunction while the device continues to operate. It can perhaps cause some system failures as well. There has been no more public information since then as to whether a smaller, portable version could emit a radio-frequency beam of sufficient power to disrupt systems dozens of meters away. Such a device is possible but may not be very practicable, except possibly from a large vehicle.

Along with this is another threat called high-intensity radio-frequency flux, which is simply interference from other electronic devices. These can be nearby transmitters, such as high-powered radio, TV, or radar systems, or transmitters in vehicles. Or there may be interference from close-by RF emitters including cell phones, computers, and devices designed for this purpose. Some of these possibilities are design issues, but when portable RF emitters are involved, the situations become infrastructure threats.

In 2004, another approach was reported that is potentially able to destroy unprotected electric and electronic system nationwide by way of an electromagnetic pulse attack (EMP). This report⁷ comes from a commission finding that a low-level nuclear explosion by a missile in the upper atmosphere could cause a massive electromagnetic pulse wave that could wreak catastrophic damage throughout most of the United States. Without extensive shielding, electrical and electronic systems could be destroyed, and power transmission systems as well. However, it appears that such an explosion must be done just right or the damage would be minimal.

The defense against all such RF threats is to shield equipment and wiring effectively. A Faraday cage can envelop and protect everything. This is usually one or more layers of copper screening that are well grounded. There also are Faraday bags to protect and store small items like cell phones or circuit boards.

However, once shielding is installed, it is wise to test that it actually works as expected. The author once toured a large, new data center of a major money-center bank. In touting the huge sums spent on extensive security protections for the new facility, someone mentioned that an impenetrable Faraday shield enveloped the entire room. The only problem was that a transistor radio on top of a cabinet was playing clearly and loudly. Had the room actually been well shielded, no broadcast signal could have penetrated.

Hazardous material incidents can include a release within a building or industrial plant, or from an aircraft, railroad, highway, or waterway accident. Many hazardous substances are routinely transported, stored, and processed throughout the United States. Many of these materials are extremely dangerous when released. They can quickly affect a wide area and may require immediate evacuation. In addition to accidental or deliberate release, these materials may be stolen to become part of an attack elsewhere. And those who attempt to steal, transport, and process the materials into a weapon may endanger others accidentally along the way.

Toxic threats include a buildup of radon within occupied space or in a water supply. Radon is released naturally by many types of rock. It is very prevalent and extremely dangerous if it can enter the body. Radon is an alpha particle that cannot be detected by most traditional measurement devices. Similarly, many toxic substances can accumulate in drinking water or building air. Any of these substances will be disruptive and cause anxiety far beyond the affected areas. Consult local health officials to identify and assess these threats.

Fire and smoke from remote events can be troublesome in several ways. Smoke from events hundreds of miles distant can cause health problems, delay supplies and deliveries, and cause food or fuel shortages. Workers may be unable to get to or from work, and may also be concerned about their families, friends, and homes. Electronic equipment is particularly susceptible to environmental damage from smoke or other airborne particles. And there may be utility problems or loss of cooling caused by a large, distant fire.

Nearby fire or smoke can be particularly troublesome. In addition to the problems just mentioned, an immediate system shutdown and personnel evacuation may be required. Power and data lines may be broken or damaged by heat or water. There may

be flooding as well, and hazardous materials released that are potentially injurious to people and equipment. There will also be the need to contain the threats and to clean up the environment before full business can be resumed.

Smoke, dust, or other airborne particles can cause equipment failures, as these block cooling systems, clog filters, and build up inside equipment, constricting ventilation and convection cooling. Although these are mostly maintenance issues, they are also potential threats.

22.5 WORKPLACE VIOLENCE AND TERRORISM. The use of force, harassment, or physical violence is an increasing reality within the workplace. Drug- and alcohol-related incidents are on the upswing, as are workplace crimes necessary to support and conceal such habits. Adding to the threats is the increasing presence of rage within or upon the workplace. Any of these incidents can cause widespread trauma and disrupt business operations for months. Actual violence or terrorism, or simply the threat or the fear of this, can be extremely costly and disruptive.

Any violence situation—whether threatened, imagined, actual, or peripheral—can seriously disrupt information systems, whether the infrastructure is actually in danger or not. Performance, productivity, and morale will all plummet and remain low for a long time following any perceived or actual threat. Full recovery can take many months—assuming that more incidents do not occur in the meantime. Therefore, a safe working environment, good security planning and implementation, and security training exercises are essential so that everyone feels safe.

The likely tools of choice for inflicting widespread injury and damage may soon be weapons of mass destruction (WMDs) rather than the old-fashioned knives, guns, bombs, or arson that inflict only limited damage. WMD devices are far more dangerous, and many are small and easily concealed in a pocket, package, or briefcase.

A small, common-looking object containing biological toxins and powered by a flashlight battery can theoretically kill every person within the largest of office buildings. A vial no larger than a lipstick can contain enough virulent hemolytic viruses to kill every person within a 20- to 50-mile radius, if it is dispersed efficiently. Because few chemical or biological WMD compounds have much odor or color when they are disbursed, occupants, visitors, bystanders, and responders are all likely to be innocent victims. Illness can begin within minutes, hours, or days. Laboratory analysis is needed to identify many of the substances. More time is needed to determine the scope and spread of the damage. Ordinary personal protective gear and breathing apparatus can provide little or no protection.

WMDs can be enormously destructive. A national FEMA, Department of Justice training exercise called TopOff that I conducted in May 2000, simulating a biological attack on Denver, Colorado, resulted in an estimate of 57,000 fatalities. Since then, similar exercises have not released fatality estimates.

WMD threats can be grouped by the mnemonic B-NICE. They include *biological* agents, such as anthrax, cholera, pneumonic plague, tularemia, Q fever, Ebola, smallpox, botulism, ricin, and some others. These are all living bacteria whose incubation periods (the time of onset following exposure) are measured in hours or days.

Nuclear and radiological releases can cause widespread panic but are not likely to cause mass casualties, except to persons nearby. Radiation levels can easily be monitored, and building structures will often serve as an effective shelter.

Incendiary devices are utilized mainly to cause structural fires. A device can be planted surreptitiously and then triggered remotely or by a timer. Rockets and small

22 · 22 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

missiles are increasingly an incendiary threat, as are 9/11-type incidents: airplanes, vehicles, or boats used as bombs.

Explosive devices are similar. These may be stolen or smuggled ordinance or, increasingly, improvised explosive devices made from commonly available materials.

Combined attacks are possible, such as explosive devices used to disburse chemical agents (but not biologicals, which are live bacteria that would be killed by an explosion) or the so-called dirty bombs, which are explosives used to disburse radioactive material.

In a worst-case scenario, all WMD events can be exceedingly dangerous and disruptive, and any of these events may someday happen within the United States. Even the rumor of a WMD event can be damaging and cause widespread hysteria, panic, and create a large army of the walking well. Whether the threat is real or imagined, WMDs are costly to combat.

Most details on WMD and extremist or terrorist threats are classified, but state and federal authorities should be able to provide some insight for an effective threat assessment. The authorities should at least be asked about perceived threats, possible target areas, and regional and local incidents and security concerns.

22.6 OTHER THREAT SITUATIONS

22.6.1 Leaks, Temperature, and Humidity. Threats involving water and other liquids that may be hazardous should be considered also, as well as temperature and humidly conditions where equipment is located. Sprinkler systems in nearby spaces can cause equipment damage, as can liquid leaks from storage tanks, cooling towers, or pipes near equipment areas. Atmospheric conditions near equipment are threat situations as well. Air temperatures that are either too high or too low can cause equipment failure. High humidity can cause condensation within equipment and, worse, a form of galvanic action that degrades connectors that will then fail eventually. Also, low humidity is a threat because this promotes static electrical discharges that can be deadly to electronic gear and is often undetected until the equipment fails without warning. (See also Chapter 23, Section 23.8.7.)

22.6.2 Off-Hour Visitors. Cleaning and maintenance personnel usually work off hours and are often hired by a contractor or landlord who rarely provides much, if any, background checking, supervision, or training. Very few of the personnel are aware of security precautions and most know very little about the IS systems their work can damage. Many are paid poorly, are forced to rush their work, and may understand little English.

One of the classic disruptions can occur when workstations and associated devices are simply plugged into wall sockets or extension cords without labels indicating that they must not be unplugged; cleaning staff may easily unplug such devices in all innocence to run their own cleaning equipment and never even notice that they have abruptly powered down the computing equipment on nearby desks.

Waxing floors and shampooing carpets are usually done off hours by outside services. Moving furniture and changing workstations are often done after hours, as are repairs, alterations in occupied office space, and other major maintenance. Almost always, these people are unescorted, and many are not even logged into or out of the premises or identified in any way. Worse yet, many of these people prop open doors so they can work faster and sometimes so they can take advantage of air-conditioning in adjacent spaces.

Persons who are unknown often come into the premises without proper authorization. Some work for the landlord or the service organization. Some are delivering food. Some are messengers. And some are snooping, spying, looking to steal, or perhaps bent on violence. Even daytime workers may show up after hours. Therefore, the best security policy is to admit no one after hours until identified positively, logged in, and a need to be there is established. Everyone should be stopped at a reception or delivery desk, with no further access into the workplace until properly cleared. Anyone leaving should be logged out as well, especially if they have been out of sight of where they first entered. Screening visitors at any hour has the added security benefit that outsiders do not see where any IS infrastructure may be located or where money, wallets, or handbags are kept. A night bell or intercom outside an always-locked door should be used to prevent entry to a sensitive facility.

22.6.3 Cleaning and Maintenance Threats. A floor-waxing machine abrades everything it touches and will very quickly destroy unprotected wiring, connectors, dangling cords, or unseen power extension cords (which, by the way, are illegal according to most electrical codes). The waxing machine operator often cannot see any of these items or may not have time to look carefully at what is plainly visible. Carpet shampooing uses a lot of liquid and can flood floor-level outlet boxes and drain into underfloor ducts and conduits. Electrical plugs, receptacles, and unauthorized extension cords for critical equipment are often unlabeled. The cleaning staff does not know they are critical and can unknowingly unplug servers to power their cleaning equipment. Therefore, the threat assessment must first determine whether premises design invites problems, even though cleaning and maintenance personnel do their work carefully.

Users often compound these threats. Many workstations may be logged off but are left running continuously. No one tells users to shut down and cover their equipment before major cleaning or maintenance.

22.6.4 Storage-Room Threats. Rooms used to store computer supplies, paper, or forms are especially dangerous if a fire occurs. For example, stored cartons of paper, forms, or stationery expand when they burn, then burst into a conflagration that spreads quickly and burns at a very high temperature. Such a fire occurred in a high-rise office building in Manhattan. Even though the fire department quickly contained the fire, some steel building columns were so weakened by the heat that the building nearly collapsed. The cause of this fire was determined to be a cigarette butt that fell between stacked cartons of paper. This was assumed to have been accidental but could well have been arson.

Any storage room containing sensitive or inflammable materials must have smoke detectors, sprinklers, or other approved fire suppression systems designed to protect both the room and its contents. There must also be fire extinguishers nearby. Storage rooms should be kept locked, and access should be limited to trusted persons, if only to protect the value of the contents. There should be access control systems with admittance limited to authorized persons only, with open-door alarms provided as well. Delivery persons should always be continuously escorted. Loitering, smoking, drinking, drugs, snoozing, or any social activities must be kept out of and away from all storage areas.

22.6.5 Medical Emergencies. Most medical emergencies will cause business disruptions. People stop work to see what is happening, and if they know the victim

22 · 24 PHYSICAL THREATS TO THE INFORMATION INFRASTRUCTURE

they may remain demoralized and unproductive for weeks afterward. Many will fixate on the circumstances and increasingly involve others to compound the problems. Even minor medical emergencies can cause large and long disruptions. In many medical emergencies, the first five minutes can decide life or death, and professional medical assistance is very likely unavailable that quickly. Any death that occurs in the workplace will result in long-term, widespread, and lasting trauma and disruption. (See also Chapter 23, Section 23.9.4.)

There must be first aid supplies, oxygen, and automatic electric defibrillators (AEDs) handy in every workplace. And there must be people nearby who are trained and currently certified in cardiovascular resuscitation and first aid. The costs of a disruption alone are far greater than those for providing ample medical supplies, equipment, and training. In addition, a first aid room and a trained nurse are wise precautions and probably a cost savings as well.

Prompt medical attention is essential for senior executives, visitors, and all workers and visitors. Medical threats will happen and will be very costly if medical assistance is not immediately available.

22.6.6 Illicit Workstation. A convenient method to set up a logical intrusion or attack is to unplug a desktop terminal or workstation that has limited functionality and substitute a full-featured machine well programmed with spyware and analytic utilities. Anyone with a full-featured notebook computer and physical access to the network may be able to connect easily.

Illicit users may then be able to log onto the network, possibly entering the user's own trusted password. They could then search for restricted information and use the full-featured machine to copy network data. Then the illicit user simply connects to a nearby telephone receptacle to export network data via a dial-up connection. (An Internet connection would likely be blocked by the firewall.) The illicit user may use hacking programs to gain supervisory status and spyware to access more sensitive information, crack passwords, steal software, or infect the network with malicious software. The illicit user may install a backdoor entrance into the network that an accomplice can use to spy, monitor network traffic, and modify or destroy data. An experienced user may then erase all evidence of any intrusion.

The intrusion might be done by an in-house employee, contractor, service technician, vendor, or consultant who could breach the network while ostensibly checking a user's machine or LAN connection. It could also be done within a hot zone using a Wi-Fi connection where there may be few, if any, firewall or security protections. Maintenance personnel working off hours also could substitute a terminal inconspicuously. However it is done, intrusion is a serious physical threat.

Security awareness is the best prevention. No one should be swapping equipment or connections unless a manager, supervisor, or nearby workers know the person's identity and what he or she is doing. If there is any possible doubt, the activity should be reported. The second best prevention is good network security, with alarms when any desktop systems is opened, disconnected, or shut down.

Chapter 15 in this *Handbook* includes detailed discussion of penetration techniques.

22.6.7 Other Local Threats. There are many threat situations specific to a group, organization, or community. Usually, many of these situations are identified and assessed as planning progresses. For example, for a community, important local

threats might include vandalism or actual damage to school buildings, schoolyards, or school buses, a building or bridge collapse, interrupted power or energy transmissions systems, damaged fuel storage facilities, or a communications failure. Many possible specific situations will likely be discussed during the planning process, while review and advice by outside experts and government officials probably will lead to more important situations. Some considerations for local threat situations include:

- **Utility disruptions.** Disruptions happen more frequently than reported. Power outages can last a few minutes, hours, or days, caused by storm damage, equipment failure, tree branches hitting power lines, highway accidents that topple utility poles, digging accidents that break transmissions lines, and vandalism or worse, such as toppling transmission line towers. There are increasing reports of transmission towers and utility poles deliberately toppled, power outages caused by insulators smashed or wires cut by bullets, and outages that occurred when wires and bus bars were stolen for the value of the metal in them. There can be static or RF interference or spikes on a utility line at any time due to atmospheric conditions, lightning, or the utility switching their feeders.
Communications outages can be even more problematic, and few of these situations are widely known. Communications providers are for-profit enterprises and cannot provide much fail-safe protection, backup, or redundancy when severe weather, vandalism, deliberate attacks, or equipment failure interrupt their services. Although there not many alternate suppliers to choose from, the only security protections are redundancy and alternate suppliers.
- **Civil, political, and economic disruptions.** Such disruptions may be indicated by an elevated Homeland Security Threat Level or by state or regional alerts. Other possible disruptive events include a demonstration, march, disorderly group, or an unruly crowd. Other economic emergencies include a plant closing, a strike or a lockout, a transportation failure, or a shutdown. There are also the threats of violence of any kind; a hostage incident or kidnapping; sabotage of any infrastructure (e.g., power lines); contamination of food, water, air, or soil; a food or fuel shortage, a spike in energy costs or a shortage; and the repercussions of a major evacuation somewhere in the region.
- **Coordinated attacks.** These attacks are also possible, perhaps even by terrorists. Here, many points of the infrastructure are attacked at once, and many forms of attack may be used. There may be diversions in order to plant surveillance devices, place stronger weapons, or simply to distract response teams and stretch their resources more thinly. And whether spying is intended or not, the goal of a coordinated attack is to inflict maximum damage and disruption.
- **Solar storms.** Solar activity can also cause large problems. Sunspots affect electrical distribution systems as well as electronic systems, and they can severely disrupt satellite, microwave, and emergency communications, and radio, TV, and radar transmissions.

22.7 CONFIDENTIAL THREAT INFORMATION. Many other threat scenarios should not be described publicly because they are easily done by anyone with a grievance, and they tend to incite copycats. Other threats that will not be described utilize simple tools or devices that are readily obtained, are inconspicuous while in use, and can be safely hidden after a crime. Avoiding such threats is difficult, and

apprehension is unlikely. Nonetheless, mitigation is possible, and sometimes even deterrence, once these threats are known and understood.

Most vendors, installers, and consultants have long lists of such unmentionable threats and ways they know of to disrupt, snoop into, or destroy specific types of information systems. No threat assessment can be complete without asking all these information sources for whatever attack methods they can suggest as well as for methods of preventing or mitigating each threat.

Many useful sources of information and guidance are not generally public—many sources, indeed, that Internet search engines have not discovered. Some of this material is simply not publicly available, and other sources may be derived from classified documents. But briefings or redacted information may be made available to those who need it. More information may be available from local, state, and federal authorities, regulatory bodies, peer groups, business or vendor associations, professional groups, and security experts and consultants. Each of these sources may be willing to share information not available to the general public.⁸

The FBI is the ultimate source of threat information. But this information is mostly classified, and without the proper security clearance and a need to know, the FBI will not divulge much. A nationwide group of people involved in IS security is sponsored by the FBI and does provide some useful (sensitive but unclassified) information, once each member is vetted and approved. This group is called InfraGard, and there are chapters in most states. Visit www.infragard.net for a list of local chapters and contact them about membership.

22.8 SUMMARY. A vast array of possible physical threat situations can disrupt the infrastructure of information systems and thereby also disrupt business productivity and performance. The list of specific threats may identify several hundred situations, and each one should be included and considered during a threat assessment process that is well done and thorough.

Some of the threat situations are obvious and well known, while many others are much less so. Many are newly emerging, suggested by recent events worldwide and by reexamination of historic data. There also are issues of apathy, denial, and ignorance, where some persons feel that such things will never affect them or that nothing can be done to prevent a disaster. Both assertions are patently false and potentially very costly if pursued. Most threat situations can and will happen somewhere, someday. But whether they do or not is a matter of statistics and not conjecture.

Every possible threat situation can be mitigated to some extent by careful security planning and concerned management to minimize injury and damage. In fact, good physical security can be affordable, effective, and efficient. The first step is a thorough threat assessment to identify and consider all possible threat situations. The next step is to determine the likelihood that each threat may occur, the potential impact if it does, and the vulnerability of the organization within the context of its current security protections. Each step can be calculated statistically to determine the best possible options.

This chapter begins a threat assessment process that takes all these factors into account. Chapter 23 then suggests some ways to protect the information infrastructure and completes the threat assessment process with a cost-benefit approximation to determine the vulnerability of each threat.

These chapters are based on a uniform and comprehensive methodology recommended by the federal government and now required for all federal, state, and local

agencies and departments. Compliance is strongly recommended for the private sector, if only as an effective means of risk management.

The value of this approach is that good security is a wise investment. Anything less than good security is a waste of time and money.

INTRODUCTION TO PART III

PREVENTION: TECHNICAL DEFENSES

The threats and vulnerabilities described in Part II can be met in part by effective use of technical countermeasures.

The chapter titles and topics in this part include:

- 23. Protecting the Physical Information Infrastructure.** Facilities security and emergency management
- 24. Operating System Security.** Fundamentals of operating-systems security, including security kernels, privilege levels, access control lists, and memory partitions
- 25. Local Area Networks.** Security for local area networks, including principles and platform-specific tools
- 26. Gateway Security Devices.** Effective recommendations for implementing firewalls and proxy servers
- 27. Intrusion Detection and Intrusion Prevention Devices.** Critical elements of security management for measuring attack frequencies outside and inside the perimeter and for reducing successful penetrations
- 28. Identification and Authentication.** What one knows, what one has, what one is, and what one does
- 29. Biometric Authentication.** Special focus on who one is and what one does as markers of identity
- 30. E-Commerce and Web Server Safeguards.** Technological and legal measures underlying secure e-commerce and a systematic approach to developing and implementing security services
- 31. Web Monitoring and Content Filtering.** Tools for security management within the perimeter
- 32. Virtual Private Networks and Secure Remote Access.** Encrypted channels (virtual private networks) for secure communication, and approaches for safe remote access

III · 2 PREVENTION: TECHNICAL DEFENSES

33. **802.11 Wireless LAN Security.** Protecting increasingly pervasive wireless networks as a majority of the world's Internet users access information through their mobile phones and tablets
34. **Securing VoIP.** Security measures for Voice over IP telephony, a cost-effective method for increasing long-distance collaboration
35. **Securing P2P, IM, SMS, and Collaboration Tools.** Securing collaboration tools such as peer-to-peer networks, instant messaging, text messaging services, and other mechanisms to reduce physical travel, and to facilitate communications
36. **Securing Stored Data.** Managing encryption and efficient storage of stored data, including cloud-storage services
37. **PKI and Certificate Authorities.** Concepts, terminology, and applications of the Public Key Infrastructure for asymmetric encryption
38. **Writing Secure Code.** Guidelines for writing robust program code that includes few bugs and that can successfully resist deliberate attacks
39. **Software Development and Quality Assurance.** Using quality assurance and testing to underpin security in the development phase of programs
40. **Managing Software Patches and Vulnerabilities.** Rational deployment of software patches
41. **Antivirus Technology.** Methods for fighting malicious code
42. **Protecting Digital Rights: Technical Approaches.** Methods for safeguarding intellectual property, such as programs, music, and video, that must by its nature be shared to be useful

23.1 INTRODUCTION. Chapter 22 in this *Handbook* describes a systematic approach to identifying threats to the physical information infrastructure. This chapter describes practical recommendations for implementing good physical-security protection for information systems (IS).

There was a time when insurance was enough to cover most threat situations. However, today disaster, workplace violence, and terrorism insurance coverage may not be available or affordable without an independent, outside security audit to ascertain a good security program is in place.

There is one nearly ironclad legal defense against negligence allegations, and this is to demonstrate that the organization is following the commonly accepted federal security planning and management procedures. Usually, such compliance alone is sufficient to prevent negligence suits from even being filed; any remaining allegations are usually minor and easily covered by insurance. Conformity to the commonly accepted federal procedures can quickly be ascertained by a recent security audit.

The security audit will examine compliance with all documented facets of the planning, preparation, policies, training and exercises, management and oversight, and response and recovery plans and procedures. These are all the necessary components for protecting the information infrastructure.

Chapter 54 in this *Handbook* discusses audits, and Chapter 60 discusses insurance for information systems.

23.2 SECURITY PLANNING AND MANAGEMENT. In the United States, there are many laws, regulations, and federal directives that should be incorporated into the security planning and management of any organization. Even when compliance is not yet mandated, it is highly recommended simply to avoid unnecessary and potentially huge costs of defending against allegations of negligence, and establishing in court that the security procedures in place are sufficient.

Some of the new requirements that may affect almost any organization in the United States are briefly summarized in the following list.

National Incident Management System (NIMS) Compliance: The National Incident Management System (NIMS) defined by the Federal Emergency

Management Agency (FEMA) requires all departments and agencies of the federal, state, and local governments to implement its standards. NIMS is an emergency-response template which supplements and unifies the incident command systems long in use by most response agencies.¹

National Response Framework: The National Response Framework (NRF) provides an emergency operations plan which all state and local governments have long been required to have. The NRF now unifies the content and format for all such plans. Compliance also requires certification of senior officials.²

National Infrastructure Protection Plan: The National Infrastructure Protection Plan (NIPP) defines recommendations for the protection of critical infrastructure and key resources. It proposes a unifying structure that includes partnership initiatives, a risk-management framework, and information sharing.³

Robert T. Stafford Disaster Relief and Emergency Assistance Act of 1988 (Public Law 100-707): In combination with the Disaster Mitigation Act of 2000 (Public Law 106-390), every state and community must have a current and FEMA-approved *All-Hazard Mitigation Plan* and a current and approved *Emergency Operations Plan* in place.⁴

The Sarbanes-Oxley Act of 2002 (SOX): Public corporations must report all of their internal financial controls, which may include those relating to security management—including future events that can materially affect future earnings. Most of the threats identified in Chapter 22 can do this, so that the possible mitigated costs of each threat as determined at the end of this chapter may need to be included in the SOX reporting.⁵

The Health Insurance Portability and Accountability Act of 2002 (HIPAA): All organizations that receive and hold personally identifiable individual health information must keep those data.⁶

The Gramm-Leach-Bliley Act of 1999: Financial institutions, lenders, advisors, accountants, and businesses that process or receive financial information must protect those data against unauthorized disclosure and modification.⁷

Emergency Management Accreditation Program (EMAP): EMAP, “an independent nonprofit organization, is a standard-based voluntary assessment and peer review accreditation process for government programs responsible for coordinating prevention, mitigation, preparedness, response, and recovery activities for natural and human-caused disasters. Accreditation is based on compliance with collaboratively developed national standards, the *Emergency Management Standard* by EMAP. Accreditation is open to all U.S. states, territories, and local government emergency management programs. Anyone can subscribe to receive standards and guidance materials.”⁸

23.3 STRATEGIC PLANNING PROCESS. The planning process must think ahead strategically to determine the best possible security options to add maximum value and contribute to profits, enhance productivity and performance, and avoid intrusiveness. The process of identifying all possible threat situations and a statistical method to predict the likelihood of injury or damage and the current vulnerability of the enterprise to each individual threat is described in Chapter 22. This chapter builds on the planning process, suggests ways to better protect the infrastructure and thereby reduce its vulnerability, and describes how to implement the security planning and management process.

23 · 4 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

Some facets of good physical protection to consider in the planning process are outlined next. These suggest some critical elements and how to protect them, and some possible weak points in the information infrastructure. Section 23.11 completes the planning and mitigation process.

23.3.1 Attractive Targets. Much of this chapter deals with what amounts to physical hacking. As with its electronic counterpart, physical attacks cannot be predicted as to when, where, or how they will occur. Electronic hacking from within the organization, over its networks, or from anywhere in the world via the Internet is still the best way to break into most information systems. However, physical intrusion can be harder to detect and locate, and often is more damaging and costly. In addition, threats from employees or contractors who are bad actors with *authorization* to be unsupervised in their work with or near the physical infrastructure of information systems are a serious threat.

Chapters 12 and 13 in this *Handbook* discuss the psychology of computer criminals and dangerous insiders.

23.3.2 Defensive Strategies. There are many effective defensive strategies to consider. The planning process must evaluate each approach and how best to combine them strategically to maximize effectiveness and minimize costs. These defensive strategies are common:

- *Prevention* so that specific threats do not affect the enterprise.
- *Deterrence* so that specific threats are not likely to occur.
- *Mitigation* to reduce each threat to tolerable consequences.
- *Redundancies* so there are no critical links in the infrastructure that cannot be bypassed. There are many methods of redundancy, such as multiple data paths; bidirectional data loops; parallel or distributed processing; alternative support systems and utilities; and many more.
- *Early warning* to detect impending trouble and delay onset, so that fast response can prevent or minimize any disruption.
- *Layers of security*, which are like the concentric layers of an onion, so that several layers of security must be penetrated before a target can be reached. This adds reliability, because a failure or breach of one layer does not compromise the other concentric layers.
- *Insurance* that can reimburse some of the recovery costs but usually few of the response costs. Insurance coverage often excludes many threats and can be costly. Insurance may not cover (or even be available for) gross negligence, some acts of God, flooding, terrorism, or acts of war.
- *Capital markets*, which are less costly than insurance and better able to lay off larger and broader risks.
- *Self-insurance* to establish retentions (which are funds accumulated for the purpose) in the hope nothing serious ever happens.
- *Contract security services* that are performed in-house, which basically transfer risks, but do not necessarily mitigate threats.
- *Outsourcing*, which is another option that introduces still other and often unrealized threats and vulnerabilities.

23.3.3 Who Is Responsible? Effective security requires both governance from the boardroom and oversight by senior management. Top management must also actively sponsor it and insist that everyone involved understands, supports, and respects the security plans and procedures. Accountability and oversight are essential, as is insistence on periodic security exercises, review, and updating.

If possible, the infrastructure-security manager should *not* also be in charge of IS or corporate or premises security. Although managers of these areas face similar threats and their groups must work closely together, their priorities and levels of response to any incident are different. It is best therefore that two or more specialized security groups report to one senior executive officer with clear lines of authority. Even if the role cannot be full time, defining a formal position for an infrastructure-security manager is a wise investment.

23.3.4 One Process, One Language. As mentioned previously, the security planning and management process must be uniform and comprehensive, and applied effectively and efficiently. There should also be a current audit done by an outside, independent group to ascertain both security preparedness and compliance with the pertinent laws, codes, and regulations. The least costly and most effective approach is to follow federal guidelines. The Department of Homeland Security (DHS) and FEMA procedures provide a uniform and comprehensive methodology and generally accepted standard practices that are uniform, comprehensive, and most likely to deter liability as well. This process is recommended for any organization, public or private.

FEMA makes the distinction between an emergency, which is a situation that an organization can handle with its own resources, and a disaster, which is when internal resources are likely to be overwhelmed and outside help is needed. The distinction is not always clear-cut. “Crisis” is not a defined term. FEMA also recommends planning and preparation for worse-case situations, which often turn out to be what happens. Many threats can become disasters to a business, even when outside resources respond quickly. For example, the consequences of an equipment room fire can be disastrous when the local fire department responds with axes and water hoses, cuts off all electrical power to the building, and smashes out windows to vent smoke. Even a major incident that occurs away from the immediate premises can necessitate an evacuation, cutting off building power, and creating serious disruption.

23.4 ELEMENTS OF GOOD PROTECTION. Protecting the infrastructure generally requires different and stronger defenses than premises security or IS logical security can provide. The infrastructure protection must be effective, efficient, and affordable. Yet it must also be nonintrusive and user friendly. Too much protection is unnecessarily costly and often counterproductive. Too little can be even more costly and endanger productivity, morale, and goodwill.

Some of the requisite elements for just the right amount of protection are provided in the sections that follow.

23.4.1 Segmented Secrets. Although *security by obscurity* is rightly derided if it is the primary focus of protection, to maintain good security, no *one* person should know or control *all* the details or inner workings of the security systems and procedures. If total understanding of the security systems is segmented into several parts and the knowledge distributed among collaborators, there is much less likelihood of misuse, fraud, or error, and less dependency on a few key persons. The shared knowledge contributes to separation of duties and pervasive vigilance.

23 · 6 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

However, the more people with knowledge of the security systems and procedures, the more these systems become vulnerable. It is easier to compromise security through coercion or extortion, or by an unwise remark inadvertently disclosing information. The list of those with inside knowledge may include managers, administrators, maintenance personnel, users, partners, suppliers, customers, vendors, and consultants. Although many individuals must know at least some of the security protections, no one needs to know all of the details.

Beyond segmenting, there is another precaution needed for good protection. If members of the same group must share sensitive knowledge, a “two-person” rule should apply—an example of separation of duties. This principle is especially important when anyone is able to modify the security infrastructure, alarms, or event logs. The two-person rule says that any modification to the security system requires two authorized persons working together and that there will always be an audit trail showing who did what and when. This procedure also is used when two or more groups share responsibility for common elements of a security system.

23.4.2 Confidential Design Details. It is often quite easy for others to locate and identify critical infrastructure components. Many times the information is clearly shown on public documents. The signage on infrastructure locations often clearly describes what is inside, and critical components are often put in spaces easily accessible to outsiders. These are all unsafe design practices.

Many types of documents clearly indicate IS areas, support systems, and other infrastructure. The documents may show the locations of equipment, wiring, utilities, and cable runs. Documents that are likely to reveal sensitive information include building plans that show floor and office layouts, furniture, wiring, and equipment locations. Architectural and engineering documents, drawings, and specifications often show sensitive information. These documents often list the function of each area, and even an occupant’s name or title. Other types of documents breach security as well. Examples may be as-built plans, alteration and construction plans, electrical and communications wiring diagrams, patch-panel and cross-connect setups, as well as contract drawings or proposals, shop drawings, installation plans, maintenance diagrams, and, especially, documents filed with code-compliance and regulatory agencies. Good protection requires that all such documents be controlled and kept securely stored. Better yet, sensitive information should be removed and alphanumeric designations that are cross-referenced to sheets than can easily be kept classified should be shown.

All of the listed documents are routinely distributed to a wide range of sources, such as interested contractors and bidders, vendors, suppliers, and maintenance providers. Building managers, landlords, and often real estate offices are likely to keep copies on file, and many other persons can readily access the documents and copy them. Most such documents are publicly available or obtainable via the sunshine laws of each state, by court order, or simply by deception. Moreover, many legitimate persons obtaining or receiving the documents have no internal document control or security provisions.

All room and area designations should always be alphanumeric. Descriptive or functional names should not be used for any area. This caveat pertains to the entire premises, all public areas of the facility, and all building mechanical and core areas. Functional designations or terms such as “treasurer,” “marketing director,” “security desk,” “computer room,” “network closet,” or “telephone room” should never appear. Nor should the names of any occupants, departments or functional groups, or individual tenants’ spaces be given. Use only alphanumeric designations.

Lists that correlate area and room numbers, functional areas, or any descriptive names should be kept secure in a locked file, as should equipment room drawings, patch panel connections, and wiring plans. All these must be readily available to system administrators in the event of a system failure or when doing maintenance or upgrades, but only on a need-to-know basis. Ideally, even managers do not have access to this information, except when accompanied by security personnel. As well as controlling access to such documents, it is equally vital that every document be kept current.

Finally, security personnel should review all plans, drawings, and documents for construction, alterations, equipment moves, or any other physical changes before the information is issued. Security personnel should also review the invitations to bid and all the drawings and specifications, review again the quotations received, and continue to review every as-built document produced throughout a project. Internal security should review all these as a matter of policy. If the security personnel do not have sufficient time or expertise to review everything quickly and thoroughly, outside independent experts can be valuable. When properly chosen, these experts can provide broad experience, perspective, and evidence of due diligence, so that management cannot later be accused of negligence in protecting information, people, or property. Finally, the security leader should sign-off that no project documents violate any internal security policies.

23.4.3 Difficulties in Protecting the Infrastructure. Decades ago, most IS equipment was housed inside a single computer room, and most of the external terminals and peripheral equipment were located nearby. Cable runs were short and generally within secure areas, and access controls, alarms, and surveillance could easily cover the critical areas. There were often security guards as well. But in those days, there were fewer threat situations and less cost if trouble did come. Many organizations then were apathetic and security was lax. They were lucky, but a few incidents did occur and often at great cost. There were also likely many undiscovered security breaches and still more that were never reported.

Today, the IS infrastructure is much larger and more complex, and the potential costs of trouble are far greater. Today's infrastructure is much more interdependent, and it now includes many more equipment and network rooms. It extends to many more telephone and utility closets, and interconnects widespread and diverse desktop, peripheral, and remote nodes. Today's infrastructure is increasingly harder to protect, and the future outlook suggests many more threat situations with the potential to cause major business disruption.

To further complicate security, there are now many more and diverse IS interfaces and a complex infrastructure to protect. Interfaces now include direct and switched wiring, wireless topologies, and infrared coupling. Access to the Internet, local area networks, and wide area networks may now utilize combinations of metal wiring and fiber optics, wireless, satellite, TV cable, and microwave links. Some of these interfaces will be dedicated, others switched, and still others temporarily patched. It will be difficult to even locate all the interfaces, yet each must be protected, as must be their cable runs and the utilities that support them. Today, the early warnings from the security alarms and defenses must be so effective that most trouble can be prevented before it happens.

23.4.4 Appearance of Good Security. The appearance of an armed fortress is usually counterproductive. This usually intimidates and obstructs both visitors and staff more than it protects them. The same is often true for too many guards and

23 · 8 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

receptionists stationed to block entry points to internal areas (unless this is deemed absolutely necessary). Such barriers tend to enrage anyone who may be already anxious, and can provoke attacks. Barriers tend to be ineffective; for example, even if the glass is bulletproof and spray-proof, the pass-through holes likely are not. Most barriers can be breached as well, and the person(s) inside injured or at least traumatized. For example, some years ago most banks rushed to put their tellers behind thick glass panels. However, they soon discovered that the glass provoked trouble rather than deterring it. The banks quickly removed both the glass and the pass-throughs, which many businesses then bought and installed, with similar results. Anger and potential violence are best avoided by good facilities design, security systems and access controls, and training in security awareness and violence prevention.

There are also considerations whether security devices should be covert or appear in plain sight for all to see. Defenses that are in plain sight can serve as deterrents and promote a feeling of safety, but they can also be vulnerable themselves. Cameras can be spray-painted, shot out, or knocked aside with a club. Any exposed wiring (which is a security no-no in itself) can be cut or shot through. The alternative is to use concealed devices and also dummy devices or “honeypots” that are obviously positioned. (Both are discussed later.)

23.4.5 Proper Labeling. Good security requires quickly locating trouble spots, with certainty that the nomenclature of every component, cable, and connector is clear and current. There must be proper and consistent labeling of all data and power cables, both inside and beyond the secure areas. No label or tagging should reveal confidential information. Many vendors, installers, contract personnel, and in-house staff tend to use their own labeling and tagging systems, some of which are clear and understandable, while others are not. The labeling and tagging must match the documentation, plans, and drawings as well. Sloppy wiring management is often the norm as changes are made but not marked or documented, or wiring abandoned and not removed. The status of in-house personnel, installers, and maintainers is likely to change frequently, creating all the more potential for misinformation and confusion. The inevitable result is poor protection and slow response to a security incident. There are generally accepted wire-management procedures, and a single method should be utilized throughout the information infrastructure. It is especially important that all authorized personnel understand and accept the labeling system.

The Telecommunications Industry Association/Electronic Industry Alliance (TIA/EIA) publishes the generally accepted authority, TIA/EIA Standard 606-B, *Administration Standard for the Telecommunications Infrastructure*,⁹ which describes labeling of cables, connectors, patch panels, cross-connections, and equipment. This standard also requires labeling firestops, grounds, special-ground circuits, and neutral wires. The *National Electric Code* (NFPA 70),¹⁰ published by the National Fire Protection Association, also includes standards for labeling cables and conduits. Local codes may augment the national codes. Generally, any substantial alterations, moves, or changes, and usually all new construction will require full compliance with the current standards throughout the premises—which is a wise security investment as well.

23.4.6 Reliability and Redundancy. The first requisite of reliable system performance is reliable equipment, systems, and infrastructure, properly installed and maintained. Unfortunately, some components may be poorly designed, subject to erratic quality control, damaged in transit, or applied wrong. Much equipment now includes a fail-over mode to maintain full performance when a failure occurs.

Another component of high service levels is *redundancy*: concurrently accessible equipment and parallel paths to take the load should one component falter. Effective redundancy for business continuity also requires alternate sites that are off premises to process and store information. It is best that there be multiple alternate sites, each within a safe environment and well distant so that problems at the primary site will not affect any alternates.

Inside each computer room, storage systems should be redundant arrays of independent disks (RAID) allowing important data to be fully replicated. For critical data, the RAID storage systems should themselves be redundant. Servers should also be redundant. Multiple parallel servers with load balancing are a wise investment, so that one server will automatically take over another's load if it falters or must go off-line for any reason. The load-balancing features also provide potentially higher throughput for the overall system by allowing parallel computations and input/output. All critical equipment should have redundant power supplies, fans, and hard drives that can be diagnosed quickly and hot-swapped easily.

Good system manageability is another vital requirement. This includes hardware that can detect trouble before it happens and, if possible, pinpoint the exact location. It also includes good management software with warning and alert capabilities and good logging systems. Remote management capabilities must also be private and secure to preclude penetration or denial-of-service attacks. Good security management also requires that any changes or disabling of alarm parameters should require two authorized persons to be physically present inside the equipment room and simultaneously logged on. Good system management adds some cost but is a wise investment in effective security and oversight.

23.4.7 Proper Installation and Maintenance. Good protection requires that all information systems, equipment, and wiring be installed properly, according to the manufacturer's instructions and the intended usage. All the wiring must conform to, or exceed, local code requirements. Data wiring should be independently tested and certified that it meets specifications, current standards, and, if possible, anticipated future needs.

Out-of-the-box equipment hookups and installations are common and the cause of many system failures. Most security features are disabled when components and software are shipped. Proper installation requires careful setup, customization, and performance testing, for which adequate time and resources must be allocated. Promptly installing the latest modifications, service packs, updates, and security patches is also vital to maintaining performance. Delays of days, weeks, and even months often intervene, while new threats emerge or threat levels escalate until the new defenses are in place. Once installed, the information systems and infrastructure must be periodically reviewed, tested, and kept up to date. Frequencies of such reviews and testing must reflect the known or estimated rates of failure and the consequences of such failures.

Administrators, installation, and maintenance personnel must be properly trained, experienced, and, in many cases, certified or licensed as well. Each person's credentials should be checked before being permitted on site. Given the limited staff, time, and budgets available, there is often more lip service than actual certainty in the process of reliability assurance. Management must understand that proper installation, upkeep, and maintenance together constitute cheap and effective assurance that IS performance is never compromised.

For more details of data backup methodologies, see Chapter 57 in this *Handbook*; for business-continuity planning and disaster recovery, see Chapters 58 and 59.

23 · 10 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

23.5 OTHER CONSIDERATIONS. There are many other factors that can significantly establish and improve physical security. A few of these are discussed in the next sections.

23.5.1 Equipment Cabinets. Most IS equipment is now open-rack mounted to save floor space, for more reliable performance, and for easier access. Although enclosed equipment cabinets cost more than racks, they offer much better protection. Equipment mounted within a closed cabinet can be better ventilated and cooled, kept freer of contaminants, and may also escape damage from external particulates, water, smoke, or liquids. Should there ever be overheating or smoke generated within an enclosed cabinet, the condition can be detected quickly and usually resolved before equipment or wiring are damaged. Locks keep out those unauthorized, or at least delay access and leave evidence of trouble. Open-door alarms provide another strong layer of protection, and wiring conduits to cabinets can also be protected. Cabinets with redundant fans can better monitor and maintain ventilation and cooling, which, in turn, facilitates more equipment mounted in less floor space. In all, closed cabinets can provide an additional layer of protection against accidental or deliberate damage to the infrastructure.

23.5.2 Good Housekeeping Practices. All food and drink must be kept out of equipment rooms, since they can cause considerable damage if spilled on equipment, a monitor, keyboard, connectors, and wiring and cable harnesses. Food also attracts insects and rodents (which are found in many buildings), many of which also like to eat wiring. In addition, grease and other contaminants from food can easily be spread by operators onto critical surfaces of equipment such as input output devices and cause read/write errors or even complete shutdown of the devices. For example, a single greasy DVD can ruin a DVD unit or high-capacity backup-tape unit. Worse, a contaminated read/write head or entry slot can in turn spread contamination to other media and then on to other devices. Space for food and drink should be provided outside the equipment room, where routine maintenance personnel can keep the food area clean. A convenient dispenser for alcohol-based hand wipes can encourage cleanliness for everyone entering the equipment room.

Loose papers, books, supplies, newspapers, and trash are fire hazards and also must be banned from every equipment room.

23.5.3 Overt, Covert, and Deceptive Protections. Effective protection of the IS infrastructure requires many hidden elements—such as concealed surveillance cameras, sensors, and detectors—and all of the wiring that supports them. But good protection also needs some clearly visible elements. It is important to consider which devices are best hidden to protect them and which should be visible as deterrents.

Overt devices are ones that are evident to workers and visitors, or whose presence is implied by other visible objects, such as warning notices. These visible devices, which suggest that some sort of security exists, are intended to deter troublemakers, so that all but the most determined attackers will go elsewhere. Examples are surveillance cameras, access controls, visible alarm boxes, and visible sensors. Although most overt devices are active and recording data, some may be inexpensive dummy devices that only look real, perhaps with slowly blinking indicator lamps to heighten the effect. Covert protection, however, must not be noticeable to either visitors or insiders. There

must be no indication that these protections exist, what they are, how they might function, or where they are located. Most effective security systems operate covertly; examples include stealth and silent alarms, concealed early-warning systems, perimeter and proximity sensors, access monitors, and many other surveillance devices that are not readily seen.

It is important also to conceal the wiring that interconnects all protective systems and the utilities that support them. Whether any part of a system is visible or not, the wiring that connects it should not be. Although overt devices may themselves be vulnerable, they will generally advertise that there is good security here and everyone within the premises can feel safe. However, visible devices can sometimes be covered or spray-painted, knocked aside with a club, or shot to disable them. An expert thief can also defeat many hidden systems, if he or she knows what they are, where they are located, or how they are connected.

Another approach to protection involves deception. Dummy devices that look like surveillance cameras, access control devices, and alarm sensors can be placed to attract troublemakers, who may think they can physically damage, disable, or circumvent the system. These visible devices are intended to distract potential troublemakers and divert them away from vulnerable areas. Some devices are deceptive in that they are not what they appear to be but are actually alarm sensors to measure motion, proximity, sound, or anything that disturbs the device. Deceptive devices often are used to divert troublemakers away from vulnerable people and infrastructure, by offering them a “honeypot”: an attractive target to distract them, but often a target equipped with an alarm device, surveillance cameras, or other means of identifying a perpetrator and gathering evidence.

There is a gray area between what management can legitimately do to protect its information systems and what may be unethical or illegal actions. Management has a legal and fiduciary responsibility to protect people and property, and those who support deception say that these techniques are increasingly necessary to protect an organization. Others insist that this amounts to entrapment or violates privacy rights. State and local regulations and interpretations vary widely and are continually changing. It is necessary to check carefully with local officials, legal advisors, and insurers to determine what is acceptable and how to manage such risks. Management must then decide to what extent these techniques may be effective and whether less contentious approaches will suffice.

Whether the protection devices themselves are overt, covert, or deceptive, the security systems behind them must not be obvious. No one seeing or knowing about the elements of a security system should be able to deduce the details of the system, the functionality, or where and how it is monitored. An observer may notice a particular device or product or the suggestion of a vendor’s standard security solution, but the particulars of the protection systems must remain obscure, and all the wiring that supports them must be hidden or disguised as well.

Everyone involved must be aware of the security policies and procedures. Conspicuous signs should advise that anyone entering the premises may be monitored, as may all communications. All of the security policies and procedures should be understood and accepted by everyone involved. Employees and other on-site personnel should receive periodic security-awareness training and briefings. And there should be periodic security exercises and drills to test the procedures and reinforce the training.

Finally, protection must not be intrusive. Security cannot limit productivity or IS performance in any way. Instead, the protection must contribute to a feeling of safety and security within the workplace and thereby enhance productivity.

23 · 12 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

23.6 ACCESS CONTROL. Access control systems are but one layer of good infrastructure protection. They are usually used in conjunction with surveillance and perimeter control systems in order to provide sufficient early warning to head off trouble before it happens. Effective access control requires three tiers of support that are described next. The strength of each tier and its integration with other security layers determines the security effectiveness.

- 1. Privileges.** This tier determines whether a person seeking entry is authorized. It is the initial entry-request process that may use an access or proximity card, radio-frequency identification (RFID) key, or a combination lock. Since many of these devices can be lost, borrowed, stolen, or copied, and many can be quickly defeated, there is usually not much effort to ascertain just who is seeking entry. Therefore, privileges alone are not strong security.
- 2. Authentication.** It is usually necessary to identify a person seeking entry with some degree of certainty. To do this, the person must possess or know something unique that others cannot readily duplicate. Examples include personal identification numbers (PINs), electronic keys, entry cards, and biometric devices. PINs and passwords may be used, provided they are strong and well implemented. Some of these approaches merely strengthen the privileges process but can still be copied or defeated.
- 3. Audit trail.** A log is required for each entry attempt to show the date and time, the identification of the person, and the action taken by the access control system. Access-denied and unable-to-identify events should trigger immediate alarms. Logs must be analyzed in a timely manner for anomalies or unusual patterns. Where better access control is needed, each person's exit also must be authenticated and logged.

See Chapter 28 for more details about identification and authentication in access controls.

23.6.1 Locks and Hardware. Strong protection begins with high-quality locks, door hardware, and access control systems that are nonintrusive yet strong enough to deter most unauthorized entry. Lock types should be hard to pick and should use keys that are hard to duplicate. Examples are Medeco® locks and keys with dimpled sides. Ace® locks with circular keyways require special tools to pick. Many types of keys can be created from lock numbers, so keep these numbers stored securely.

No lock is completely safe. Someone with equipment, experience, and time can open any lock, often very quickly and without causing attention. Where key mastering is used, an experienced person with a key to any single door can open the lock cylinder and copy the mastering system. Therefore, additional layers of protection are needed.

Interior areas accessed only by a few people usually can be secured with a strong push-button combination lock. Key locks are not appropriate, because the keying cannot be changed periodically or quickly when a key is lost or someone leaves. And misplaced or lost keys may not be reported for days or weeks. However, key locks tend to be stronger and less vulnerable to vandalism, so keys may be the best alternative for outside areas or for doors that remain open during business hours. Wherever keys access critical areas, there should be spare lock cylinders and a new set of keys stored on site that can be utilized quickly when a change is needed. Once a lock cylinder is changed, the old cylinder should be rekeyed and a new set of keys produced.

Locks that use an electronic key are particularly effective. Electronically activated cylinders can replace existing mechanical cylinders, and many do not require any wiring, so the hardware and operating costs are minimal. Most electronic keys have a small cylindrical tip that is touched to the lock for access. Both the lock and the key can log each event, identify the specific lock or key used, the date and time, and whether access was granted. And conveniently, electronic keys are not much larger than mechanical keys. However, both can be defeated with the proper equipment and skill. Often, two independent entry locks are utilized to provide stronger, relatively inexpensive protection.

RFID devices can provide good access control, provided the activating device is not lost or stolen. RFID can be an improvement over card entry systems in that it can activate a lock from several feet away. RFID access cards can include photo ID, name, and perhaps an optical stripe for encrypted identity information. As with other systems, RFID can be breached with the right equipment and skills.

Another inexpensive upgrade of key locks is the card-access lock similar to the ones used by hotels. Many do not require wiring and are battery operated, so the keying of each door remains unchanged and an old key remains valid. Therefore, without central wiring, most card-access locks offer limited security and cannot trigger an alarm although some do at least log events.

To prevent intruders from bypassing the lock mechanisms by using credit cards or thin metal sheets to push the bolts inward, the area over the actual latch should be protected with an *astragal*—a flap of metal bolted to the door. In addition, latches should include anti-tampering features that block external movement of the moveable elements into the door when the locks are active. The hinges for doors should not be accessible from outside the secured area when the doors are closed: It is a simple matter to break and remove the hinge bolts and remove a locked door if the hinges are on the outside.

No matter how strong the access control systems, doors have their limitations. Absent a vault-type door and hardware, a determined attacker with pistol and silencer can gain access readily. A small water cannon that is transported in what looks like a toolbox can breach a standard metal door, or the partition surrounding it, with one shot and very little noise.

23.6.2 Card Entry Systems. One of the best means of physical access control is a card entry system, especially the newer systems that are increasingly capable and less costly as well. A central card entry system often controls the entire premises: all entrances, exits, elevators, rest rooms, and many other interior doors. Access cards are usually similar to a credit card and can be carried concealed or worn as identification badges. Access cards are usually imprinted with a full-face photo, the individual's name, the organization's logo, and often a printed stripe with biometric information. Access cards often show number codes to indicate authorized areas of access, and are usually color-coded to indicate status and whether the person must be escorted.

For more details of identification and authentication systems and card entry systems, see Chapter 28 in this *Handbook*.

23.6.3 Proximity and Touch Cards. Some cards can be held near a sensor (*proximity cards*) and some can be held in contact with a sensor (*touch cards*). Both types of tokens can reduce wear on physical tokens that have to be put directly in contact with the sensors.

23 · 14 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

For more details of identification and authentication systems and proximity and touch cards, see Chapter 28 in this *Handbook*.

23.6.4 Authentication. Anyone can use an access control token that may be borrowed, lost, copied, altered, stolen, or taken by force. Therefore, authentication is another layer of security that is needed to establish the identity of the person seeking entry with some degree of certainty. Authentication devices commonly include a biometric scanner, a numeric keypad, and visual or voice identification by a computer or by another person. All such devices come in varying security strengths and each can be used in combination.

When an access token is read, the system must verify that the *token* has the requisite privileges for that place, date, and time. If it does, it then becomes necessary to authenticate the identity of the person using the token. For this purpose, a numeric keypad was once the most common device whereby the token user entered a personal identification on a number keypad. Now most use a touch screen where the numbers will appear in random order. If the system validated the PIN, it activated an electric door strike to momentarily unlock the door. This system can be slow, cumbersome, and easily compromised. In some systems, everyone uses the same PIN and is supposed to keep it private. However, PINs can be forgotten, lost, or discovered by others.

Visual authentication is a better approach. This can be done by a computer or by a security guard or receptionist who can see the entrance or monitor it via a surveillance camera or a video intercom. Emergency-type video intercoms work well because they provide the remote authentication with a visual image and can monitor sound continuously, so that the authenticator can speak with and challenge whoever approaches the door. When identity is verified, the system or other person activates the electric door strike to unlock the door. This system offers stronger security and is faster than a keypad. It also facilitates recording and logging all entrances and exits, especially during off-hours. Breaches can happen, if the person seeking entry can deceive the guard or receptionist.

Biometric scanners offer the strongest security. They offer faster, more positive identification of every individual and do away with the need to remember a PIN. Biometric scanners can read any of these personal attributes, which are listed somewhat in order of their current popularity: fingerprint patterns, facial characteristics, voiceprint, handprint, signature, retinal details, or height and weight.

Most biometric systems can be adjusted to be highly sensitive (which is slower and may require repeated entry attempts, but is very hard to breach) or less sensitive (which is still fast but may result in some false authentications). Before choosing a biometric system, it is necessary to determine that the users understand and will accept it. For example, some people balk at having to use a retinal scanner, while others may feel that any biometric device invades their privacy. The latter reason is invalid because most biometric systems cannot be used to identify any person not already known to the system. Increasingly, especially in critical public places, these systems can check every individual against criminal and terrorist databases and quickly alert law enforcement. It is difficult to steal an identity using biometrics because one must also know the encoding algorithms used.

Fingerprint scanners are the most common and are becoming increasingly powerful. Initially, these utilized optical scanning, which could be fooled by photographs, wax impressions, or by a severed digit. The newer capacitive scanners use electronics rather than optics and can provide nearly certain identification. Usually, three of the user's fingers are "enrolled" in the system in case some fingers are later bandaged or dirty. If

all the enrolled fingers are incapacitated, single-use passwords can be used to bypass the system.

Most fingerprint scanners cannot identify an individual by name, but only that a person seeking entry matches the person whose biometric identity has been enrolled. Most scanners do not conform to the uniform, automatic fingerprint identification standards used by law enforcement. Instead, they scan a small area of the finger and apply proprietary algorithms and encryption. A template from one system is usually meaningless to another.

Accuracy of fingerprint scanning is affected by the angle and position of the finger and by the pressure applied. Most systems allow sensitivity adjustment to optimize enrollment and verification times and success rates as well as to minimize delays and false negatives that require repeated access attempts. While well suited to most applications, fingerprint scanners may not be appropriate where the user could have dirty or thickly callused hands or must wear gloves (such as healthcare workers).

Facial recognition is the basis of another popular scanning system. It uses graphics technologies and any surveillance camera to measure the size and relationship of prominent facial elements. Most systems are proprietary and cannot be used to identify an individual by name, but some others are compatible with law enforcement standards. Sensitivity and accuracy are dependent on the distance, position, and angle of the head as well as on the background lighting. Cameras at all entry points must be positioned to photograph the subject at the same angle that their faces were enrolled. Not all facial recognition systems offer strong security; some can be fooled by a face mask or a photograph. Others are best left at their highest sensitivity settings to avoid spoofing, which may require increased false positives and multiple attempts at entry.

Voice-print scanning can be used, but mostly for access to a terminal or workstation. The better systems display random words on the monitor so a prerecorded response cannot be used. Most use the workstation's microphone or, increasingly, a cell phone. Voice scanners can be affected by hoarseness, so there should be a one-time password access provision. These systems can be useful for remote login, especially while traveling, although the low bandwidth of dial-up circuits may lessen the system's usefulness.

Retinal or iris scanners are considered the best security, but authentication can take a few seconds. For access control, the user must generally look closely into an eyepiece, which is traumatic to some people. But for access to a terminal or workstation, a Web camera is generally placed on top of the monitor, 17 to 19 inches from the eye. The user's head must be positioned to align a white dot within a colored circle. The user must hold still, without blinking, while the scan proceeds automatically. The camera can be used for surveillance to see who is near the workstation.

For details of biometric authentication, see Chapter 29 in this *Handbook*.

23.6.5 Integrated Access Systems. Biometric scanners are used increasingly by other applications, and most can readily coordinate with an access control system. Applications include network user authorization, and access to terminals and workstations and to software applications and data. Biometric readers can be built into laptops, keyboards, mice, or peripheral readers. They can be used with access cards, badges, and proximity or RFID devices for authentication with some degree of certainty. Scanners that are mostly proprietary are currently integrated with encryption systems (e.g., virtual public networks, public key infrastructure, and smart cards) to authenticate transactions including credit cards, financial, banking, and automatic teller machines. Biometrics are increasingly used to identify hospital patients, welfare

23 · 16 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

recipients, people who frequently enter the United States, and similar applications that involve identifying a diverse or widely dispersed group.

Infrastructure security protection can be independent of, or integrated into, a comprehensive premises security system. Either cards or badges can provide many other functions beyond basic access control. Applications include off-hour access to the building, elevators, and premises; control of building entrances, restrooms, and parking areas (especially at night); purchases at a cafeteria or company store, or for charging stationery or materials picked up from a supply room. They can also be used to receive classified documents.

For greater protection and efficiency, an integrated enterprise-wide, Web-based system can control access to various premises, locked doors, infrastructure components, networks, workstations, applications, secure data, and Web connections. This arrangement offers comprehensive security by logging every event. Centralized logs can yield much more meaningful security information, because an integrated system provides better early warnings to head off trouble before it happens.

23.6.6 Portal Machines. Airportlike security checkpoints are increasingly being installed outside airports. A portal machine is the archway one must walk through during the airport security process. It detects concealed metal, such as guns and knives, and tools that might be used to cause trouble. A portal and can be used to detect IS components (such as storage media) being smuggled into or out of the premises. For example, the Texas Capitol building had such a system installed in May 2010; however, Texans carrying concealed handguns need merely show their license to be able to circumvent the scans entirely.¹¹

Newer trace-portal machines can detect many explosives as well. The person entering is asked to stand still for a few seconds while the machine releases several puffs of air and captures samples that are then analyzed for a number of hazardous or explosive substances. When a guard is not present, a computerized voice instructs the person to proceed, or a turnstile can hold the person in place.

Such devices might be appropriate for all who enter premises requiring ultra-high security and at entrances to critical areas or equipment rooms as well.

In January 2013, the Transportation Security Administration (TSA) announced that 200 specific full-body scanners would be removed from U.S. airports because of concerns over the resolution of the nude images produced by the RapiscanTM machines.

In December 2012, the DHS announced that it would contract with National Academy of Sciences for a thorough study of the intensity of electromagnetic radiation in security scanners.¹²

23.6.7 Bypass Mechanism. Whatever the systems used, there should be one bypass key that can open every door that uses electronic or electrical controls. The bypass key is for emergency use only. It is a unique key that is not on any mastering system and is available only to a few highly trusted people. The cylinders should be heavy duty and very hard to defeat, with the keys nearly impossible to copy. Careful control and protection of each key is essential. The loss of a key may not be discovered quickly, and the time and costs of rekeying every lock will be substantial. Meanwhile, every door on the access control system is vulnerable.

Bypass passwords for individual users also may be needed. These passwords should trigger a silent alarm whenever used, so that security can respond to the site or verify identity by telephone, surveillance, or intercom. One-time passwords provide the best security.

23.6.8 Intrusion Alarms. Intrusion alarms are necessary to provide perimeter and early-warning alarms and are usually needed as extra layers of security. There are several methods of intrusion detection. Digital surveillance cameras with motion detection are best because they can monitor visually what is happening and record what they see. Other methods include proximity and pressure sensors mounted within the perimeter walls or floors or inconspicuously within the room. Most of these sensors can detect intrusion and forced entry and can pinpoint the location of trouble, but they provide no details, monitoring, or evidence-recording capabilities. Proximity and pressure sensors can protect long-distance perimeters, cable runs, and utilities inexpensively. Concentric layers of such devices are necessary for sufficient early warning to prevent trouble from happening.

The best motion detectors use digital closed circuit television (CCTV) surveillance cameras that can sense movement while observing and recording the event. Miniature cameras that are inconspicuous or concealed are particularly effective and increasingly inexpensive. Several cameras can record pictures from many angles and often can identify an intruder positively. In a larger area, cameras often use swivel-tilt mounts and zoom lenses, which can be controlled automatically and remotely as well. Color cameras are preferable, as are cameras that automatically adjust to light conditions, including near darkness.

Some CCTV cameras include a military-type night-scope mode, which is relatively inexpensive and functions well in near-total darkness. These cameras also work well in normal light and can switch automatically to night-scope mode when necessary to see clearly and to record evidence. Other types of cameras, such as infrared, work well where there is no (humanly) visible light.

Other intrusion detectors use radar technology or measure changes in capacitance or inductance to sense intrusion. Most cameras and detectors can trigger an alarm as soon as they are disabled or lose power. Detectors may be wall- or ceiling-mounted devices as an overt means of deterrence, but these may then be vulnerable to spray paint, wire cutters, a gun, or a club. Therefore, intrusion detection sensors are usually concealed, or at least inconspicuous.

Perimeter alarms are especially important in building core areas, or public areas within or outside a building, to provide ample early warning of an intrusion that might soon affect a secure area. Digital video cameras are best for this but may be ineffective over large areas or long distances. Therefore, many proximity devices are used to monitor intrusion. Most utilize long sensor wires that are surface-mounted inconspicuously or hidden within partitions, ceilings, and sometimes inside of conduit. These systems detect the presence of a standing adult or a large animal that may come within a few feet of the sensor wire. The sensor wires can be very long, so zoning is often necessary to pinpoint an incident at least within a general location.

A better and cheaper alternative can be fiber optic perimeter alarms. Developed for the military and national security installations, the fiber optic systems are very sensitive and can monitor, evaluate, and record events. The sensor wires can also be embedded inside drywall or masonry partitions, ceilings, floors, or conduit and will detect both pressure changes and ambient sound. Because they do not measure proximity and can monitor and evaluate events, false alarms are less likely. They can warn of an impending accident or efforts at forced entry, and may soon be able to locate the event as well. These systems use software that can discriminate between recognized events and situations that are unknown or potentially dangerous. All the events are recorded and can be replayed and reviewed by a remote operator at any time.

23 · 18 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

Increasingly, inexpensive monitors are available that connect wirelessly via Wi-Fi, mesh networks, cell phone, satellite, a radio channel, or sometimes via microwave. Such devices save the high costs of direct wiring to remote areas and the need to protect and conceal the wiring. But there is also a trade-off with reliability and security, as any radio-frequency device can be monitored or jammed and may also be spoofed.

In addition to intrusion alarms, environmental alarms should be provided to measure temperature, humidity, and smoke, fire, and flood situations within all critical areas and equipment cabinets as well, as described in Section 23.8.1.

23.6.9 Other Important Alarms. A duress alarm system is recommended within most critical areas. This is usually a large red button or an emergency intercom conspicuously mounted near the exit. It is used if someone is injured or ill, when trouble occurs that other alarms will not immediately sense, or if violence is threatened. The emergency intercom types are best because each party can talk and listen. Those with a CCTV camera are described here, but many inexpensive emergency intercoms that provide audio only can be useful. Security personnel can constantly monitor all sounds within a secure area, and anyone inside can readily talk with security personnel. Duress alarms are usually silent. And activation devices can be concealed or located inconspicuously in case a potentially violent situation erupts. Duress alarm activators inside of cash drawers, in the knee wells of desks, or under counters have been common for years.

Another form of duress alarm can be integrated into card-access systems or password systems, for example, swiping the card backward may allow access but also silently trigger alarms at security stations. Proximity cards could be programmed to recognize peculiar methods of waving the cards which might pass inspection of those applying duress yet initiate appropriate defenses and alarms. Entering a keycode with an additional sequence could do the same. All such duress-alarm signals should be part of every employee's training for use of the security systems.

Beyond access control and authentication, it is also important to know whenever a locked door is not fully closed. There should be a sensor that warns whenever an access-controlled door is open or ajar. The sensor is normally built into the door buck (frame) to provide a silent alarm. An open-door alarm system delays for a few seconds in order for one authorized person to enter or exit normally. A short delay prevents leaving a door ajar for someone else to push open, piggybacking when another person enters or leaves, and tends to prevent anything large being taken in or out. The open-door alarm also prevents a door from being propped open at any time. The door-ajar sensors should be concealed at all times so users are unaware of their existence. Otherwise, they may be taped, jammed, or otherwise defeated.

A final security protection is to prevent *double-dipping* whereby an authorized person requests multiple entries in order to admit unauthorized persons. The access control system can prevent this; once persons enter a space, they must be logged out before they can try again to enter.

23.7 SURVEILLANCE SYSTEMS. Today, surveillance systems are designed and laid out to document fully every event, to facilitate positive personal identification, and to provide legal evidence when needed. Today's digital cameras, controllers, and recorders can do all this and more. The old analog or film cameras and recorders are inadequate and should be replaced, especially since the new surveillance systems are much less expensive.

If the protection is designed well, cameras can provide an undisputable, accurate, historical record that is available instantly. Cameras never sleep and are not distracted by repetitive tasks or boredom. More important, cameras can provide early warning, and can document events from many perspectives, concurrently and synchronously. Cameras increasingly incorporate microphones and interface with emergency audio intercoms, the better to assess a situation, assist people on the scene, or challenge suspicious persons. The very presence of visible but inaccessible cameras usually deters most troublemakers. Protecting the infrastructure requires both early warning and identifying the nature of trouble before it can happen. The new surveillance systems can do this effectively. And they can be integrated with other alarms and with premises security systems for strong, seamless protection.

23.7.1 Surveillance Cameras. Surveillance cameras are far more effective and much less expensive than guards, watchmen, or extra receptionists. However, for strong, redundant, and flexible security protection at important locations, both cameras and people will be needed.

Surveillance capabilities are becoming increasingly effective protective devices. They can now see more, detect some dangerous hidden materials, and, increasingly, decide what is important to monitor.

Equipment rooms and other sensitive areas once relied on motion detectors for security, but now digital cameras with motion detection work better. Digital cameras also function well indoors and outside, and under most light conditions, from sunlight shining into the lens to near, if not total, darkness. When used outdoors, digital cameras are immune to all but very severe weather conditions. They are, however, affected by heavy smoke, snow, ice, and rain. Wind-blown objects and sometimes birds or small animals can distract their motion-detection systems.

Today's digital systems are far more capable and reliable than the earlier analog or film cameras. Cameras were once the weak link because the details were not clear or too small. Many of the old cameras were needed to cover an area, and even then, necessary details were often out of focus. Now cameras are much smaller, less expensive, and take advantage of auto-focus, tilt, and zoom capabilities to yield much better pictures. Almost all cameras now use color as well for better clarity. Some also incorporate an inexpensive, monochrome, night-scope mode that works well in total darkness. Digital cameras automatically correct electronically and mechanically for varying ambient light conditions. Most can correct for background lighting conditions that would otherwise cause subjects to be underexposed, for sunlight glaring directly into the lens, and for unusual brightness that would otherwise wash out a useful image. All of the images can be viewed in real time, and one or more persons can simultaneously control the views and scroll back to freeze and enlarge frames. All viewers can adjust the brightness, contrast, colors, and zoom, and can apply filters to bring out foggy details. Any viewer can save anything viewed.

All but the smallest indoor cameras now include a microphone so that both video and audio are recorded. Outside the facilities, some installations interface with an emergency intercom so background sound is continuously monitored and dialog recorded. Emergency intercoms are particularly good deterrents because security personnel can confront possible troublemakers and advise them that they are being recorded. Most will back off or flee before trouble occurs. Although many camera control systems provide electronic zoom, the primary zoom function should be mechanical. Electronic zoom systems are inexpensive, but they lose resolution and images can quickly become unidentifiable.

23 · 20 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

Miniature cameras can be particularly useful and save money as well. Cameras less than one inch in diameter can provide sharp detail. Some units with zoom lenses and pan and tilt mounts can be hidden within any common object.

Opinions vary as to the ethics of using concealed cameras, and some state laws limit their use as invasions of privacy. Generally, the rules of good surveillance practice are the same as monitoring telephone conversations, email, and Internet use. In order to protect itself, the organization has a right to see and hear whatever is going on in and around its premises. But signs should be posted so that workers and the public are advised that all persons entering the premises may be monitored for safety and security purposes. Company policies should explain this, and why surveillance is necessary.

23.7.2 Camera Locations and Mounts. To serve as a deterrent, some cameras should be readily visible, but this may present some problems. Overt cameras placed too high are not good for identifying people, while cameras placed too low can be spray-painted, covered, or smashed. Any visible camera can be shot out (perhaps unnoticed using a silencer). Older cameras are good for overt use because they are large and may provide backup surveillance. Another option is dummy cameras, some of which have visible indicator lights or automatically pan to attract attention. Some dummy cameras are in fact alarms that will trigger if the unit is disturbed or if its wires are cut.

Surveillance of a wide area requires an elevated camera that can see greater distances, zoom in on details (especially faces and vehicle license plates), and closely follow an event. Wide-area views are also necessary to spot multiple troublemakers. Several camera angles will likely be needed to gather good evidence.

Outdoor cameras are usually attached to a swivel, tilt mount, and inside of weather-proof domes or larger enclosures when large zoom lenses are needed. There is usually no attempt at concealment because the cameras are too high to reach, and they provide good deterrence as well. Many may be inconspicuous, however, or even disguised. When large cameras and enclosures are used, the direction the camera is looking in may be obvious. Often, troublemakers will create a distraction to lure the cameras away from the real problems.

23.7.3 Recording Systems. Once VCRs were the norm, but now most recording is done with hard drives that can store hundreds of hours of audio and video taken from multiple sources. Increasingly, solid state drives are also used.

Once, only one person could review the tapes and then, usually, only after the recording was complete. Now one or more people may access and analyze the information simultaneously. Once, 31 VCR tapes were recommended for each system: one tape for each day of the month, after which the tape was inspected and reused. Now one hard drive can record a month's data, which can then be inexpensively archived on DVDs or at remote storage locations. The VCRs often recorded in a lapse-time mode to save tape until an event occurred to trigger real-time recording. Now everything can be recorded continuously in real time to examine fully the happenings before, during, and after an event.

23.7.4 Camera Control Systems. Camera control systems commonly can direct the swivel (pan), tilt, mechanical zoom, aperture, and background lighting of each camera. Some control systems can automatically pan cameras back and forth across large viewing areas and also provide motion detection. Some control systems

can also stop panning and zoom in on any unusual event. This is a valuable feature that must be carefully programmed so the system is not distracted by spurious events or deliberate diversions. Usually, each camera can also be controlled manually and often from remote locations.

A major advantage of a digital system is that each camera provides continuous images, usually at about 30 frames per second, which fiber optic and other broadband connections bring to the recording system in real time and high resolution. The control systems usually allow one or more persons to roll back the images without affecting the real-time recording. Each viewer can scroll backward and forward, freeze frames, zoom, crop, or enhance the image electronically, and save any material to another medium or system as evidence.

23.7.5 Broadband Connections. The advantage of broadband camera connections is that the information is available in real time and with high resolution, and that more camera control functions are possible. Fiber optic cabling does this best, but it should be dedicated and well protected. Remote cameras can also be connected via a LAN, wireless, or broadband Internet connection using Transmission Control Protocol/Internet Protocol (TCP/IP), if done carefully, so that the data are secure and other traffic is not impeded.

Digital multiplexing is another advantage of broadband connections. Multiplexing over metal wiring once necessitated delays, lower resolution, and fewer frames transmitted per second, even though each camera was providing continuous, high-quality images. Now digital multiplexing over fiber connections allows all data from all cameras to be transmitted simultaneously. Multiplexing is accomplished remotely as signals from several cameras are combined into a single broadband connection to the control system. Connections among control systems are also multiplexed to minimize line charges. The signal interfaces between each camera and the multiplexer can be fiber optic, microwave, a network, or the Internet. This way, hundreds of cameras can be networked economically.

Another benefit of today's TCP/IP connections for cameras is that they can be Internet-enabled, allowing monitoring stations to receive data without having to retrofit special-purpose cables throughout the structure. A disadvantage of such systems is that they are therefore susceptible to the same attack methods that are developed to hack any other Internet-based systems. Proper use of encryption (e.g., virtual private networks) for camera output and controls can help protect the surveillance systems against electronic tampering. Encryption can also interfere with the *playback attacks* so popular in movies, where criminals insert devices to cause an infinite loop of playback and fool observers into believing that all is well in the compromised surveillance zones.

For additional information on penetration techniques, see Chapter 15 in this *Handbook*.

Radio or microwave multiplexing is another option, but it is not very fast and is subject to interference or disruption during severe weather conditions.

23.8 FACILITIES DESIGN. Good protection begins with good facility design that will ensure the safety of the information infrastructure and the people who use it. Protective systems become expensive and inefficient when the premises themselves do not facilitate good security. Proper interior design, facilities layout, engineering, and construction can maximize security effectiveness, minimize costs, enhance productivity

23 · 22 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

and morale, and generally boost profits. The starting point is an inspection of all sites and review of all as-built plans and construction documents.

Premises security inspection and review are best augmented by using independent, outside security experts. Comprehensive and objective architectural, design, engineering, IS infrastructure, and premises security experience are all needed and may not all be available internally or from vendors. The inspection and review process always must be threat-specific and must relate to a thorough threat assessment (which is described in Chapter 22). The premises inspection can then serve to validate the vulnerabilities identified by the threat assessment. Once some of the vulnerabilities are corrected, the premises inspection should be repeated.

Effective infrastructure protection can prevent trouble from happening. To do this, there must be ample early warning, which, in turn, requires good facilities planning and design, effective premises and infrastructure security in place, and the awareness and vigilance of everyone in the area. All must work together seamlessly, efficiently, and proactively.

Good facilities design can be efficient, nonintrusive, cost effective, and inexpensive—even within existing facilities. Here are some guidelines and suggestions.

23.8.1 Choosing Safe Sites. If possible, the building site for any facility that will house IS infrastructure—especially for highly secure applications—should be far from obvious manmade threats such as fuel depots, railway lines, suspension bridges, high-speed highway overpasses, and airport flyways. Sites should avoid obvious natural threats such as floodplains, areas subject to forest fires, active volcanoes, and old underground mines subject to subsidence of the overlying areas.

Access to the site should include provision for emergency evacuation of employees and visitors and access for emergency vehicles to reach the facility even if the main public access is blocked.

In cities, the building should not be situated in high-crime neighborhoods or in industrial parks with inadequate security supervision or histories of theft, vandalism, or sabotage. Decisions should include attention to public records indicating sufficiently competent police and fire-response teams; interviews with other users of industrial or commercial buildings in the area may be helpful in making decisions about the final choice of location.

Sites for equipment rooms and utility closets should be protected from possible threats. Infrastructure sites should be located far away from all piping, tanks, or equipment that uses any liquid that could possibly leak or spill. Most plumbing tends to leak unexpectedly at some time or can be intentionally breached, so it is well to assume that any pipe, connection, container, or pump will eventually burst or leak. Placing sensitive sites at a distance from such threats is safer and cheaper than any other form of protection. The danger zone where leaks may spread must include an ample vertical distance and horizontal area. Begin the danger zone with a pyramid from any leak source, downward several floors, and outward horizontally well beyond the infrastructure areas.

Most buildings require fire-suppression sprinklers in all areas. Any may activate by accident, vandalism, or an actual fire, and may cause considerable flooding. Also, infrastructure sites should be located away from windows, exterior walls, roofs, skylights, building setbacks, and storm drains, which are all potential sources of flooding. Treated water used in heating, air conditioning, and solar systems presents a worse problem, in that the chemicals can quickly destroy electronic equipment, connectors, and wiring.

If all of the infrastructure cannot be positioned at a safe distance from all liquids and hazardous materials, there must be special protections and alarms. Protections include sealed, waterproof construction, drains, berms or other diversion devices, and proper materials close at hand to control any spill. There should be environmental alarm sensors near where leaks or spills could occur. Floor drains must also protect the equipment areas, especially those that use sprinklers; otherwise, cleanup will be difficult.

Infrastructure sites should not be visible or accessible from any public area. Infrastructure wiring or cables should not run through the building core, public, or mechanical areas, including rest rooms, slop sinks, janitorial closets, and stairwells. Avoid placing equipment or cables where any persons might loiter. All equipment room entrances should be clearly visible from workplaces where employees can readily observe all comings and goings. Choosing inherently safe sites and entrances greatly reduces both risk and costs because less security is needed.

For effective security control, there should only be one access point to each critical area, used for both entry and exiting. However, if local fire or building codes require a secondary means of egress, a delayed-access panic bar is usually acceptable. Such a system delays releasing the exit lock for a few seconds, while an alarm sounds and a surveillance camera is triggered. There should also be surveillance cameras with motion detection throughout all secured areas. All locked doors should look as alike as possible from the outside and be identified only by a room number that looks similar to that of any other premises door. No functional name, person's name or title, or any other means to identify what is inside a locked area should be apparent. No signage or directory should include a functional, personal, or departmental name, but only area or room numbers and directional arrows if needed. Only floor, room, or suite numbers should appear on premises signs, on floors.

23.8.2 Physical Access. Access to the facilities site should be controlled. Guard stations at the entrance won't stop terrorists, but they can provide early warning of trouble. All such stations should be under constant surveillance and have panic buttons installed for emergency notification of the security teams that there's a problem at the entrance to the site.

Reinforced concrete bollards can prevent physical attack on a building by interfering with even high-speed ramming by ordinary vehicles such as cars, vans, and light trucks. They will not necessarily prevent attacks using commandeered large vehicles such as loaded dump trucks.

The entrances to buildings should not include large glass walls, which could be demolished easily to gain access to entrance halls for detonation of bombs.

Physical access to all parts of the information infrastructure should be restricted. All information system and network equipment must be inside equipment rooms that are always locked and accessible only to those who need to be there. All utility and wiring closets, power distribution panels, patch panels, wiring blocks, and terminations should be located inside equipment rooms that are always locked. If possible, do not allow unrelated systems, equipment, or utilities inside a restricted area, so that a technician working on an unrelated system cannot access the information infrastructure. If this cannot be avoided, IS personnel should always escort others entering these areas. In high-security areas, all persons entering should be escorted, or use two-trusted-person teams where each person observes the other. Guards and facilities-security personnel are good premises-security escorts but probably do not know the infrastructure and are not the best choice here. IS personnel are better escorts, even though they may

23 · 24 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

not know all the security details. In any event, all persons entering must be positively identified and each visit logged.

It is wise to put critical electrical distribution panels inside an equipment room, so they are quickly accessible and also protected. This is a safety issue as well; someone working on equipment or wiring can readily see that the circuit breaker is off. Otherwise, electrical distribution panels should be located inside a locked area that is unmarked from the outside other than by a coded location number. Panels are often located in public areas in many buildings; they must then be securely locked and alarmed as well. Whenever an electrical panel controls anything critical, access to the area should be restricted and the room alarmed. These precautions reduce any loss of power to critical systems by accident or intentionally.

One of the cases used in training courses about facilities security is the unlocked patch panel discovered by a physical-security expert in the public hallway of a hospital; the director of the intensive care unit (ICU) was horrified to realize that the breakers controlling the life-support equipment for the patients in the ICU were open to any child or malicious person.

A mantrap can best control access to critical equipment rooms. A mantrap is a two-door arrangement with an inner door, outer door, and a short corridor in between. Both doors are interlocked; one must be closed before the other can open. The corridor usually is constructed with a shatterproof, full-height glass partition (often one-way glass) on one or both sides for surveillance. Both the doors are usually windowless. And each door must have a strong access control system. But for safety, the outer door can usually be opened from inside the corridor using an alarmed panic bar. Usually, one or more surveillance cameras are positioned to identify anyone entering or leaving the mantrap.

Emergency intercoms within the mantrap corridor and at the entrance and exit points are strongly suggested. Conspicuous duress/assistance buttons should activate silently, so security personnel can monitor the area and speak with or challenge anyone who cannot pass through properly. The alarms are best silent so that anyone under duress is not further threatened. Emergency intercoms often include small cameras that are inconspicuous or concealed, so that security personnel can see what is happening, assist if someone is ill or somehow becomes trapped, and avoid public-safety issues. A well-designed mantrap can be valuable for all but heavily traveled entrances.

Mantraps can tighten security in many ways and are usually not intrusive. They can detect *piggybacking*, when one or more extra persons closely follow someone who is authorized to enter. Mantraps in themselves do not preclude propped-open doors, but they make removal of objects from the room difficult and risky. The access control log and surveillance recordings can identify troublemakers and provide strong evidence to convict those who might otherwise be suspects or persons unknown.

23.8.3 Protective Construction. The design of a new building can improve physical security.

- Avoid vulnerable construction methods such as using structural columns in large, open spaces on the ground floor; destroying such columns using explosives could cause serious damage to the structural integrity of the building.
- Don't allow architects to include decorative indentations on the outside of the building; such vertical patterns can provide the means for rock-climbing attackers to climb the walls easily.
- Place all IS in a hardened, isolated area.

Equipment rooms require sturdy partitions for good security and to support the considerable weight of wiring and equipment. Moreover, the partitions and walls must remain safe and stable during any seismic activity, such as heavy road traffic or a sonic boom, explosion, or earth tremor. Floors may also need to be reinforced. Sturdy partitions deter forced entry, which may be otherwise accomplished with little more than a pocketknife and a fist. Existing walls, partitions, and floors should be inspected and any subsequent alterations approved by a structural engineer. Consider too what might be needed long into the future; changes later may be very costly or simply impractical.

By definition, windows are not sturdy partitions. Avoid allowing nonsecurity personnel to pressure architects into including large windows, allowing visibility and possible intrusion into secured areas. Allowing uncontrolled visibility into operations centers may allow malefactors to learn more than they should about personnel, procedures, and schedules simply through observation.

Security doors should be sturdy also. They should be metal, fire-rated, and relatively heavy and use heavy-duty hardware. Try not to call attention to controlled doors by any distinctive external appearance. If many occupied areas use wood doors, the security doors should not stand out. Use wood-faced metal doors and hardware that looks similar to all the other doors. Sometimes secure-looking dummy doors that lead to nothing important are used for deception or as an alarmed honeypot to draw troublemakers away from secure areas.

Well-constructed partitions and ceilings will also seal out smoke and contain smoke in the event of an interior fire. Weatherstripping around the perimeter of each door is recommended to keep out dust, contaminants, and humidity and to trap any smoke.

If possible, wiring that must run inside a door should be routed within the hinges so that no wires are visible at any time. Exposed wires can be damaged by accident by cutting, or compromised in many ways. The major hinge manufacturers can supply special hinges to conceal most wiring and match the appearance of other premises hardware.

Masonry partitions are usually unnecessary unless there are special structural or very high security requirements. Drywall partitions with metal studs are usually sufficient but should be extra sturdy. Type-X fire-rated drywall panels at least three-quarters of an inch thick are recommended. Better yet, use double half-inch- or five-eighths-inch-thick panels. Existing drywall partitions can easily be double-paneled for added security and strength. Masonry partitions, especially, and often drywall as well are usually faced with sturdy fire-rated plywood for attaching equipment supports and wiring. Whether the plywood is mounted on stand-offs so that wiring can be run behind it is a matter of preference. Usually, it is more efficient to run all wiring exposed inside a secured area.

Do not use a suspended (hung) ceiling in any equipment room. Suspended ceilings just add cost, inconvenience, and diminish the volume of the room. The plenum space above the suspended ceiling is a fire hazard, and everything inside it must be fire rated, including any exposed cables, which adds unnecessary costs. Most building codes require separate fire detection zones and suppression heads within every plenum, which is a major cost. Remove any suspended ceilings and get more useful space for cables, better air circulation, and easier maintenance.

Avoid raised floors for the same reasons. They are very costly, functionally unnecessary for most installations, and take up extra floor space for ramps. Like suspended ceilings, raised floors create a plenum space that needs separate fire detection zones and suppression heads. Raised floors usually restrict the ceiling height because the space was not designed for this, so the room must be enlarged to accommodate everything,

and often with little expansion provision for the future. Raised floors soon become dust traps and, in time, usually a clutter of new, old, and abandoned cables that no one can figure out. Many equipment failures have been caused by overheating due to airflow restricted by too shallow a raised floor or by too many obstructing cables. A raised-floor plenum is rarely needed to supply cooling air. Surface-mounted ducts and registers usually can do the job better and much cheaper, and are easily cleaned and modified. All of the wiring can usually be routed efficiently above and between the equipment or by using inexpensive cable troughs mounted on walls and ceilings. If needed, floor outlets can access trench ducts in the floor, which may already exist, unused. Conduit can be installed through the floor slab and along the ceiling below for special needs.

It is important for all wiring outside of equipment rooms to be protected inside of metal conduit. This conduit should not be thin-wall or plastic but rugged, heavy-duty metal. Thick-walled metal conduit is strong, harder to damage or breach, and provides good magnetic and electronic shielding as well. Metal conduits can easily be, and should be, well grounded. Obtain expert advice on where and how to connect the grounds to avoid interference. Metal conduit also may serve as a proximity sensor to warn when something gets too close. Alarm wire concealed within the conduit offers early warning of trouble and often can pinpoint where it is located. Sometimes an inert gas or gel is used to pressurize conduits to protect the wires; a pressure drop indicates a leak or a breach but does not indicate where it may be.

All conduits should look alike, whether they carry power or data or control security systems. Although the diameter of the conduit must vary, the general appearance should be the same. Do not label or mark the outside of any conduit except with an alphanumeric code. Cables inside of a conduit should not be marked either, except alphanumerically. Generally, any wires within conduit should emerge only inside of a secure closet, equipment room, or junction box, where the wires should be labeled with appropriate codes that can be deciphered using up-to-date electronic summaries available only with authorization.

Data cables and wiring are fragile, whether copper or fiber optic. Any undue pressure, bending, stretching, vibration, or crimping can alter transmissions or cause failure. Fiber optic cables are especially fragile; metal conduit is usually the best and least expensive protection. This avoids special sheathings that are often cumbersome and costly.

Any wiring, whether metal or optical fiber, can be improperly specified, installed, or terminated. Substandard wiring or installations may function well temporarily, but future failure is likely, possibly hard to locate quickly, and will be costly to fix. Therefore, it is important that all cables be acceptance-tested and certified by an independent expert before the installer is fully paid.

Critical cable runs should be equipped with alarm facilities from end to end, whether the conduit carries power, data, or security. There are several ways to alarm a cable run. Outdoor conduits are often pressurized with nitrogen to keep out humidity, or with a special gel to keep out oxygen and humidity and to stabilize the wires inside. Interior conduits can be pressurized and alarmed in the same way. Monitoring the pressure provides an alarm when trouble starts (including failed seals that must be fixed quickly). The system is effective and provides early warning, but breaches cannot be pinpointed, and any future wiring changes may be difficult.

Proximity and pressure-sensitive sensors also can alarm the entire length of critical cables. A monitored run of conduit can be very long and may continue through areas that are difficult to protect or offer no concealment. While surveillance and intrusion detectors can protect most vital areas, there is often much infrastructure that can be

protected only by sensor wires running the full length of the conduit. Mechanical pressure sensors will detect unusual vibration, while proximity sensors indicate a change in the magnetic or electronic environment surrounding the cable or conduit. Newer systems utilize fiber-optic sensors that monitor sound pressure. Some of these systems are smart enough to distinguish routine, harmless events from possible trouble, and many can roughly pinpoint the location as well. Sometimes the conduit itself is the sensor, or an external wire is attached to the conduit, but these approaches are often ineffective.

23.8.4 Using Existing Premises Alarms. Various codes require workplaces to have visible and audible fire alarms. And most workplaces have voice paging, emergency intercom, surveillance, and premises security systems as well. All of this equipment can be utilized effectively to augment and support information infrastructure security. Audible alarms are used when persons at the scene must take immediate action, such as to lock down or to evacuate. Conversely, silent alarms provide early warning and allow security to monitor the scene discreetly, gather evidence, and respond and assist as needed. All these alarms can be integrated into infrastructure protection systems to provide better early warning and extra layers of protection.

All alarms and alerts should be transmitted to a central security desk or guard station. The purpose is to document and manage incident response, summon assistance quickly, monitor the scene, accumulate evidence, and support all of the response resources. Central management is especially necessary when threats cascade or multiple events occur, as they often do. Security managers, IS managers, the infrastructure security manager, and key department heads also should be notified immediately. Some of these people may be offsite or at remote locations but will need to communicate effectively with at least the operations center. Notifications and the subsequent communications should be quick, private, secure, and logged to document the events. One or more online backup security control and operations centers provide redundancy, support and assistance, and strong security.

An effective method of premises-wide alert uses voice codes broadcast over a paging system. These are usually scripted and often prerecorded so that alerts can be initiated automatically, remotely or manually. Hospitals do this effectively with their color-named codes, equivalent to silent alerts, which do not seem unusual to the public. An effective system of alert codes in a large organization also uses the names of fictitious persons. In a smaller setting, such as a school, where the names of all personnel are known, there can be alert messages to an individual to take an innocuous action, which is understood to be an alert code. Additional alphanumeric information in a message can identify the general location of an incident. As in a hospital, it is well to add similar codes for other routine purposes, so the public will generally tune out all the paging. This system is particularly useful when violence is threatened or has erupted.

Although most security personnel now have portable radios, there may be many areas of no reception, and few use earpieces so others cannot readily hear what is happening. However, all security personnel must know immediately when trouble looms, and they must be alerted in a way so as not to excite others. Also, everyone inside the premises needs to know when an emergency threatens. Indeed, everyone has a legal right to know and to promptly receive instructions for their own safety. Anything short of this will result in considerable liability. Therefore, effective procedures, clear simple instructions, good preparation, and periodic training can protect everyone and provide strong security.

The widespread availability of mobile phones has added another channel for emergency notification. Employees can be notified of emergencies using the Short Message Service (SMS) for text messages. Using computer-generated messages or even manual messages, security personnel can quickly and easily reach many of the people involved in emergency response. If phones are configured to use a characteristic tone for such messages, and if the phones are not generally used for casual messaging, such arrangements may be useful adjuncts to other notification methods.

23.8.5 Clean Electrical Power. Protecting electronic equipment requires a source of electrical power that is consistently *clean*. Clean power usually means alternating current with tightly limited variations of amplitude and waveform. Power outages and brownouts (low-voltage states) can cause obvious trouble, but numerous other disturbances can disrupt or damage the information infrastructure. Some of these include dips and sags, spikes, transients, and magnetic or radio-frequency interference. Most of these are intermittent and not necessarily present when the circuit is tested. Understanding each term is not as important as knowing that a wide variety of problems commonly occur in power lines, randomly and without warning.

Brownouts are particularly harmful. These are voltage reductions by the electric utility that can cause air-conditioning equipment, cooling water pumps, and ventilating systems to malfunction or to shut down. The associated equipment may be damaged unless it is quickly shut down or switched over to an uninterruptible power supply or a motor generator.

Few power disturbances will destroy circuits or crash systems immediately, but most can cause cumulative damage. Each incident can weaken electronic circuits that will eventually fail for no apparent reason. Poor equipment quality is often blamed, because the cumulative effect was not recognized. Worse, replacement equipment will probably soon fail also.

Power disturbances can be measured to determine whether a particular circuit seems to be clean. Usually, a recording device is left in place continually for at least a week to measure and log the details of every event that occurs. (Avoid any test instrument that merely logs an unnamed event but provides no details.) An independent engineer who is not a vendor may best provide testing that is objective, comprehensive, and covers the entire facility.

Some circuits are likely to show intermittent disturbances caused by something nearby or within the building and sometimes by faulty wiring. Knowing what power problems arrive via the main service helps to determine whether the utility is at fault and to isolate where in the building other disturbances may originate. There may indeed be numerous causes of power disturbances, and all of them may be intermittent, which is why continuous seven-day, 24-hour monitoring is the minimum recommended.

Another major electrical problem is improper grounding that can damage sensitive equipment and cause interference in cables. Electricians must comply with national and local electrical codes, but they do not necessarily understand or provide the special grounding necessary for sensitive IS platforms. Most heavy equipment manufacturers require that each unit have an isolated ground connection with a dedicated wire all the way back to the central building ground bus. A few manufacturers do not provide installation specifications unless asked, and some installers disregard them to remain price competitive.

Opinions vary as to the best building ground configuration for information systems, and as local conditions can vary significantly, no one approach is best. It is wise to consult an independent engineer to inspect the grounding configurations, and to

recommend and certify local code compliance. It is also important to provide separate circuits for all IS equipment, and where the equipment plugs into a receptacle, there be no more than a single receptacle. Separate circuit breakers are usually required for all equipment that can draw high current, especially if the load may cycle on and off. This is required by code for large motors, such as pumps, air conditioning, and elevators, whose cycling can cause dirty power on other branch circuits. But copiers and large laser printers (especially older ones) can also create electrical disturbances when starting and when the fuser-heaters cycle. All types of lights can cause a dip or a surge when many fixtures are switched on or off at once. (The newer fluorescent light fixtures with electronic ballasts conserve power and cause much less interference.) A separate circuit connection somewhat isolates the hot and neutral wires from other circuits, but interference may be generated through the grounding connections that often are daisy-chained with many other circuits to cut costs.

Do not share a dedicated circuit with any of this equipment, which can readily disrupt and damage electronic equipment: time stamps, electric staplers, coffeepots, refrigerators, heaters, fans, or any other device with a motor or solenoid. Even if inaccessible, a dedicated outlet should be a single receptacle, not a duplex. It is all too easy for vacuum cleaners, power tools, or maintenance equipment to use the other half of the duplex outlet. This will cause a severe disturbance and may trip the circuit breaker. There must be plenty of convenience outlets that are readily accessible for all noncritical needs.

Yet another cause of power problems is excessive solar activity. These events can be measured only when they occur, which is randomly during an unpredictable interval of several years that peaks about every 11 years. Solar disruptions occur only during daylight hours. High solar activity occurred in 1988, causing major power outages and radio interference in Montreal, Canada. Daily solar activity reports, forecasts, pictures, and historical records are available at www.dxlc.com/solar and other sites. (See also Section 22.6.7.)

There are several remedial options when power disturbances are suspected, encountered, or even possible.

1. Eliminate the problem at the power distribution panel. Better grounding, more separate circuits, suppressors, filters, and isolation transformers may help. But this type of remediation can be difficult, costly, or unreliable.
2. Use a surge suppressor near the equipment it protects. This is inexpensive but useless against brownouts, outages, and severe disturbances.
3. Employ an uninterruptible power supply (UPS), which provides battery backup power, for each piece of critical infrastructure equipment. One type of UPS is activated only when the incoming power fails, although its battery is always being charged. A better type is always online, acting to filter the incoming power, suppress most surges, compensate for minor brownouts, and maintain full system power for five to 10 minutes following an outage—enough time to allow an orderly system shutdown. A third and best type of UPS always powers its load from its batteries, thus isolating the load from the power line and providing optimum protection.
4. For systems that draw high wattage, a motor-generator (MG) set will eliminate most power problems. An MG set is an electric motor driven by the utility power. The motor is coupled to a generator that will always supply clean power to the load. The generator is usually voltage-regulated automatically, although the

frequency can vary, which may disrupt some timing circuits. Usually, if there is a power outage, mechanical momentum of the unit will provide sufficient power for an orderly equipment shutdown. Motor generators are still used for the ultimate in filtration and regulation, but there must be an electrical bypass to facilitate maintenance.

UPS units should power and protect the servers, network and telephone equipment, computers, and critical monitors. Most UPS units provide outlets with no backup power but with noise suppression for printers, transformer “bricks,” fax machines, and peripherals that do not need to be kept running. Most of these devices are somewhat expendable and quickly replaced by spare units if one is damaged.

Individual UPS units, placed near the equipment they protect, cost less and can be powered off by the operator to better protect equipment that may be vulnerable, even when the equipment is already shut down. This can provide an extra layer of protection where lightning might strike. Larger UPS units are used in equipment rooms where they can also monitor and log all power events and trigger remote alarm indications. Most good UPS units can initiate an automatic equipment shutdown when the power fails, the UPS batteries are low, or someone intervenes manually. There can be an issue, however, when some of the protected equipment cannot be restarted until the UPS batteries are fully recharged. Some UPS units are also network devices that can report their condition to a remote location.

Many UPS units also provide telephone and Ethernet line filtering and suppression, and these features should be used if possible. Lightning transmitted over communications wires can readily damage telephone instruments and modems. Power and communication line spikes can occur asymmetrically, and can devastate equipment that one disturbance alone would not damage. A good UPS unit with communications line suppression is best able to stop both types of spikes.

Another benefit of UPS units is that when an emergency generator is on line, the electrical power is usually much dirtier than normal. The extra filtration and stabilization provided by the UPS units may be the difference between having IS equipment operating or crashing.

23.8.6 Emergency Power. Most of the critical systems and infrastructure must remain fully operational during any electrical power problem. Filtration and suppressors cannot compensate for power outages, handle most brownouts, or cope with major electrical interference. Disturbances might come from lightning (even when it is too distant to be seen or heard), severe solar activity, or radio-frequency interference corrupting the utility power. UPS units can deal with some of these conditions, but only briefly. Therefore, a backup emergency generator may be the only way to continue operations during sustained power problems.

Although backup generators are often the only alternative, they are not a panacea. Generators are expensive and complex to install, require at least monthly exercise, and are not always reliable. Their voltage regulation is marginal; during sudden load changes, the output voltage and frequency may fluctuate as well. As the load increases, more current is drawn, and, if the generator is overloaded, the voltage will drop and the frequency may drop below 60 Hertz (which can disrupt IS timing circuits). Because the load current increases to meet the power demand, the amount of heat generated by the equipment being powered will increase as the square of the current. Much of the IS equipment powered is inductive, and there can be a large starting power surge when it is turned on or restarted. Generators, therefore, must have ample reserve capacity

beyond the anticipated equipment loads. And given their cost, generators should have ample reserve capacity for the future as well.

Another issue is whether a particular generator can provide sufficiently “clean” electrical power to operate IS equipment as well as power for the other emergency needs of the facility. Be sure, therefore, that the generator specified has ample capacity and that it is intended for use with electronic equipment. Even then, interference from large motors or lighting systems can affect the electronic equipment.

Because backup generators are expensive and complex, planning is often shortsighted, and many installations are not well designed or adequately tested. The inevitable result is that many generators do not perform as expected. Here are a few examples of what can be overlooked.

After considerable discussion at a major money-center bank in Manhattan about what seemed to be the excessive cost of a backup generator, the project was begrudgingly approved. The generator was to power two identical computer systems running in tandem to support a critical securities trading operation. Because the generator would actually cost more than the two computers, cost was an issue until the bank realized that the generator would pay for itself within one day of use. Soon after completion, a sudden citywide blackout erupted and the outage lasted for three days. Despite much inconvenience carrying fuel from the elevator up a flight of stairs to the rooftop generator, the unit performed flawlessly—one of the few systems in Manhattan that did.

Many other generators did not start or cut over properly, despite warm, clear weather conditions. And others did not support the necessary infrastructure. Some installations did not think to include the power requirements of HVAC, so the computers had to be shut down within a few minutes to avoid overheating, even though there was ample electrical power for them. Generator power for other necessary support functions was neglected. These included network components and communications systems, lighting for users, an elevator for access by key people and to carry fuel to the generator, security and access control systems, and at least basic electrical provisions for food and rest for those keeping the vital systems running. Very few businesses thought to include all of the necessary support functions on their emergency power systems. This incident happened some years ago when power outages were considered very unlikely in Manhattan. Generators then were somewhat of a status symbol. But today, sudden blackouts anywhere are far more common.

A related example of shortsightedness occurred in a large suburban luxury hotel operated by a prestigious hotel chain. Following a severe thunderstorm, the power utility advised the hotel that they must lose power for several hours to repair a damaged substation. Given ample notice, the hotel set out hundreds of candles in the corridors, dining, lounge, reception, and pool areas, and started their emergency generator, which then cut over automatically as soon as the blackout occurred. Emergency exit signs and emergency lights in the corridors and stairs all worked properly. As expected, their batteries soon died but the candles functioned long and well. The generator also powered one elevator, the computer and telephone systems, the access control system, and all the room locks. The generator performed as expected, but the emergency response process did not.

Even with ample warning, no one thought to shut down the other elevators or to post signs to use the stairs. Two very frightened people were trapped in the dark, between floors, proving that a generator can be a liability and not a benefit unless operating procedures are carefully planned, well implemented, and periodically reviewed. There should have been a security checklist used whenever the generator started.

23 · 32 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

Another recent example involved a state's emergency operations command center, designed to remain safe and fully operational no matter what events might occur. A large generator powered all the critical systems. Everything had been tested many times and had operated smoothly as expected. But then trouble came during a heavy thunderstorm in the vicinity. Electrical power for most of the city flickered several times and then returned to normal. However, the generator tried to start at the first sign of trouble and then faltered as the power returned. A few seconds later when the power again flickered, the generator system had been damaged and was unable to start. The state was lucky that the generator was not needed then, but it was out for several days for repairs.

Most power failures begin with flickering and momentary outages, which can incapacitate a generator system that is not set up properly. Most mission-critical generators are set up to start the engine automatically, and many transfer power automatically as soon as the generator comes up to speed. Manual start-up and transfer are more reliable and cheaper, if trained personnel are always available. The best way to sequence automatic operation follows.

1. After the first start-up signal, the start-up sequence must continue until the engine starts, a failed-start timeout occurs, or the sequence is terminated manually.
2. Power does not transfer until the generator is fully up to speed, at a reliable operating temperature, and the utility power is unusable. All three conditions should occur before transfer, and there can be manual overrides as well.
3. All transfers back to utility power and the generator shutdown should be done manually. It is best also to be able to transfer each circuit individually to utility power.

There are countless examples of critical backup generators failing to operate as expected. Here are some suggestions to determine whether a generator is necessary for protecting information systems and how to utilize a generator efficiently and economically.

- Investigate the outage history of the utility feeders that serve the premises. The electric utility can usually provide this data; if not, the state's Public Utilities Commission usually can. Be sure to ask how the terms are defined, because an "outage" may only include interruptions that continue for more than several minutes. Also ask whether more reliable feeders are available. Loop feeders that are powered from both ends are more reliable and often serve critical equipment. Ask whether the distribution transformers isolate and filter out power disturbances, whether they can also regulate the incoming voltage, and, if so, the specifications.
- Find out which other customers share the same feeders, and visit them to discuss their experiences and to determine if they use heavy machinery. Although some safeguards are possible and may be at little or no cost to the utility customer, past history is not always a reliable guide to the future. The distribution grid changes as more heavy loads are added. Today, the threat of extended power problems is far greater than in the past and is increasing rapidly. UPS units, motor-generator sets, and backup generators may all be a necessity in mission-critical applications.
- Determine which of the IS infrastructure components need backup power from an emergency generator. Most critical information systems, equipment, networks, and infrastructure must be at peak performance at all times. And so must all the

office areas, support systems, utilities, and personnel needed to operate them. Outages can drag on for days or weeks with key people isolated and living inside the facility to keep the systems running. The generator power must serve all of these needs.

- Consider these support systems that may require emergency power:
 - All the IS security systems, protection and monitoring devices; perimeter surveillance, and access control systems, the security stations and consoles.
 - Fire stairs (which may become the primary means of entry and egress), emergency exit doors, fire alarms, and intercoms whose batteries will quickly discharge. Also the need for these batteries to begin recharging immediately as soon as backup power is available.
 - Heating, ventilation, air-conditioning (HVAC), and process-cooling systems, including all the controls, fans, pumps, and valves needed to operate the critical and support systems. In addition to equipment cooling, it is best to provide room comfort for users, operators, and administrators. Area air conditioning may not be possible, but at least supplementary heating in winter and adequate ventilation will be needed.
 - Sufficient lighting for key personnel, equipment rooms, utility closets, corridors, rest rooms, and food service. Many individual light switches can conserve power and generator fuel. Battery-powered lights are suitable only for immediate emergency egress and cannot provide area lighting.
 - Enough live convenience outlets for test equipment, work lights, and any accessories that must be used. Live receptacles may also be needed for portable fans.
 - Sufficient food service equipment and refrigeration, running water and sanitary facilities, and a sleeping area for 24/7 operations that may have to continue for several days.
 - An elevator for critical access to the site, for medical emergencies, delivery of food and supplies, and to carry fuel for the generator.
- Compile a list of all the items a generator must power. Then total the rated power of each item to determine the size of the generator and the number of circuits needed. Power ratings for equipment usually are shown on a nameplate near the power connection and listed in the instructions. Ratings may be given in watts, amperes, or volt-amps. Generally, watts and volt-amps are assumed as equivalent. The latter value is the product of multiplying the rated voltage (e.g., 120 volts) by the rated amperes, while the former multiplies that number by the equipment's power factor. Large generators are rated in kilowatts (1,000 watts) of power. Units intended for short duty cycles cost less and may fail during prolonged, continuous duty. An experienced engineer should review this process.
- Consider the costs per hour of lost productivity, business, and goodwill if any information systems are disrupted. Add to this the recovery costs. In the example of the bank given earlier, the first day that the generator was needed saved the entire cost of the backup power system. The second and third days of that particular outage were sheer delight to the bank as most of their competitors faltered.

Electric codes may require, and good practice dictates, that a generator be sized to handle the sum of the individual start-up loads. This may seem wasteful, because not

23 · 34 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

all loads start up at once and an average operating load will be somewhat less than the sum of the parts. It is nonetheless a wise practice to provide for the maximum rated load, with additional spare capacity for improved reliability and future additions. There are several reasons for oversizing the generator. When power is first transferred to the generator, the sum of the initial surges can far exceed the anticipated load. All of the UPS units and other battery-operated devices will begin to recharge, and all equipment motors may concurrently draw their maximum surge currents. Extra generator capacity ensures a smoother transfer with better voltage regulation and enhances the system's reliability.

Most large generators produce three-phase power. And each of the three outputs should be balanced so that each "leg" draws about the same power. To do this, heavy motors, multiple light fixtures controlled by one switch, and other surge-producing equipment may have to be divided among the three legs. Existing wiring at the distribution panels probably will need changing to balance the legs. It is desirable, but not always possible, to reserve one leg for clean power to critical single-phase electronic systems. Balancing each leg is a tricky business best done in consultation with an independent engineer.

As many electronic systems as possible that are powered by a generator should also be protected by UPS units as discussed earlier, even though these add to the generator's load. There will be large voltage surges, dips, sags, and over-voltage conditions as the generator loads are switched and constantly change. Power disturbances will be much greater because electrically noisy motors and lighting cannot be isolated. The UPS units should include noise suppression and voltage regulation as well. And even with all of this, IS equipment will be stressed and may fail.

Locating the generator is the next challenge. The choices are on a roof or setback, inside the premises, or outdoors. Each site has advantages and obstacles. Outdoor generators can be the easiest and cheapest to install but also more expensive to operate. Outdoor generators are noisy, often unsightly, subject to vandalism, and local ordinances may restrict them. When located outside, weatherproof housings are needed to protect the engine, generator, and fuel tank. Most engines used outdoors need to be kept heated, which can become a high overhead expense. Noise is another problem, and persons nearby may object. It is important to use good mufflers and to get written permission from nearby property owners and other tenants. Outdoor units should be fenced with plenty of room for maintenance and fueling. A generator shed is best, if possible, but this does not reduce the need for heating and a good muffler. The whole installation should be securely locked and protected by an open-door alarm and motion detectors, and be in the view of surveillance cameras. Floodlights may deter vandalism and will assist refueling.

Generators on roofs or building setbacks present other problems, and these installations too may be restricted by local codes. The first problem is weight. Structural reinforcement probably will be needed. The next problem is getting the unit in place, which may require a crane or a licensed rigger. Very few building elevators come up to the roof level, and they may not be able to handle even a disassembled generator's parts. All the generator components may have to be rigged up outside of the building or manhandled up the fire stairs.

Installations on top of building setbacks will need a special access door, and moving heavy equipment across a finished floor requires heavy planks and floor protection (e.g., sheets of Masonite or plywood) under the casters to avoid considerable floor damage. There must be sufficient space on the roof or setback to fuel and service the generator safely. Noise will usually be a problem and vibration as well.

Indoor installations offer both advantages and challenges. An indoor location that is sometimes feasible is a heated garage-type ground-floor room with a standard garage door to open when the generator operates. This arrangement is good because it is inconspicuous, fireproof, easily protected, and convenient for fueling and maintenance. And, should a generator fail, a trailer-mounted unit can be hooked up easily.

Inside generators may be prohibited by building or fire codes. Large rooms are needed to facilitate fueling and maintenance, and large ventilation systems to dissipate the considerable engine heat. The engine exhaust can be well muffled and piped outside, while engine-intake air is ducted in from outside. Heating and ventilating the room must be designed correctly for both very hot and very cold weather. The room must be fireproof and soundproof with fire alarms and a suppression system that uses chemicals or dry-head sprinklers that cannot freeze. The floor may need reinforcement and vibration isolators. A floor drain is advisable and must be environmentally approved.

There are advantages to indoor installations. The generator and its fuel can be kept warm easily. Starting is easier and more reliable. Fueling is easier without having to brave the elements. There is less chance of water in the fuel, which can be fatal to diesel engines and maintenance is much easier.

Problems with building installations include building codes that allow only small day tanks for fuel. Every few hours, a lot of fuel must be carried in to keep the generator running. Fuel cannot be stored inside most buildings, and an elevator may not be running or available to help bring in fuel cans.

There are many possible fuels for emergency generators. Diesel fuel is the most efficient, and diesel engines can operate continuously for days but are hard to start, especially in cold weather, and cannot be hand cranked. Home heating oil is basically the same as diesel fuel and can be substituted at any time that diesel fuel is not available, but this requires extra fuel filtering.

If liquid fuel is used, the fuel tank should be full at all times to avoid condensation. Fuel additives can prevent gumming and assist starting. Make sure all diesel fuel is treated for use in a cold climate. Refiners normally do not use this process except in winter, but untreated diesel fuel turns to a gel near freezing temperatures and the fuel will not flow. Never let a dealer “cut” diesel fuel with kerosene, which is corrosive. Diesel fuel also requires additives to avoid bacteria buildup that will clog fuel lines. There should be OSHA-approved cleanup materials ready for any future spills or leaks.

Natural gas or propane are the most convenient fuels. Either one eliminates the day tank and refueling. These engines are the least polluting, and they start much easier, require no preheating, and can be hand cranked. But most are not designed for prolonged continuous duty. Gasoline engines are prohibited by many building codes and are rarely used except for small, portable generators. Gasoline is far more dangerous to handle and store, and gasoline engines do not hold up well under heavy loads.

Continually monitor the engine oil level and be ready to add oil as soon as it is needed. Most generators automatically shut down when the oil level is low. Some also shut down when overheated. Any unexpected generator shutdown will be catastrophic, so monitor closely for early warning signs of trouble.

Once the desired size and type of generator is decided, there are other considerations:

- Automatic engine controls and load transfer switches can be unreliable and may cause damage. Avoid these if possible. However, generators can be monitored and controlled remotely, as well as on site.

23 · 36 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

- Automatic starting can be unreliable. If the engine does not start quickly, the battery will quickly discharge, especially diesel engines in cold weather, which require glo-plug heaters. If at all possible, someone should be present during the starting process, using a checklist to verify proper operations and then transferring the load manually when the generator is ready. Switches that automatically transfer the load are expensive and sometimes fail. Always transfer back to utility power manually, and do this only after sensitive systems are put into a standby mode. Automatic transfer can cause major damage if the utility power flickers and goes out again or if the voltage or the frequency fluctuates during transfer, as it often does. Do not shut off the engine automatically. This is best done manually, and not until utility power is flowing smoothly.
- The best transfer switches allow each of the major circuits to be transferred individually to minimize the inevitable fluctuations likely to occur when everything is switched over simultaneously.
- An emergency generator must be exercised regularly. The manufacturer will specify when and how the units should be exercised. Usually, this must be done monthly and at medium to heavy load. When critical systems are involved, good security practice is to exercise the generator weekly. There should be a written, initialed log entry for each event, including each exercise, inspection, maintenance, oil check, and refueling. Always log operating hours.

Despite the cost and complexity, there is a great feeling of contentment in having a good emergency generator system that functions smoothly, especially when other organizations may be floundering. Once the generator performs well during a real emergency, even skeptics realize the value added.

23.8.7 Environmental Control. Even though today's information systems do not need as much cooling or the precise environmental controls that legacy systems once demanded, good control of temperature and humidity, good ventilation, and clean air are still important. Information systems can function reliably only when proper environments are maintained in both equipment rooms and user workplaces. But each area requires a different approach.

Air conditioning is basically intended to cool people; equipment should be cooled by a functionally different system, which is best called process cooling. The systems should not be intermixed, nor should either one substitute for the other. Building codes require HVAC within all occupied spaces, where people may congregate, or where there are workstations. Building codes also set minimum ventilation requirements for occupied space, including a minimum percentage of makeup (outside) air to be constantly brought into each occupied space so the inside air does not become stale. Most codes do not consider the needs of electronic equipment.

Electronic equipment has many special needs, and many are incompatible with the people comforts required by the codes. Most electronic equipment operates continually, whereas air conditioning operates mostly during business hours. Air-conditioning cooling systems may be shut down for maintenance, during a power brownout, off hours, or in cool weather. By contrast, process cooling must operate continuously and every day, so parallel and redundant systems are often used. The same air should be well filtered and recirculated with no makeup air added to introduce dust or contaminants. This also reduces the cooling capacity needed, so process-cooling equipment can be of smaller capacity and cheaper to operate.

Electrical equipment and wiring also need good humidity control, which process-cooling systems are designed to provide. These systems are designed to be easier, and faster to clean and maintain. Often many components are redundant and hot-swappable. Increasingly, the cooling unit is on the floor or ceiling of the equipment room, so that few ducts, dampers, or registers are needed.

All IS processing, storage, and network equipment should be inside dedicated equipment rooms, which also should be designated as unoccupied spaces to avoid the code-imposed air-conditioning requirements. Avoid using terms such as “computer room” or “data center,” which are usually construed to be occupied spaces.

Both the process cooling in equipment rooms and the air conditioning in work areas must provide humidity control. It is important that relative humidity be controlled between 40 and 60 percent at all times, regardless of the climate or season.

When the relative humidity falls below 40 percent, which can easily happen in cold weather, static electricity is generated as people move about. Static charges can quickly accumulate to become many thousand volts, and a spark will jump to any object a person touches that is differently charged. Even though such a spark may not be felt, several thousand volts can annihilate electronic circuits. For example, a static charge jumping from a fingertip to a keyboard can cause serious damage to storage media and circuits. Much of the damage may not be readily apparent. Actual failure may be delayed, so the cause is not identified. Grounded strips can be installed on workstations, and service personnel should wear grounded wrist straps, although these do not completely stop the problem. The only effective solution is always to keep the relative humidity above 40 percent.

Relative humidity above 60 percent also causes problems that will eventually destroy equipment and wiring. Above 60 percent, condensation and mold will begin to damage some components. Above roughly 80 percent, galvanic action occurs and will eventually cause serious trouble. The process is often called silver migration because most electronic connections are silver-plated. The phenomenon is similar to electrolysis (electroplating), but here the two metals are immersed in high humidity rather than a liquid and there is no external current needed for galvanic action to occur. Molecules of one conductor begin to physically move toward and attach themselves to another less active metal. Even though both surfaces may be gold or silver or copper plated, it is likely that they differ slightly in composition. Therefore, galvanic action will occur whenever the humidity is too high. Connector pins and sockets can disintegrate, fuse together, or fail electrically due to pitting. Printed circuits can also fail. Although this galvanic action happens slowly, it accumulates and is irreversible. The failures are usually without warning, and almost always, poor quality is blamed, rather than high humidity.

The only protection is to control humidity in both equipment rooms and work areas. Process-cooling and air-conditioning systems commonly do this by several methods. Both systems dehumidify naturally when cooling and can use a reheat coil to warm output air if the humidity is too low. Also when the humidity is too low, water is added using a spray, atomizer, or a wet screen through which the supply air is pumped.

There are additional protections, which are wise to install and maintain. In a cold climate, all areas and workplaces with electronic equipment should have low-static floor surfaces. This can be low-static carpeting or floor tile made for this purpose. Do not rely on sprays to control static electricity; they soon dissipate. Be sure that equipment room walls and doors are well sealed so that humidity, dust, and contaminants cannot migrate. Be sure the walls are well sealed from slab to slab and that the slabs themselves are impervious to dust and humidity.

23.8.8 Smoke and Fire Protection. Smoke and fire must be prevented within any equipment room because otherwise, considerable damage and disruption will occur quickly. No matter how small the incident, the effects of either smoke or heat are cumulative. Systems will eventually fail and usually without warning. Obviously, smoking tobacco and other substances must be prohibited—but equipment rooms can be tempting for untrained staff because these rooms may seem to be a safe, cool place to sneak a smoke—and they may even be largely unattended.

Equipment room doors should never be propped open by cleaning, delivery, or maintenance personnel, or others working outside when the air conditioning is off.

The first level of prevention is to keep everything combustible outside of equipment rooms. Paper and supplies not in actual use should be stored outside, never within an equipment room. Although most documentation is now made available electronically, reference materials or documents for emergency response when systems are down may be kept within the room; these should be stored inside fire-resistant files or cabinets for secure and rapid access in an emergency. There should be no trash receptacles within an equipment room, and shredders should be outside, under strict control. There should be a clear and firm policy that nothing combustible can remain inside an equipment room, and frequent inspections should be held to verify compliance.

Equipment and suppliers storage contents rooms should be designed to protect and not to accommodate people. There should be no unessential furniture within equipment rooms, especially desks that can become cluttered and that are not rated as fire resistant. A metal table with one small drawer and one or two metal chairs with fire-resistant upholstery are usually sufficient.

Inadequate firestops are a major threat that is often overlooked. A firestop is usually a sleeve and a special material to prevent smoke or heat from penetrating an opening in a partition, floor, or ceiling. It also stops the spread of flame. Many firestops are needed throughout the premises, including the building core and the mechanical, utility, and equipment areas—even within a one-story building. Firestops are rigorously required by most codes, but compliance is often inadequate and the devices often are breached by subsequent alterations or wiring changes.

Partitions, building walls, floors, and ceilings must all be fire-rated in accordance with the national and local building codes and other regulations. Proper construction usually is specified by an architect or engineer, and compliance is inspected or certified as soon as the construction is complete. Inspection often occurs before all of the mechanical systems and wiring installations are finished. Subsequently, if any penetration or opening is made through a wall, floor, or ceiling, its fire rating is thereby invalidated and should be recertified. The walls for all equipment-rooms must be slab-to-slab construction with no access for air transfer below or above the walls.

The Underwriters Laboratory (UL) or similar recognized authority rates and approves commercial firestops before they can be sold legally. Each manufacturer then specifies the approved applications, installation, and maintenance procedures necessary for compliance. It is therefore wise to utilize specialized vendors with extensive training and experience installing and inspecting firestops and to have them conduct periodic premises inspections and certifications.

Inadequate firestops are particularly common in the core areas of older buildings or where tenants occupy multiple floors. While proper firestops may have been provided during construction, installation of piping, cables, conduit, and subsequent wiring changes often breach them. Wires often poke through large, gaping holes hidden by a hung (suspended) ceiling or behind equipment racks or wire troughs. Proper firestops must be installed and inspected whenever changes occur. Many installers do

not understand this, or cut corners hoping no one will notice, or assume others will take care of it.

Without proper firestops throughout, fire and smoke can, and probably will, spread surprisingly quickly. And so will dust. There can be substantial liabilities if any people are harmed or equipment is damaged because of improper firestops or inadequate fire-rated construction. The costs, time lost, and reputational damage will be huge. Periodic and thorough fire inspections by an independent and qualified expert will quickly discover building and firestop violations.

Smoke is far more dangerous than flame. And all smoke is toxic! It contains high levels of carbon monoxide, which is invisible, odorless, and quickly fatal. Smoke is the product of the combustion of many materials, and most of these are dangerous to breathe. Some are immediately fatal. Even a little smoke can do considerable harm to humans and much harm to electronic equipment. Smoke is deceptive; even when there does not seem to be very much smoke or heat, and visibility looks good, people within or passing through the area quickly become disabled and some may soon die.

The first priority is the safety of people. Get everyone away from any smoke immediately, and keep everyone away. Only trained responders with proper protective clothing, equipment, and self-contained breathing apparatus should enter any smoky area. Generally, respirators are not enough protection and may leak as well. There must be no heroics; crawling through smoke on the floor or breathing through a wet rag are desperate measures that should be attempted only when unavoidable to escape the area. Everyone should wait in a safe place until firefighters arrive and then follow their instructions.

The best way to prevent an equipment room fire is to keep anything combustible outside the room. Documents, manuals, and supplies should be stored outside the room in closed metal cabinets. Inside furniture should be limited to a metal table and a chair or two. All waste receptacles should be outside. Once combustible materials are eliminated, the only smoke that develops will be from electrical overheating. Electrical fires rarely occur in an equipment room, and those that do occur are likely to be very small, brief, and cease as soon as electrical power is removed. (Note that most computing components now operate on five volts or less, so that a short circuit is no more dangerous than, for example, a shorted flashlight, which presents no smoke hazard.) While sometimes noticeably acrid, there is usually little visible smoke. Therefore, sensitive fire and smoke detectors and an effective means of fire suppression are needed and required by most building and fire codes. Good detectors can provide enough early warning to ward off trouble and injury.

Enough smoke or heat to cause actual equipment damage requires an electrical current higher than most components can draw. Circuit breakers and fuses usually will open before there is much smoke or damage. Perhaps the greatest risk is smoke from the ballasts in low-quality fluorescent light fixtures, which can put out considerable black smoke. Any smoke is corrosive and may condense on connectors and printed circuits, which may then eventually fail.

There should be smoke detectors in every equipment room that are connected to a central alarm system. There should be enough detectors to cover the entire volume of each room. Each detector should include an electric eye to look for haze or smoke, ionization sensors to detect products of combustion well before any are noticed by humans, and rapid-rise-in-temperature detectors in case there is enough heat buildup to cause damage. Even though detected, nothing will stop smoke generated by overheated wiring or components until the electrical power is cut off or other heat source is removed.

23 · 40 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

There must be a fire suppression system in every equipment room. Both code compliance and good security practice requires this. Fire suppression is best accomplished with sprinkler heads that spray water mist, even though some unprotected equipment may be damaged if the water is not effective quickly. Special waterproof protective covers are often kept near equipment in case of accidents such as ceiling leaks or a damaged sprinkler head. But if an area is already smoky, no one should attempt to place the covers.

Wiring, connections, and most components will dry themselves, even when soaked. The process may be hastened with lint-free towels and careful use of hair dryers. Keyboards, monitors, UPS units, power supplies, some disk or tape drives, and especially printers may be damaged and should be replaced until they can be inspected. Hard drives are usually hermetically sealed and unaffected. A few other components could be damaged by excessive heat, although water mist is very effective in quenching heat sources. Plenty of replacement items should be safely stored nearby. Handling damaged low-voltage components (such as most circuit boards) presents little risk to people—provided there is not too much water and the persons know what they are doing and how to avoid damaging the components. If in doubt, shut down the components temporarily.

Enclosed equipment cabinets offer the best protection regardless of the room's fire suppression system. Enclosed cabinets can monitor temperature and humidity, detect and contain smoke, sound alarms, and often contain systems to suppress a fire before trouble occurs.

Halon 1301 fire suppressant was once widely used in critical areas. But Halon is a fluorocarbon whose manufacture has been banned for many years. Today's chemical systems are designed differently; one example uses the FM200 Suppression Agent made by Siemens. The claimed advantage of the chemical suppressants is that humans can breathe the agent, at least while they are exiting the area. Another fire suppression system uses carbon dioxide, which is effective and less expensive, but can extinguish people as well as fires. The problem with all chemical agents, including carbon dioxide, is that they quickly mix with smoke and become very toxic. The agent itself may be safe to breathe, but the smoke mixed with it is not. These systems are also very expensive.

Regardless of the suppression system, there should be controls and a shutoff near the room's exit, but not accessible to a perpetrator. Generally, an audible, continuous alarm indicates that the suppression system is about to activate. There should be postpone buttons on the control panel, and perhaps remotely as well, that will delay activation for about two minutes while someone intervenes. The postpone mode generally pulses the audible alarm. A silent alarm indication should remain activated whenever a fire suppression system is disabled or the alarms are silenced.

The next level of protection utilizes several fire extinguishers. These are the most useful protections because the suppressant can be aimed where it is needed and not throughout the room. Carbon dioxide is best because it does not leave a residue. Chemical, powder, and foam extinguishers also work well but are hard to clean up. ABC-type extinguishers are best because they are effective for combustible materials, flammable liquids, and electrical fires, respectively. Several handheld extinguishers are better than a few large, heavy units. All fire extinguishers should be conspicuously wall-mounted or placed immediately inside and outside of entrances. An OSHA-approved red patch placed on the wall nearest to every extinguisher highlights its location. Also, check other OSHA, local code, and insurance requirements that may apply.

Supply air from the process-cooling equipment should be shut down quickly and automatically to avoid recirculating the smoke. The IS equipment may have to be shut

down soon thereafter before it overheats. It is best to shut down everything promptly and automatically in an orderly sequence—cooling, IS equipment, electrical power, and lighting—and then evacuate. Shut down the lighting, in case it is part of the problem. Shut-down should occur automatically with manual intervention from controls inside the room or remotely. Battery-powered exit and emergency room lighting are advisable so responders do not need flashlights.

A so-called crash cart is a good investment. This is used during a smoke condition, a water leak, and, it is hoped, before a fire suppression system activates. A crash cart is kept outside or nearby major equipment rooms and rolled to where it is needed. The cart usually contains covers to keep smoke and water out of racks and off equipment, large fire extinguishers, and sometimes respirators or self-contained breathing apparatus. The crash cart should include quick-reference procedures, and a checklist for protecting and shutting down the room, as well as safety and notification procedures—usually printed on plastic. The crash cart should be inspected and the procedures reviewed monthly, and there should be periodic training and exercises to practice using the equipment. Before the smoke and water covers are used, be sure the equipment is first powered off. Crash carts were important for yesterday's computer rooms but are increasingly unnecessary in a well-designed equipment room.

Finally, be sure to have smoke-exhaust systems available to quickly purge the areas of smoke. Most fire departments have portable purge fans with long fabric and wire hoses to reach outside. Do not allow anyone to use a respirator or breathing apparatus unless it is approved for this purpose and has been properly fitted to a trained person.

23.9 MITIGATING SPECIFIC THREATS. Several other threats should be considered before good infrastructure protection is possible. Some of these situations are unlikely but potentially very costly if they should ever occur.

23.9.1 Preventing Wiretaps and Bugs. Most wiretaps are placed at wiring junction points. Vulnerable spots are within equipment rooms, wiring closets, junction boxes, wiring blocks, or data receptacles. The tap wire can be fiber or coax or utilize a pair of unused conductors inside an existing cable. It is likely to be a small wire that is hardly noticeable, running to an inconspicuous place where monitoring and recording can occur. Once removed to a safe place, the data can be extracted by phone, wireless, Internet, or manually. Tapped data may even be encoded and stored on the victim's own network. Video and/or audio bugs used for spying are similar to wiretaps in that once the data is monitored, it must then be sent elsewhere for retrieval.

Unless all system data are encrypted—including all data, voice, and video traffic—wiretap protection must be strong because detection is difficult at best. First, determine which cables are critical and inspect the entire cable run. All cables should be inside of metal conduit. Data and power conduits should look similar and with no markings or labels except alphanumeric codes. Keep critical conduits as inconspicuous as possible, and away from places the public might access. There must be strong access controls, intrusion alarms, motion detectors, or surveillance where terminations, connectors, or wires can be accessed. Critical cable runs must be protected over their entire length. See Section 23.8.3 for ways to protect conduit and exposed cables.

Data cables between the desktop and wall or floor outlets are potential wiretap sites. Cables, harnesses, and connectors within office furniture systems may also be compromised. Reasonably good protection is possible with careful design, with devices that harden the data cabling against the possibility of a wiretap, and that detect disconnecting or tampering with any data wires.

23 · 42 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

For continued protection against wiretaps and bugs, even when all data are fully encrypted, there must be periodic and thorough visual inspections, sweeps for any unusual radio-frequency transmissions, and careful cable testing to determine any anomalies. Everything done must be logged and quickly analyzed. Unfortunately, most spying is never detected and can continue undetected at the will of the perpetrators.

23.9.2 Remote Spying Devices. There are very sensitive radio receivers that can monitor information system data through walls or from outside the building without the use of an inside bug or wiretap. These devices can simply listen to the data from afar. Such equipment is not available publicly and is well beyond the means of all but the best-financed spies. However, there are many such systems in use today, and many more will be available as prices drop. Any organization whose data are very valuable is a potential target. The best protection is good shielding around equipment rooms and thick-wall metal conduit for data cables, and everything must be properly grounded. There are also interference transmitters that may help; these broadcast white noise that can overwhelm signals radiated from the IS infrastructure.

23.9.3 Bombs, Threats, Violence, and Attacks. Violent events are unpredictable and potentially devastating. These are not accidents, but deliberate attacks, intended to disrupt, cause damage, and spread fear. The tragic attacks of 9/11 and their aftermath have proven the vulnerability of people and of their infrastructures. The vulnerabilities remain today, and the risks are even greater.

Protection against violence must be threat-specific, and all possible threats must be addressed as described in Chapter 22. Effective deterrence and mitigation then become a matter of strengthening the protections described throughout this chapter, which need not be very costly considering the response and recovery costs that could otherwise result. Premises or corporate security must deal with most threats of violence, but the infrastructure needs special protections to avoid disruption and to mitigate the downtime and cost consequences of any such event.

Reasonably good protection and mitigation measures can be simple and inexpensive. State and regional bomb squads or explosives units can advise and assist in many ways, including current briefings. Weapons of mass destruction (WMDs), other than nuclear weapons, are fast becoming a real threat, especially because many such devices are small and easily concealed. WMDs include chemical and biological agents and incendiary devices, while even small amounts of radioactive materials disbursed by an explosive *dirty bomb* can spread panic. The government considers these devices very serious threats, with businesses and their infrastructures as likely targets.

New federal office space must now be certified as bomb resistant, so that an explosion or the impact of a truck bomb cannot collapse the building. Officials can usually provide a current threat briefing and suggest protective measures. Although small areas may be destroyed, the structure will not collapse.

Just like some possible threats, there are also effective protection devices that cannot be mentioned. These are not marketed publicly and therefore are unknown to dealers, resellers, or distributors. The costs can be reasonable because they are only sold direct. Developers may supply classified systems for military or government use and offer declassified versions to other selected users. In this way, developers can restrict knowledge of their products to as few people as possible, so that others cannot discover how to recognize or circumvent them.

Many consultants who have worked with financial, regulated, or very large private companies know some of these specialty vendors. Usually, a consultant will approach

the vendor and discuss what is needed; the vendor may then contact the customer directly.

Finally, given today's environment of violence, get to know key local, state, and federal law enforcement and investigative officials, and ask their suggestions how best to protect an organization.

23.9.4 Medical Emergencies. Mitigating medical emergencies requires a first aid room on the premises, first aid and some medical supplies, a registered nurse if possible, and many workers trained in first aid and cardiopulmonary resuscitation (CPR). All security personnel and guards should be certified in first aid and CPR.

An automated external defibrillator (AED) on site will save lives and can be operated by anybody in an emergency. A portable AED currently costs about \$1,000, and the suggested training is inexpensive. An AED is now required in all federally managed buildings. Many shopping malls, places of public assembly, and commercial aircraft are now equipped with one or more units.

Oxygen is often necessary to save lives and prevent permanent impairment. Most sites equipped with an AED also have oxygen units. Good portable units cost \$800 or less.

23.10 COMPLETING THE SECURITY PLANNING PROCESS. The last step necessary to protect the information infrastructure has four components. Absent any of these components completed thoroughly, good security is not possible. They include:

1. Develop an all-hazard mitigation plan.
2. Develop all of the mitigation options for each identified threat and perform a cost-benefit analysis to determine which options are best.
3. Develop an overall security response plan to show who is responsible for what.
4. Complete the necessary implementation, accountability, and follow-up procedures.

23.10.1 All-Hazard Mitigation Plan. FEMA provides extensive resources for *Multi-Hazard Mitigation Planning* on a wide range of topics and including email updates.¹³ *State and Local Mitigation Planning How-to Guides* can be helpful in this final step.¹⁴

- FEMA Publication 386-1, *Getting Started: Building Support for Mitigation Planning*, establishes the hazard-mitigation process.¹⁵
- Publication 386-2, *Understanding Your Risks: Identifying Hazards and Estimating Losses*, shows a method of cost-estimating potential losses due to flooding using tables rather than by calculation. These tables quickly show that losses can be far greater than expected.¹⁶
- Publication 386-3, *Developing the Mitigation Plan: Identifying Mitigation Actions and Implementation Strategies*, provides guidance on developing the mitigation strategy.¹⁷
- Publication 386-4, *Bringing the Plan to Life: Implementing the Hazard Mitigation Plan*, discusses guidance on implementation.¹⁸

23 · 44 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

- Publication 386-5, *Using Benefit-Cost Review in Mitigation Planning*, provides heuristics for selecting among mitigation options to maximize cost effectiveness of expenditures.¹⁹
- Publication 386-6, *Integrating Historic Property and Cultural Resource Considerations into Hazard Mitigation Planning*, discusses how to work with local planning authorities to protect cultural capital.²⁰
- Publication 386-7, *Integrating Manmade Hazards Into Mitigation Planning*, explores how to plan for terrorist or criminal attacks in emergency planning.²¹
- Publication 386-8, *Multi-Jurisdictional Mitigation Planning*, emphasizes the importance of collaborative response planning (Federal Emergency Management Agency 2006).²²

Once all possible threat situations have been identified and assessed as described in Chapter 22, the next step is to develop as many options as possible to prevent, deter, or mitigate disruption, injury, or damage from each threat. Although some threats cannot be prevented, there are always ways to prepare for and mitigate their impact. Usually, there are many mitigation options, so the objective is to determine which options are the most practical and affordable. The only objective way to do this is with cost-benefit analysis (described in Section 23.11.2).

In actuality, the options to protect against many different threats will be similar, but each option should be retained until the best mitigation strategy for each threat is determined. Here also there is likely to be one common mitigation strategy that covers many different threats. All credible threats should be listed in the mitigation plan, but the mitigation projects laid out will be far fewer in number.

When the next step is finished, the All-Hazard Mitigation Plan can be completed. The FEMA 386 how-to manuals described above provide the suggested format and content. FEMA's *How-To Guide #9* (FEMA 386-9), entitled *Using the Hazard Mitigation Plan to Prepare Successful Mitigation Projects*, is an extensive guide to using all the other resources mentioned above.²³

The complete mitigation plan should be for official use only, and not released except to those with a need to know this information. The complete plan would be very helpful to a potential troublemaker because it shows where the organization is vulnerable, and to which threats. If disclosure of the complete plan is not well controlled, its contents could be leaked by, extorted from, or sold by an insider. However, the executive summary of the plan and abbreviated findings should be circulated widely, so that all stakeholders know that much is being done to protect them.

23.10.2 Cost-Benefit Analysis. Security is pointless unless it is cost effective and also adds value: that is, the cost of mitigating each threat must be less than the potential benefits and savings of the event not occurring, because if the protection is effective. The costs of every option can easily be determined; these are the initial and ongoing costs. Some future benefits, though, will be intangible, and all will have to be approximated. The long-term benefits of something not happening must reflect the approximated costs of:

- Disruptions that would reduce the productivity of the business and the performance of its information systems
- Morale and performance that could plummet, and remain very low because people feel unsafe and unprotected

- Loss of business or customers until operations could be restored to normal
- Response and recovery costs including extra time and overtime, expenses including lodging and meals, temporary facilities, public relations, and legal defense costs that are all likely to be incurred
- Legal, public relations, and other services and expenses to repair reputational damage, and fallen stock price, and to restore goodwill

Not all of these costs will follow every threat. But then again, there may also be additional, unexpected costs as well. In general, the response and recovery costs of any major security event tend to be far greater than expected. Nonetheless, each situation can be studied and some costs determined in order to facilitate a statistically valid cost-benefit analysis.

Cost and benefit information have no meaning unless each is associated with a common time frame. The likelihood of each threat should be assessed on an annualized basis (see Section 22.3.4), so that both the mitigation costs and the potential benefits can be amortized over the same life cycle.

There are many methods for cost-value analysis, and most are beyond the scope of this chapter. However, for those who are not financially trained, the federal government has a good system, freely available, that is widely required within the government. The U.S. government calls this system *BCA*, which stands for benefit-cost analysis. As part of this system, FEMA has developed a *Benefit-Cost Analysis Tool*, which assists grant applicants with financial analyses, such as net present value. The same site includes hazard data.²⁴

One particular advantage of the *BCA* system is that the OMB publishes current cost-of-funds data needed to project any costs. Some of the private models tend to use wildly optimistic (or grossly out of date) future interest rates, which invalidates meaningful results. Again, it is wise to use a federal government model simply as a matter of risk avoidance. The *BCA* model is widely used and required for many grant applications.

23.10.3 Security Response Plan. A hazard mitigation plan is needed to document the threat assessment done in Chapter 22 and to list the mitigation options and the predicted costs and benefits associated with each; a security response plan is also needed to direct each stakeholder according to the type of threat experienced. The purpose of the security response plan is to define clearly who is in charge and who will do what, when and how, when any threat occurs.

The new NRF format revises and reestablishes the Emergency Support Functions (ESF) concept for each support activity that each organization may need.²⁵ There are now 16 numbered ESFs, beginning with ESF-1, “Transportation,” ESF-2, “Communications & Alerting,” and on through ESF-16, “Animal Health.” It is recommended that the standard ESF titles be retained, even though many may not be applicable to a nongovernment organization, if only to maintain a uniformity and language that everyone understands. Additional ESFs will be needed to mount an effective response, but number these as 17 and upward.

One useful quick reference in the new response plan format is an Emergency Support Function Assignment Matrix (which is often Figure 1), a one-page graphic that shows which agency or department has primary, secondary, or support responsibility for each ESF. This is a handy quick-reference guide for management and staff when trouble comes.

23 · 46 PROTECTING THE PHYSICAL INFORMATION INFRASTRUCTURE

Once a response plan is ready, standard operating procedures should be written by each affected department to outline the procedures it will use to respond. The term is in quotes because these are usually issued as guidelines so that there can be some flexibility to adjust to the actual conditions. The requirement for rigid adherence to a procedure is an invitation that invites litigation.

The complete security response plan should also be for official use only, and released only to those with a need to know. After all, this plan shows troublemakers just how the organization will respond. However, a press release summarizing the plan should be widely circulated so that all stakeholders know the organization is trying to protect them.

23.10.4 Implementation, Accountability, and Follow-Up. Once all the plans are completed and signed off by management and key officials, the job of implementation begins. Of the How-To Guides mentioned earlier, FEMA 386-4, *Bringing the Plan to Life*, will be helpful here.

This first implementation step is the most critical to the security-protection process. It begins with training so that everyone involved understands and accepts the procedures. There must then be periodic exercises and drills to test the response plan and to validate that the training has been effective. Plans that are not periodically tested are soon forgotten.

Every exercise and drill must be reviewed to determine what went right and, more important, what did not, and how to do better in the future. So too should every emergency response be reviewed. Documentation before, during, and after the event is important. There will be some lessons learned from each event, and these lessons should be used to update and improve the security systems to work better in the future.

It is also critical to establish accountability for the infrastructure security. There should be only one person in charge of each function. Responsibility cannot be spread among management or departments, nor can responsibility be worn as a second hat for someone with many other duties. The senior responsible authority must set up schedules for periodic review and update of the plans and procedures, training, and exercises to make sure that the security program remains current and effective.

Good security management must also include oversight. Good planning must begin in the boardroom, and the directors must also provide continuing oversight to ascertain good security. Outside, independent, auditors who are directed from the boardroom are best able to validate the current condition of the security program. The auditor's written opinion is evidence of whether the organization is fully compliant or not. The best procedure for an infrastructure security audit is suggested in Section 23.2.7.

For management's own peace of mind (and possibly as a requirement for maintaining insurance and obtaining credit), there may be periodic security inspections, testing of defenses, and some penetration tests, including deceptions to gain access done by independent professionals.

23.11 FURTHER READING

The further readings suggested in Chapter 22 will also be helpful in this chapter. The Congressional Research Service report to Congress dated June 2006, entitled *Federal Emergency Management and Homeland Security Organization: Historical Development and Legislative Options*, is interesting reading for anyone burdened with security planning and management. This outlines the federal government's struggles since 1947 to get the system right. It also lists legislation

before the 109th Congress to fix the problems. The report can be downloaded free at www.fas.org/sgp/crs/homsec/RL33369.pdf

For an interesting discussion of the inner workings of federal response systems and how better security planning and management can be implemented, see Christopher Cooper and Robert Block, *Disaster: Hurricane Katrina and the Failure of Homeland Security*, Holt Paperbacks (ISBN 978-0805086508), 2007: 352 pp.

24.1 INFORMATION PROTECTION AND SECURITY. This chapter reviews the principles of security in operating systems. Some general-purpose tools can be built into computers and operating systems (OSs) that support a variety of protection and security mechanisms. In general, the concern is with the problem of controlling access to computer systems and the information stored in them.

One of the core concepts in all such discussions is the *process*, which is defined as the execution of a specific piece of code by a particular user at a particular time on a particular processor.

Four types of overall protection policies, of increasing order of difficulty, have been identified:

1. **No sharing.** In this case, processes are completely isolated from each other, and each process has exclusive control over the resources statically or dynamically assigned to it. With this policy, processes often “share” a program or data file by making a copy of it and transferring the copy into their own virtual memory.

24 · 2 OPERATING SYSTEM SECURITY

2. **Sharing originals of program or data files.** With the use of reentrant code, a single physical realization of a program can appear in multiple virtual address spaces, as can read-only data files. Special locking mechanisms are required for the sharing of writable data files, to prevent simultaneous users from interfering with each other.
3. **Confined, or memoryless, subsystems.** In this case, processes are grouped into subsystems to enforce a particular protection policy. For example, a “client” process calls a “server” process to perform some task on data. The server is to be protected against the client discovering the algorithm by which it performs the task, while the client is to be protected against the server’s retaining any information about the task being performed.
4. **Controlled information dissemination.** In some systems, security classes are defined to enforce a particular dissemination policy. Users and applications are given security clearances of a certain level, while data and other resources (e.g., input/output [I/O] devices) are given security classifications. The security policy enforces restrictions concerning which users have access to which classifications. This model is useful not only in the military context but in commercial applications as well.¹

Much of the work in security and protection as it relates to OSs can be roughly grouped into three categories.

1. **Access control.** Concerned with regulating user access to the total system, subsystems, and data, and regulating process access to various resources and objects within the system.
2. **Information flow control.** Regulates the flow of data within the system and its delivery to users.
3. **Certification.** Relates to proving that access and flow control mechanisms perform according to their specifications and that they enforce desired protection and security policies.

This chapter looks at some of the key mechanisms for providing OS security and then examines Windows 2000 as a case study.

24.2 REQUIREMENTS FOR OPERATING SYSTEM SECURITY

24.2.1 Requirements. Understanding the types of threats to OS security requires a definition of security requirements. OS security addresses four requirements:

1. **Confidentiality.** Requires that the information in a computer system be accessible only for reading by authorized parties. This type of access includes printing, displaying, and other forms of disclosure, including simply revealing the existence of an object.
2. **Integrity.** Requires that only authorized parties be able to modify computer system assets. Modification includes writing, changing, changing status, deleting, and creating.

3. **Availability.** Requires that computer system assets are available to authorized parties.
4. **Authentication.** Requires that a computer system be able to verify the identifier of a user, a device or a process.

24.2.2 Computer System Assets. The assets of a computer system can be categorized as hardware, software, and data.

24.2.2.1 Hardware. The main threat to computer system hardware is in the area of availability. Hardware is the most vulnerable to attack and the least amenable to automated controls. Threats include accidental and deliberate damage to equipment as well as theft. The proliferation of personal computers and workstations and the increasing use of local area networks (LANs) increase the potential for losses in this area. Physical and administrative security measures are needed to deal with these threats. Chapters 22 and 23 in this *Handbook* discuss physical security.

24.2.2.2 Software. The OS, utilities, and application programs are what make computer system hardware useful to businesses and individuals. Several distinct threats need to be considered.

A key threat to software is an attack on availability. Software, especially application software, is surprisingly easy to delete. Software also can be altered or damaged to render it useless or dangerous. Careful software configuration management, which includes making backups of the most recent version of software, can maintain high availability. A more difficult problem to deal with is software modification that results in a program that still functions but that behaves differently from before. A final problem is control or possession of software. Although certain countermeasures are available, by and large the problem of unauthorized copying of software has not been solved.

Chapters 38, 39, and 40 of this *Handbook* discuss software security in some detail.

24.2.2.3 Data. Hardware and software security typically are concerns of computing center professionals or individual concerns of personal computer users. A much more widespread problem is data security, which involves files and other forms of data controlled by individuals, groups, and business organizations.

Security concerns with respect to data are broad, encompassing confidentiality, control or possession, integrity, authenticity, availability and utility. For a sound theoretical treatment of the attributes of information that must be protected through security measures, see Chapter 3 in this *Handbook*.

In the case of availability, the concern is with the *destruction* of data files, which can occur either accidentally or maliciously, and with delays in timely access to data.

The obvious concern with confidentiality is the unauthorized reading of data files or databases, and this area has been the subject of perhaps more research and effort than any other area of computer security. A less obvious secrecy threat involves the analysis of data and manifests itself in the use of so-called statistical databases or *data mining*, which provide summary or aggregate information and potentially lead to discovery of unpublicized tendencies, relations, or trends. Aggregate information does not necessarily threaten the privacy of the individuals involved. However, as the use of statistical databases grows, there is an increasing potential for disclosure of personal information through induction or deduction. In essence, characteristics of constituent

24 · 4 OPERATING SYSTEM SECURITY

individuals may be identified through careful analysis. To take a simple example, if one table records the aggregate of the incomes of respondents A, B, C, and D and another records the aggregate of the incomes of A, B, C, D, and E, the difference between the two aggregates would be the income of E. This problem is exacerbated by the increasing desire to combine data sets. In many cases, matching several sets of data for consistency at levels of aggregation appropriate to the problem requires a retreat to elemental units in the process of constructing the necessary aggregates. Thus, the elemental units, which are the subject of privacy concerns, are available at various stages in the processing of data sets.

Finally, data integrity is a major concern in most installations. Modifications to data files can have consequences ranging from minor to disastrous.

24.2.3 Design Principles. Saltzer and Schroeder identify a number of principles for the design of security measures for the various threats to computer systems. These include:

- **Least privilege.** Every program and every user of the system should operate using the least set of privileges necessary to complete the job. Access rights should be acquired by explicit permission only; the default should be “no access.”
- **Economy of mechanisms.** Security mechanisms should be as small and simple as possible, aiding in their verification. This usually means that they must be an integral part of the design rather than add-on mechanisms to existing designs.
- **Acceptability.** Security mechanisms should not interfere unduly with the work of users. At the same time, the mechanisms should meet the needs of those who authorize access. If the mechanisms are not easy to use, they are likely to be unused or incorrectly used.
- **Complete mediation.** Every access must be checked against the access-control information, including those accesses occurring outside normal operation, as in recovery or maintenance.
- **Open design.** The security of the system should not depend on keeping the design of its mechanisms secret. Thus, the mechanisms can be reviewed by many experts, and users can have high confidence in them.²

24.3 PROTECTION MECHANISMS. The introduction of multiprogramming brought about the ability to share resources among users. This sharing involves not just the processor but also:

- Memory
- I/O devices, such as disks and printers
- Programs
- Data

The ability to share these resources introduced the need for protection. Pfleeger and Pfleeger point out that an OS may offer protection along this spectrum:

- **No protection.** This is appropriate when sensitive procedures are being run at separate times.

- **Isolation.** This approach implies that each process operates separately from other processes, with no sharing or communication. Each process has its own address space, files, and other objects.
- **Share all or share nothing.** The owner of an object (e.g., a file or memory segment) declares it to be public or private. In the former case, any process may access the object; in the latter, only the owner's processes may access the object.
- **Share via access limitation.** The OS checks the permissibility of each access by a specific user to a specific object. The OS therefore acts as a guard, or gatekeeper, between users and objects, ensuring that only authorized accesses occur.
- **Share via dynamic capabilities.** This extends the concept of access control to allow dynamic creation of sharing rights for objects.
- **Limit use of an object.** This form of protection limits not just access to an object but the use to which that object may be put. For example, a user may be allowed to view a sensitive document but not print it. Another example is that a user may be allowed access to a database to derive statistical summaries but not to determine specific data values.³

The preceding items are listed roughly in increasing order of difficulty to implement but also in increasing order of fineness of protection that they provide. A given OS may provide different degrees of protection for different objects, users, or applications.

The OS needs to balance the need to allow sharing, which enhances the utility of the computer system, with the need to protect the resources of individual users. This section considers some of the mechanisms by which OSs have enforced protection for these objects.

24.3.1 Protection of Memory. In a multiprogramming environment, protection of main memory (random-access memory, or *RAM*) is essential. The concern here is not just security but the correct functioning of the various processes that are active. If one process can inadvertently write into the memory space of another process, then the latter process may not execute properly.

The separation of the memory space of various processes is accomplished easily with a virtual memory scheme. Either segmentation or paging, or the two in combination, provides an effective means of managing main memory. If complete isolation is sought, then the OS simply must ensure that each segment or page is accessible only by the process to which it is assigned. This is accomplished easily by requiring that there be no duplicate entries in page and/or segment tables.

If sharing is to be allowed, then the same segment or page may appear in more than one table. This type of sharing is accomplished most easily in a system that supports segmentation or a combination of segmentation and paging. In this case, the segment structure is visible to the application, and the application can declare individual segments to be sharable or nonsharable. In a pure paging environment, it becomes more difficult to discriminate between the two types of memory, because the memory structure is transparent to the application.

Segmentation, especially, lends itself to the implementation of protection and sharing policies. Because each segment table entry includes a length as well as a base address, a program cannot inadvertently access a main memory location beyond the limits of a segment. To achieve sharing, it is possible for a segment to be referenced in the segment tables of more than one process. The same mechanisms are available in a paging system. However, in this case the page structure of programs and data is not visible

24 · 6 OPERATING SYSTEM SECURITY

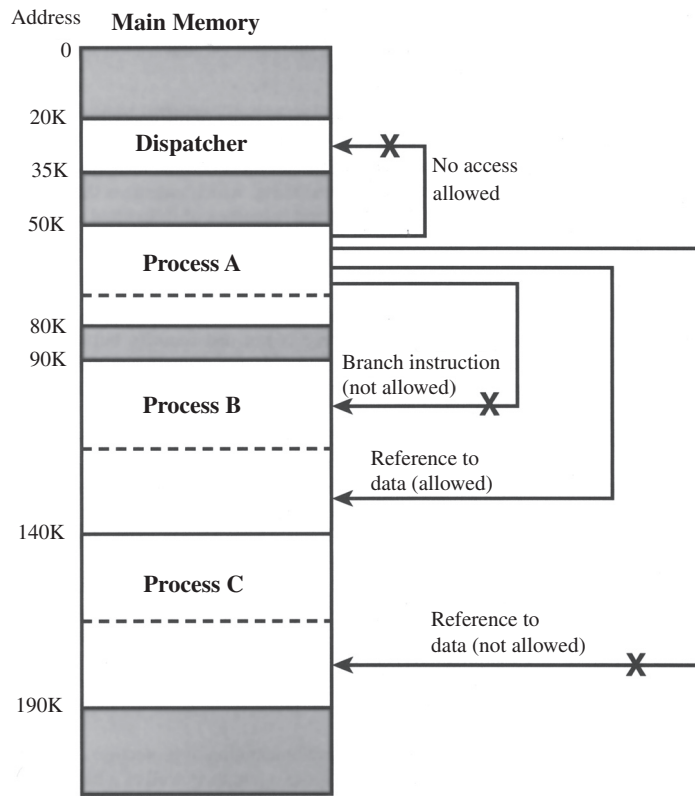

EXHIBIT 24.1 Protection Relationships between Segments

to the programmer, making the specification of protection and sharing requirements more awkward. Exhibit 24.1 illustrates the types of protection relationships that can be enforced in such a system.

An example of the hardware support that can be provided for memory protection is that of the IBM System/370 family of machines, on which OS/390 runs. Associated with each page frame in main memory is a 7-bit storage control key, which may be set by the OS. Two of the bits indicate whether the page occupying this frame has been referenced and changed; these bits are used by the page replacement algorithm. The remaining bits are used by the protection mechanism: a 4-bit access-control key and a fetch-protection bit. Processor references to memory and direct memory access (DMA). DMA I/O memory references must use a matching key to gain permission to access that page. The fetch-protection bit indicates whether the access-control key applies to writes or to both reads and writes. In the processor, there is a program status word (PSW), which contains control information relating to the process that is currently executing. Included in this word is a 4-bit PSW key. When a process attempts to access a page or to initiate a DMA operation on a page, the current PSW key is compared to the access code. A write operation is permitted only if the codes match. If the fetch bit is set, then the PSW key must match the access code for read operations.

24.3.2 User-Oriented Access Control. The measures taken to control access in a data processing system fall into two categories: those associated with the user and those associated with the data.

The most common technique for user access control on a shared system or server is the user logon, which requires both a user identifier (ID) and some form of *authentication*, such as providing a password, a token, or biometric attributes. Authentication refers to the binding of a real-world identity (for example, a named employee or a named role in an organization) and the ID being presented. The system will allow a user to log on only if that user's ID is known to the system and if the user knows the password associated by the system with that ID.

Once a user has established a *session*, the operating system can then *authorize* different forms of access (e.g., read, write, append, lock, or execute) to different types of data (e.g., specific files, databases, devices, or communications).

User access control in a distributed environment can be either centralized or decentralized. In a centralized approach, the network provides a logon service, determining who is allowed to use the network and to whom the user is allowed to connect.

Decentralized user access control treats the network as a transparent communication link, and the destination host carries out the usual logon procedure. The security concerns for transmitting passwords over the network must still be addressed.

In many networks, two levels of access control may be used. Individual hosts may be provided with a logon facility to protect host-specific resources and application. In addition, the network as a whole may provide protection to restrict network access to authorized users. This two-level facility is desirable for the common case, currently, in which the network connects disparate hosts and simply provides a convenient means of terminal-host access. In a more uniform network of hosts, some centralized access policy could be enforced in a network control center.

Chapters 28 and 29 of this *Handbook* present more information about identification and authentication.

24.3.3 Data-Oriented Access Control. Following successful logon, the user is granted access to one or a set of hosts and applications. This is generally not sufficient for a system that includes sensitive data in its database. Through the user access-control procedure, a user can be identified to the system. Associated with each user, there can be a profile that specifies permissible operations and file accesses. The OS can then enforce rules based on the user profile. The database-management system, however, must control access to specific records or even portions of records. For example, it may be permissible for anyone in administration to obtain a list of company personnel, but only selected individuals may have access to salary information. The issue is more than just one of level of detail. Whereas the OS may grant a user permission to access a file or use an application, following which there are no further security checks, the database management system must make a decision on each individual access attempt. That decision will depend not only on the user's identity but also on the specific parts of the data being accessed and even on the information already divulged to the user.

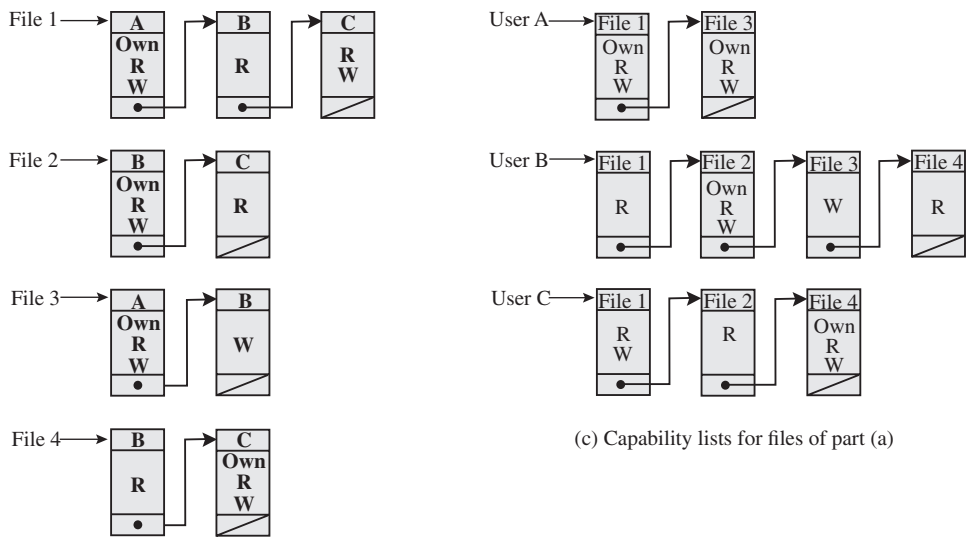

A general model of access control as exercised by a file or database management system is that of an *access matrix* (see Exhibit 24.2a). The basic elements of the model are:

- **Subject.** An entity capable of accessing objects. Generally, the concept of subject equates with that of process. Any user or application actually gains access to an object by means of a process that represents that user or application.
- **Object.** Anything to which access is controlled. Examples include files, portions of files, programs, and segments of memory.
- **Access right.** The way in which an object is accessed by a subject. Examples are read, write, and execute.

EXHIBIT 24.2 Example of Access-Control Structures
Source: Based on a figure in Sandhu (1996).

One dimension of the matrix consists of identified subjects that may attempt data access. Typically, this list will consist of individual users or user groups, although access could be controlled for terminals, hosts, or applications, instead of, or in addition to, users. The other dimension lists the objects that may be accessed. At the greatest level of detail, objects may be individual data fields. More aggregate groupings, such as records, files, or even the entire database, also may be objects in the matrix. Each entry in the matrix indicates the access rights of that subject for that object.

In practice, an access matrix usually is sparse and is implemented by decomposition in one of two ways. The matrix may be decomposed by columns, yielding *access-control lists* (see Exhibit 24.2b). Thus, for each object, an access-control list lists users and their permitted access rights. The access-control list may contain a default, or public, entry. This allows users who are not explicitly listed as having special rights to have a default set of rights. Elements of the list may include individual users as well as groups of users.

Decomposition by rows yields *capability tickets* (see Exhibit 24.2c). A capability ticket specifies authorized objects and operations for a user. Each user has a number

of tickets and may be authorized to lend or give them to others. Because tickets may be dispersed around the system, they present a greater security problem than access-control lists. In particular, the ticket must be unforgeable. One way to accomplish this is to have the OS hold all tickets on behalf of users. These tickets would have to be held in a region of memory inaccessible to users.

Network considerations for data-oriented access control parallel those for user-oriented access control. If only certain users are permitted to access certain items of data, then encryption may be needed to protect those items during transmission to authorized users. Typically, data access control is decentralized, that is, controlled by host-based database management systems. If a network database server exists on a network, then data access control becomes a network function.

24.3.4 Protection Based on an Operating System Mode. One technique used in all OSs to provide protection is based on the mode of processor execution. Most processors support at least two modes of execution: the mode normally associated with the OS and that normally associated with user programs. Certain instructions can be executed only in the more privileged mode. These would include reading or altering a control register, such as the program status word; primitive I/O instructions; and instructions that relate to memory management. In addition, certain regions of memory can be accessed only in the more privileged mode.

The less privileged mode often is referred to as the *user* mode, because user programs typically would execute in this mode. The more privileged mode is referred to as the *system mode*, *control mode*, or *kernel mode*. This last term refers to the kernel of the OS, which is that portion of the OS that encompasses the important system functions. Exhibit 24.3 lists the functions typically found in the kernel of an OS.

EXHIBIT 24.3 Typical Kernel Mode Operating System Functions

Process Management

- Process creation and termination
- Process scheduling and dispatching
- Process switching
- Process synchronization and support for interprocess communication
- Management of process control blocks

Memory Management

- Allocation of address space to processes
- Swapping
- Page and segment management

I/O Management

- Buffer management
- Allocation of I/O channels and devices to processes

Support functions

- Interrupt handling
 - Accounting
 - Monitoring
-

24 · 10 OPERATING SYSTEM SECURITY

The reason for using two modes should be clear. It is necessary to protect the OS and key OS tables, such as process control blocks, from interference by user programs. In the kernel mode, the software has complete control of the processor and all its instructions, registers, and memory. This level of control is not necessary, and for safety is not desirable, for user programs.

Two questions arise: How does the processor know in which mode it is to be executing, and how is the mode changed? Regarding the first question, typically there is a bit in the program status word that indicates the mode of execution. This bit is changed in response to certain events. For example, when a user makes a call to an OS service, the mode is set to the kernel mode. Typically, this is done by executing an instruction that changes the mode. When the user makes a system service call, or when an interrupt transfers control to a system routine, the routine executes the change-mode instruction to enter a more privileged mode and executes it again to enter a less privileged mode before returning control to the user process. If a user program attempts to execute a change-mode instruction, it will simply result in a call to the OS, which will return an error unless the mode change is to be allowed.

More sophisticated mechanisms also can be provided. A common scheme is to use a ring-protection structure. In this scheme, lower-numbered, or inner, rings enjoy greater privilege than higher-numbered, or outer, rings. Typically, ring 0 is reserved for kernel functions of the OS, with applications at a higher level. Some utilities or OS services may occupy an intermediate ring. Basic principles of the ring system are:

- A program may access only those data that reside on the same ring or a less privileged ring.
- A program may call services residing on the same or a more privileged ring.

An example of the ring protection approach is found on the VAX VMS OS, which uses four modes:

1. **Kernel.** Executes the kernel of the VMS OS, which includes memory management, interrupt handling, and I/O operations.
2. **Executive.** Executes many of the OS service calls, including file and record (disk and tape) management routines.
3. **Supervisor.** Executes other OS services, such as responses to user commands.
4. **User.** Executes user programs, plus utilities such as compilers, editors, linkers, and debuggers.

A process executing in a less privileged mode often needs to call a procedure that executes in a more privileged mode; for example, a user program requires an OS service. This call is achieved by using a change-mode (CHM) instruction, which causes an interrupt that transfers control to a routine at the new access mode. A return is made by executing the REI (return from exception or interrupt) instruction.

24.3.5 Protection Based on Virtualization. With the growing availability of memory (e.g., tens to hundreds of gigabytes of RAM), disk space (terabytes to petabytes of storage), faster processors (tens of gigahertz), and multicore systems (potentially thousands of processors working in parallel), *virtualization* of computers has progressed to practical and widespread usability. Instantiations of an operating environment can coexist using shared resources without permitting any direct communication among them. Each instantiation is encapsulated and completely protected against

intrusion or interference from processes running on other virtual machines sharing the same physical resources.

24.4 FILE SHARING. Multiuser systems almost always require that files can be shared among a number of users. Two issues arise: access rights and the management of simultaneous access.

24.4.1 Access Rights. The file system should provide a flexible tool for allowing extensive file sharing among users. The file system should provide a number of options so that the way in which a particular file is accessed can be controlled. Typically, users or groups of users are granted certain access rights to a file. A wide range of access rights has been used. The next list indicates access rights that can be assigned to a particular user for a particular file.

- **None.** The user may not even learn of the existence of the file, much less access it. To enforce this restriction, the user would not be allowed to read the user directory that includes this file.
- **Knowledge.** The user can determine that the file exists and who its owner is. The user is then able to petition the owner for additional access rights.
- **Execution.** The user can load and execute a program but cannot copy it. Proprietary programs often are made accessible with this restriction.
- **Locking.** The user can change the status of a logical *flag* that indicates temporary restrictions on access to data. Database management systems provide for locking to control concurrent access to records so that different processes can avoid overwriting each other's modifications.
- **Reading.** The user can read the file for any purpose, including copying and execution. Some systems are able to enforce a distinction between viewing and copying. In the former case, the contents of the file can be displayed to the user, but the user has no means for making a copy.
- **Appending.** The user can add data to the file, often only at the end, but cannot modify or delete any of the file's contents. This right is useful in collecting data from a number of sources.
- **Updating.** The user can modify, delete, and add to the file's data. This normally includes writing the file initially, rewriting it completely or in part, and removing all or a portion of the data. Some systems distinguish among different degrees of updating.
- **Changing protection.** The user can change the access rights granted to other users. Typically, only the owner of the file holds this right. In some systems, the owner can extend this right to others. To prevent abuse of this mechanism, the file owner typically is able to specify which rights can be changed by the holder of this extended right.
- **Deletion.** The user can delete the file from the file system.

These rights can be considered to constitute a hierarchy, with each right implying those that precede it. Thus, if a particular user is granted the updating right for a particular file, then that user also is granted these rights: knowledge, execution, reading, and appending.

24 · 12 OPERATING SYSTEM SECURITY

One user is designated as owner of a given file, usually this is the person who initially created the file. The owner has all of the access rights listed previously and may grant rights to others. Access can be provided to different classes of users:

- **Specific user.** Individual users who are designated by user ID.
- **User groups.** A set of users who are not individually defined. The system must have some way of keeping track of the membership of user groups.
- **All.** All users who have access to this system. These are public files.

24.4.2 Simultaneous Access. When access is granted to append or update a file to more than one user, the OS or file management system must enforce discipline. A brute-force approach is to allow a user to lock the entire file when it is to be updated. A finer grain of control is to lock individual records during update. Issues of mutual exclusion and deadlock must be addressed in designing the shared access capability.

Chapter 52 in this *Handbook* discusses application controls in more detail.

24.5 TRUSTED SYSTEMS. Much of what has been discussed so far has concerned protecting a given message or item from passive or active attack by a given user. A somewhat different but widely applicable requirement is to protect data or resources on the basis of levels of security. This is commonly found in the military, where information is categorized as unclassified (U), confidential (C), secret (S), top secret (TS), or beyond. This concept is equally applicable in other areas, where information can be organized into gross categories and users can be granted clearances to access certain categories of data. For example, the highest level of security might be for strategic corporate planning documents and data, accessible only by corporate officers and their staff; next might come sensitive financial and personnel data, accessible only by administration personnel, corporate officers, and so on.

When multiple categories or levels of data are defined, the requirement is referred to as *multilevel security*. The general statement of the requirement for multilevel security is that a subject at a high level may not convey information to a subject at a lower or incomparable level unless that flow accurately reflects the will of an authorized user. For implementation purposes, this requirement is in two parts and is simply stated. A multilevel secure system must enforce:

1. **No read up.** A subject can only read an object of less or equal security level. This is referred to in the literature as the *simple security property*.
2. **No write down.** A subject can only write into an object of greater or equal security level. This is referred to in the literature as the **-property* (pronounced *star property*).

These two rules, if properly enforced, provide multilevel security. For a data processing system, the approach that has been taken, and has been the object of much research and development, is based on the *reference monitor* concept. This approach is depicted in Exhibit 24.4. The reference monitor is a controlling element in the hardware and OS of a computer that regulates the access of subjects to objects on the basis of security parameters of the subject and object. The reference monitor has access to a file, known as the *security kernel database*, that lists the access privileges (security clearance) of each subject and the protection attributes (classification level) of each

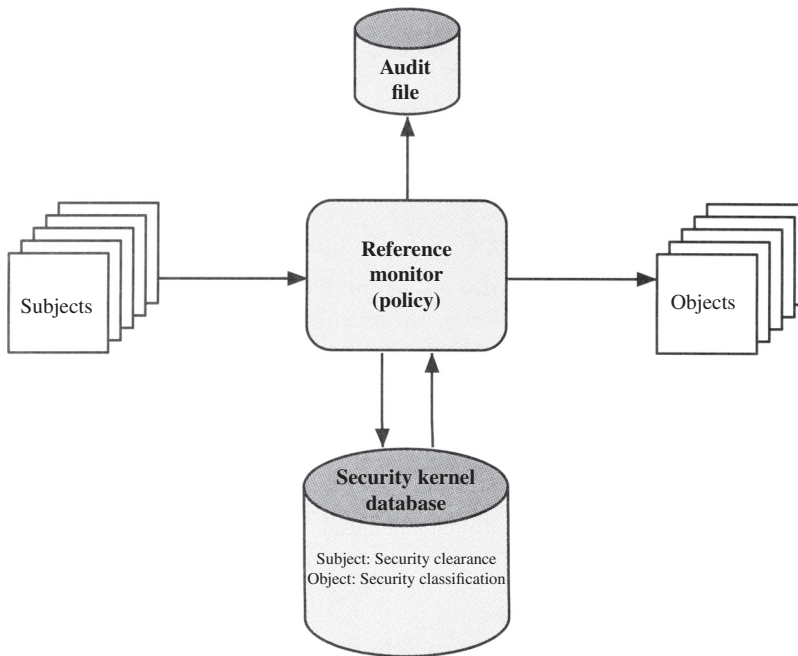

EXHIBIT 24.4 Reference Monitor Concept

object. The reference monitor enforces the security rules (no read up, no write down) and has these properties:

- **Complete mediation.** The security rules are enforced on every access, not just, for example, when a file is opened.
- **Isolation.** The reference monitor and database are protected from unauthorized modification.
- **Verifiability.** The reference monitor's correctness must be provable. That is, it must be possible to demonstrate mathematically that the reference monitor enforces the security rules and provides complete mediation and isolation.

These are stiff requirements. The requirement for complete mediation means that every access to data within main memory and on disk and tape must be mediated. Pure software implementations impose too high a performance penalty to be practical; the solution must be at least partly in hardware. The requirement for isolation means that it must not be possible for an attacker, no matter how clever, to change the logic of the reference monitor or the contents of the security kernel database. Finally, the requirement for mathematical proof is formidable for something as complex as a general-purpose computer. A system that can provide such verification is referred to as a *trusted system*.

Chapter 9 in this *Handbook* discusses mathematical models of computer security in more detail.

A final element illustrated in Exhibit 24.4 is an audit file. Important security events, such as detected security violations and authorized changes to the security kernel database, are stored in the audit file.

24 · 14 OPERATING SYSTEM SECURITY

In an effort to meet its own needs and as a service to the public, the U.S. Department of Defense in 1981 established the Computer Security Center within the National Security Agency (NSA), with the goal of encouraging the widespread availability of trusted computer systems. This goal is realized through the center's Commercial Product Evaluation Program. In essence, the center attempts to evaluate commercially available products as meeting the security requirements just outlined. The center classifies evaluated products according to the range of security features that they provide. These evaluations are needed for Department of Defense procurements but are published and freely available. Hence, they can serve as guidance to commercial customers for the purchase of commercially available, off-the-shelf equipment.

24.5.1 Trojan Horse Defense. A *Trojan horse* attack involves software that appears to have acceptable functions but which conceals additional, unauthorized functionality. Chapters 2 and 15 in this *Handbook* provide details of many Trojan horse attacks.

One way to secure against Trojan horse attacks is by the use of a secure, trusted OS. Exhibit 24.5 illustrates an example. In this case, a Trojan horse is used to get around the standard security mechanism used by most file management and OSs: the access-control list. In this example, a user named Bob interacts through a program with a data file containing the critically sensitive character string "CPE170KS". User Bob has created the file with read/write permission provided only to programs executing on his own behalf: that is, only processes that are owned by Bob may access the file.

The Trojan horse attack begins when a hostile user, named Alice, gains legitimate access to the system and installs both a Trojan horse program and a private file to be used in the attack as a "back pocket." Alice gives read/write permission to herself for this file and gives Bob write-only permission (see Exhibit 24.5a). Alice now induces Bob to invoke the Trojan horse program, perhaps by advertising it as a useful utility. When the program detects that it is being executed by Bob, it reads the sensitive character string from Bob's file and copies it into Alice's back-pocket file (see Exhibit 24.5b). Both the read and write operations satisfy the constraints imposed by access-control lists. Alice then has only to access Bob's file at a later time to learn the value of the string.

Now consider the use of a secure OS in this scenario (see Exhibit 24.5c). Security levels are assigned to subjects at logon on the basis of criteria such as the terminal from which the computer is being accessed and the user involved, as identified by password/ID. In this example, there are two security levels, sensitive (gray) and public (white), ordered so that sensitive is higher than public. Processes owned by Bob and Bob's data file are assigned the security level sensitive. Alice's file and processes are restricted to public. If Bob invokes the Trojan horse program (see Exhibit 24.5d), that program acquires Bob's security level. It is therefore able, under the simple security property, to observe the sensitive character string. When the program attempts to store the string in a public file (the back-pocket file), however, the *-property is violated and the attempt is disallowed by the reference monitor. Thus, the attempt to write into the back-pocket file is denied even though the access-control list permits it: The security policy takes precedence over the access-control list mechanism.

24.6 WINDOWS 2000 SECURITY. A good example of the access-control concepts discussed in this chapter is the Windows 2000 (W2K) access-control facility, which exploits object-oriented concepts to provide a powerful and flexible access-control capability.

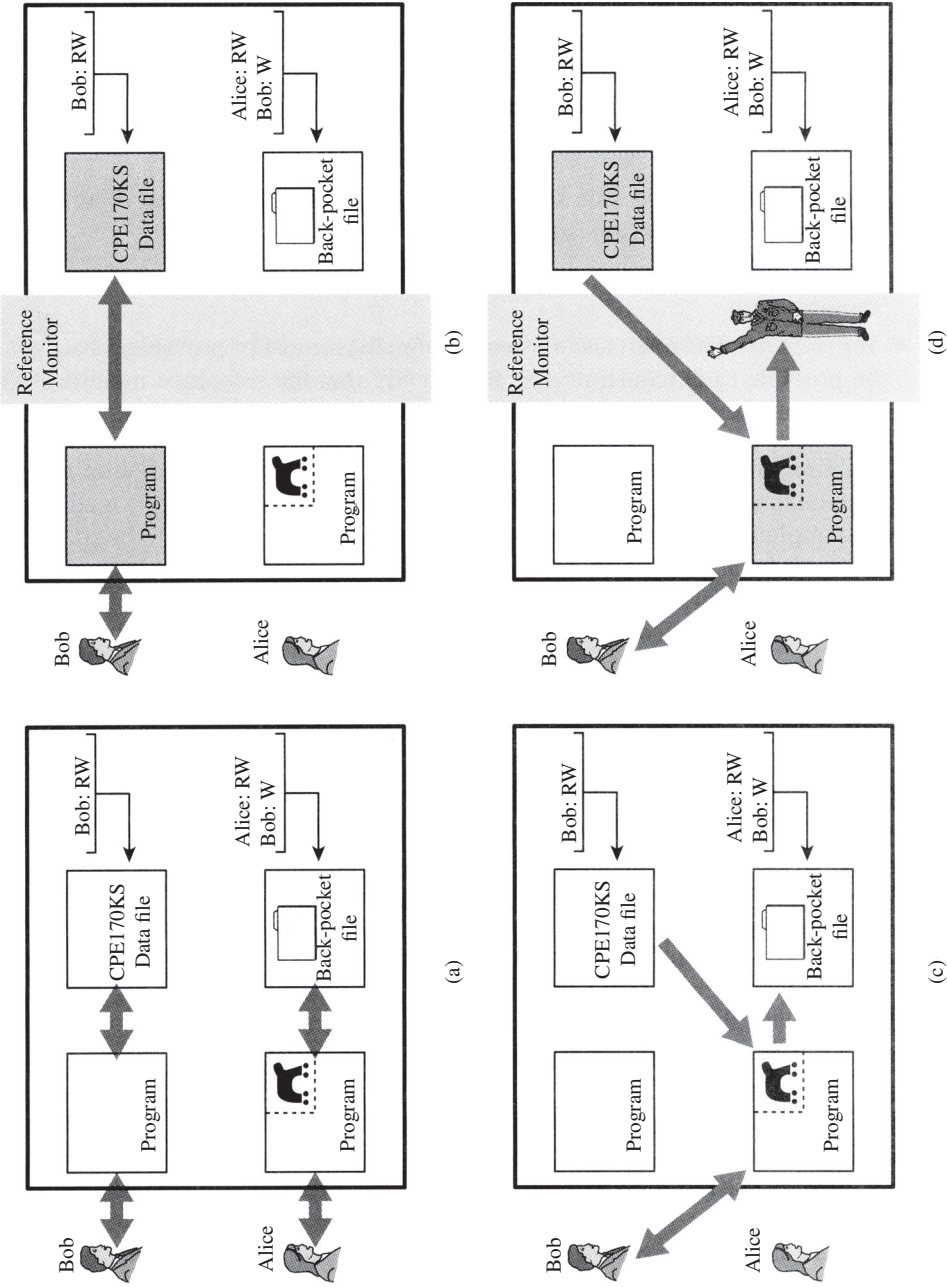

EXHIBIT 24.5 Trojan Horse and Secure Operating Systems

24 · 16 OPERATING SYSTEM SECURITY

W2K provides a uniform access-control facility that applies to processes, threads, files, semaphores, windows, and other objects. Access control is governed by two entities: an access token associated with each process and a security descriptor associated with each object for which interprocess access is possible.

24.6.1 Access-Control Scheme. When a user logs on to a W2K system, W2K uses a name/password scheme to authenticate the user. If the logon is accepted, a process is created for the user and an access token is associated with that process object. The access token, whose details are described later, include a security ID (SID), which is the identifier by which this user is known to the system for purposes of security. When the initial user process spawns any additional processes, the new process object inherits the same access token.

The access token serves two purposes:

1. It keeps all necessary security information together to speed access validation. When any process associated with a user attempts access, the security subsystem can make use of the token associated with that process to determine the user's access privileges.
2. It allows each process to modify its security characteristics in limited ways without affecting other processes running on behalf of the user.

The chief significance of the second point has to do with privileges that may be associated with a user. The access token indicates which privileges a user may have. Generally, the token is initialized with each of these privileges in a disabled state. Subsequently, if one of the user's processes needs to perform a privileged operation, the process may enable the appropriate privilege and attempt access. It would be undesirable to keep all of the security information for a user in one systemwide place, because in that case enabling a privilege for one process enables it for all of them.

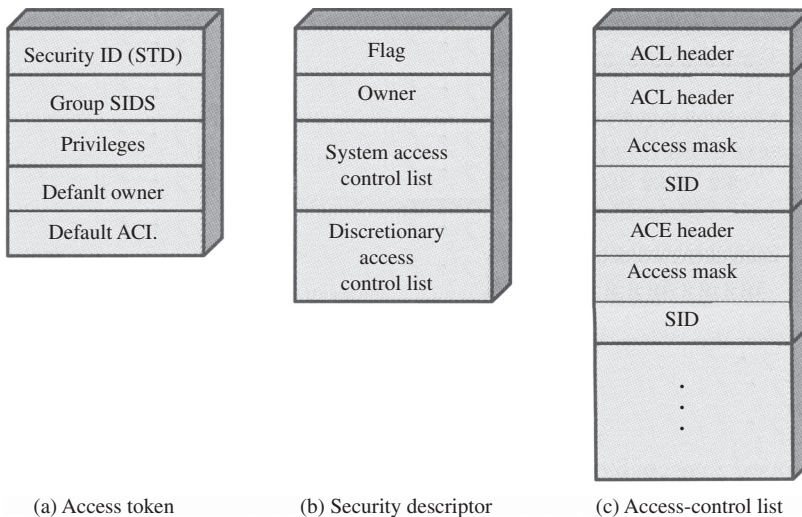

A security descriptor is associated with each object for which interprocess access is possible. The chief component of the security descriptor is an access-control list that specifies access rights for various users and user groups for this object. When a process attempts to access this object, the SID of the process is matched against the access-control list of the object to determine if access will be allowed.

When an application opens a reference to a securable object, W2K verifies that the object's security descriptor grants the application's user access. If the check succeeds, W2K caches the resulting granted access rights.

An important aspect of W2K security is the concept of impersonation, which simplifies the use of security in a client/server environment. If client and server talk through a remote procedure call (RPC) connection, the server can temporarily assume the identity of the client so that it can evaluate a request for access relative to that client's rights. After the access, the server reverts to its own identity.

24.6.2 Access Token. Exhibit 24.6a shows the general structure of an access token, which includes these parameters:

- **Security ID (SID).** Identifies a user uniquely across all of the machines on the network. This generally corresponds to a user's logon name.
- **Group SIDs.** A list of the groups to which this user belongs. A group is simply a set of user IDs that are identified as a group for purposes of access control. Each

**EXHIBIT 24.6** Windows 2000 Security Structures

group has a unique group SID. Access to an object can be defined on the basis of group SIDs, individual SIDs, or a combination.

- **Privileges.** A list of security-sensitive system services that this user may call. An example is create token. Another example is the set backup privilege; users with this privilege are allowed to use a backup tool to back up files that they normally would not be able to read. Most users will have no privileges.
- **Default owner.** If this process creates another object, this field specifies who is the owner of the new object. Generally, the owner of the new process is the same as the owner of the spawning process. However, a user may specify that the default owner of any processes spawned by this process is a group SID to which this user belongs.
- **Default access control list (ACL).** This is an initial list of protections applied to the objects that the user creates. The user may subsequently alter the ACL for any object that it owns or that one of its groups owns.

24.6.3 Security Descriptors. Exhibit 24.6b shows the general structure of a security descriptor, which includes these parameters:

- **Flags.** Defines the type and contents of a security descriptor. The flags indicate whether the system access-control list (SACL) and discretionary access control list (DACL) are present, whether they were placed on the object by a defaulting mechanism, and whether the pointers in the descriptor use absolute or relative addressing. Relative descriptors are required for objects that are transmitted over a network, such as information transmitted in an RPC.
- **Owner.** The owner of the object generally can perform any action on the security descriptor. The owner can be an individual or a group SID. The owner has the authority to change the contents of the DACL.
- **System access control list (SACL).** Specifies what kinds of operations on the object should generate audit messages. An application must have the corresponding

privilege in its access token to read or write the SACL of any object. This is to prevent unauthorized applications from reading SACLs (thereby learning what not to do to avoid generating audits) or writing them (to generate many audits to cause an illicit operation to go unnoticed).

- **Discretionary access-control list (DACL).** Determines which users and groups can access this object for which operations. It consists of a list of access-control entries (ACEs).

When an object is created, the creating process can assign as owner its own SID or any group SID in its access token. The creating process cannot assign an owner that is not in the current access token. Subsequently, any process that has been granted the right to change the owner of an object may do so, but again with the same restriction. The reason for the restriction is to prevent a user from covering his or her tracks after attempting some unauthorized action.

Let us look in more detail at the structure of access-control lists, because these are at the heart of the W2K access-control facility (see Exhibit 24.7). Each list consists of an overall header and a variable number of access-control entries. Each entry specifies an individual or group SID and an access mask that defines the rights to be granted to this SID. When a process attempts to access an object, the object manager in the W2K executive reads the SID and group SIDs from the access token and then scans down the object's DACL. If a match is found—that is, if an ACE is found with a SID that matches one of the SIDs from the access token—then the process has the access rights specified by the access mask in that ACE.

Exhibit 24.7 shows the contents of the access mask. The least significant 16 bits specify access rights that apply to a particular type of object. For example, bit 0 for a file object is File.Read_Data access, and bit 0 for an event object is Event_Query_Status access.

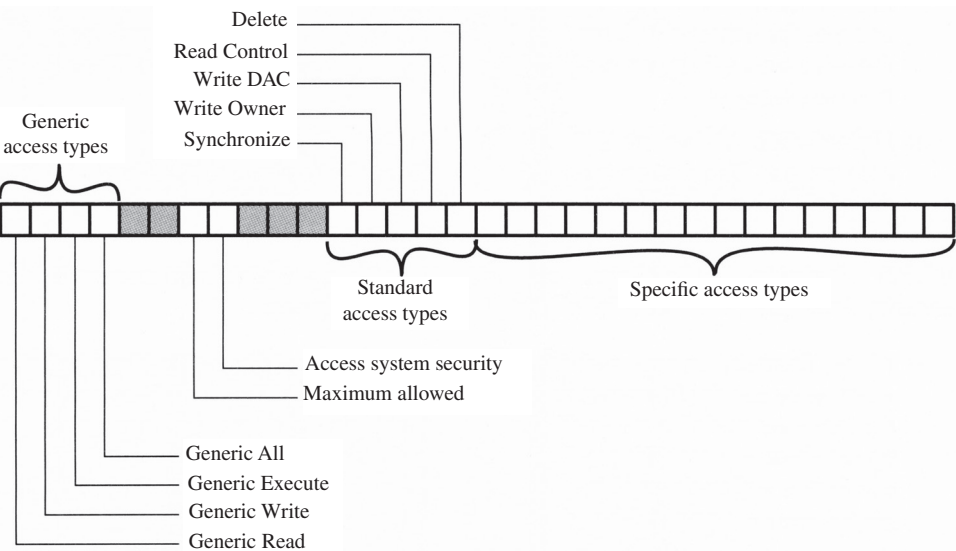

EXHIBIT 24.7 Windows 2000 Access Mask

The most significant 16 bits of the mask contains bits that apply to all types of objects. Five of these are referred to as standard access types:

1. **Synchronize.** Gives permission to synchronize execution with some event associated with this object. In particular, this object can be used in a wait function.
2. **Write_owner.** Allows a program to modify the owner of the object. This is useful because the owner of an object always can change the protection on the object. (The owner may not be denied Write DAC access.)
3. **Write_DAC.** Allows the application to modify the DACL and hence the protection on this object.
4. **Read_control.** Allows the application to query the owner and DACL fields of the security descriptor of this object.
5. **Delete.** Allows the application to delete this object.

The high-order half of the access mask also contains the four generic access types. These bits provide a convenient way to set specific access types in a number of different object types. For example, suppose an application wishes to create several types of objects and ensure that users have read access to the objects, even though read has a somewhat different meaning for each object type. To protect each object of each type without the generic access bits, the application would have to construct a different ACE for each type of object and be careful to pass the correct ACE when creating each object. It is more convenient to create a single ACE that expresses the generic concept *allow read*; simply apply this ACE to each object that is created and have the right thing happen. That is the purpose of the generic access bits, which are:

- **Generic_all.** Allow all access.
- **Generic_execute.** Allow execution if executable.
- **Generic_write.** Allow write access.
- **Generic_read.** Allow read-only access.

The generic bits also affect the standard access types. For example, for a file object, the Generic_Read bit maps to the standard bits Read_Control and Synchronize and to the object-specific bits File_Read_Data, File_Read_Attributes, and File_Read_EA. Placing an ACE on a file object that grants some SID Generic_Read grants those five access rights as if they had been specified individually in the access mask.

The remaining two bits in the access mask have special meanings. The Access_System_Security bit allows modifying audit and alarm control for this object. However, not only must this bit be set in the ACE for a SID, but the access token for the process with that SID must have the corresponding privilege enabled.

Finally, the Maximum_Allowed bit is not really an access bit but a bit that modifies W2K's algorithm for scanning the DACL for this SID. Normally, W2K will scan through the DACL until it reaches an ACE that specifically grants (bit set) or denies (bit not set) the access requested by the requesting process or until it reaches the end of the DACL, in which latter case access is denied. The Maximum_Allowed bit allows the object's owner to define a set of access rights that is the maximum that will be allowed to a given user. With this in mind, suppose that an application does not know all of the

24 · 20 OPERATING SYSTEM SECURITY

operations that it is going to be asked to perform on an object during a session. There are three options for requesting access:

1. Attempt to open the object for all possible accesses. The disadvantage of this approach is that the access may be denied even though the application may have all of the access rights actually required for this session.
2. Only open the object when a specific access is requested, and open a new handle to the object for each different type of request. This is generally the preferred method because it will not unnecessarily deny access, nor will it allow more access than necessary. However, it imposes additional overhead.
3. Attempt to open the object for as much access as the object will allow this SID. The advantage is that the user will not be artificially denied access, but the application may have more access than it needs. This latter situation may mask bugs in the application.

An important feature of W2K security is that applications can make use of the W2K security framework for user-defined objects. For example, a database server might create its own security descriptors and attach them to portions of a database. In addition to normal read/write access constraints, the server could secure database-specific operations, such as scrolling within a result set or performing a join. It would be the server's responsibility to define the meaning of special rights and perform access checks. But the checks would occur in a standard context, using systemwide user/group accounts and audit logs. The extensible security model should prove useful to implementers of foreign files systems.

25.1 INTRODUCTION. This chapter discusses generic issues surrounding local area network (LAN) security. Securing the LAN is essential to securing the Internet because LANs are where most of the attackers, victims, clients, servers, firewalls, routers, and other devices reside. Compromised LAN systems on the Internet open other nodes on that local network to attack and put other systems at risk on the Internet as a whole. Many of the general issues mentioned herein are described in more specific terms in other chapters of this *Handbook*, such as Chapters 15, 22, 23, and 47 in particular.

25.2 POLICY AND PROCEDURE ISSUES. Thirty years ago, nearly all computer users had accounts on a shared mainframe or minicomputer. A single system manager was responsible for security, backup, disaster recovery, account management, policies, and all other related issues. Today all users are system managers, and, in many cases, individuals have responsibility for several systems. Since the vulnerability of a single computer can compromise the entire LAN, it is imperative that there be rules in place so that everyone can work together for mutual efficiency and defense. But where policies and procedures can be centralized, they should be, because most users do not take the security procedures seriously enough.

25 · 2 LOCAL AREA NETWORKS

The next list, modified from the Internet Engineering Task Force (IETF) Request for Comment (RFC) 2196, is a rough outline of LAN-related security policies and procedures that should at least be considered.¹

- 1. Administrative Policies Framework**
 - a. Information security issues**
 - i. Password management procedures**
 1. Are passwords assigned or chosen by user?
 2. Are password auditing procedures in place?
 3. Are password policies enforced (e.g., minimum length, allowed and required characters, expiration, blacklisting)?
 4. How many passwords are required to access all systems?
 - ii. Virus protection**
 1. Are servers protected?
 2. Is there an e-mail “viruswall”?
 3. Is virus protection a centrally managed activity, or up to each user?
 4. How do users maintain the current virus signature database?
 - iii. Encryption and certificates**
 - iv. Security event handling**
 - b. Network connectivity issues**
 - i. Dial-up access**
 - ii. Hubs versus switches**
 - iii. Identification and authentication**
 1. Passwords and management
 2. Authentication systems
 3. Two-factor authentication?
 4. Single sign-on?
 5. Biometrics
 - c. Physical site security and disaster recovery**
 - i. Physical security of systems**
 - ii. Dial-up access lines and modems**
 - iii. Scheduling backups**
 - iv. Access to servers**
 - v. Storing and limiting access to backup media**
 - vi. Disaster recovery and contingency plans**
 - d. Operating system and LAN security**
 - i. Operating system-specific issues**
 1. Monitoring operating system security vulnerabilities
 2. Applying security patches
 3. Securing the operating system (OS) during installation
 4. Auditing the systems

- ii. Is Dynamic Host Configuration Protocol (DHCP) employed?
 - iii. Log analysis software and procedures
 - iv. Vulnerability testing
 - v. Intrusion detection tools
- 2. User Policies Framework
 - a. Written, published network security policy
 - b. Network/Internet appropriate use policy (AUP)
 - c. User training and education
 - i. Security (general issues)
 - ii. Importance of protecting customer data, client information, and other private information such as medical claim records and patient information
 - iii. Policies and AUPs
 - iv. Suggestions for how to be safe
 - d. Virus protection
 - i. Using antivirus software
 - ii. Maintaining a current virus signature database
 - e. Choosing good passwords
 - f. Best practices
 - i. Email (netiquette and handling attachments)
 - ii. Browser (ensure that Java, JavaScript, ActiveX, and other auto-execution code is current as specified by the manufacturer. See “Notes”² for helpful links.)
 - iii. Microsoft Office Suite
 - 1. Use of macros
 - 2. Implications for document management
 - iv. Protecting files on the server and your own system
 - 1. Use of Windows “shares” and UNIX Network File System (NFS)
 - 2. Use of NetWare, New Technology File System (NTFS), and UNIX access controls
 - i. Spotting a possible compromise (methods for identifying intrusions or other unauthorized activity)
 - ii. What to do and whom to contact if a compromise is suspected

Not every issue will apply to all networks, but each LAN is an ever-evolving entity, and the policies guiding its operation also must evolve.

25.3 PHYSICAL SITE SECURITY. The physical protection of the site is very important but too often overlooked. One reason that site security is often lacking is that some of the policies and procedures can be perceived as messages to employees that they are not trusted. Nevertheless, physical site security includes many aspects of protecting network servers, communications facilities, individual user’s systems, and information.

For more information on facilities security, see Chapters 22 and 23 of this *Handbook*.

25 · 4 LOCAL AREA NETWORKS

25.4 PHYSICAL LAYER ISSUES. The LAN itself has a number of additional vulnerabilities because the systems and media are so widely dispersed. This section discusses securing the LAN infrastructure.

25.4.1 Sniffers and Broadcast LANs. Traditional LAN media access control (MAC) schemes operate assuming a logical, if not physical, broadcast topology. In a broadcast network, every station hears every transmission. When operating in *promiscuous mode*, a LAN station will read every frame that goes by regardless of whether the frame is addressed to the station or not.

When protocol analysis, or *sniffer*, software became available in the 1980s, every station on the LAN became a potential network analysis and management tool—or a surreptitious eavesdropper. Since so many of the network’s applications—particularly Transmission Control Protocol/Internet Protocol (TCP/IP)-based applications—transmit passwords and files in plaintext, this type of software is potentially very dangerous.

A number of sources offer very powerful and very flexible commercial packet-sniffing software, such as Network Associates’ SnifferPro and Novell’s LANalyzer. These packages usually have additional capabilities, such as network monitoring, performance monitoring, and traffic analysis. Prior to 1990, network protocol analysis required a special piece of hardware with a connection to the network. Today, a large number of software packages that do TCP/IP packet sniffing can help an intruder because they can be installed directly on an individual’s laptop or desktop computer. Some of these packages include:

- WireShark (Windows, MacOS, and UNIX)
- BUTTsniffer (Windows NT)
- Network Monitor (free with, and for, Windows NT)
- Sniffit (Linux, SunOS, Solaris, FreeBSD, Irix)
- snort (UNIX and Windows)
- Solsniff (Solaris)
- tcpdump (MacOS and UNIX)
- WinDump (DOS)

Relatively few countermeasures can be taken against these kinds of tools. Fortunately, they are effective only on a broadcast network, such as a hubbed LAN. If an Ethernet hub, for example, is replaced with a switch, the only traffic broadcast to all hosts on the network are those frames actually addressed to the LAN’s broadcast address. In this case, a station can sniff only that traffic that is going to or coming from the station with the sniffer software. Replacing all hubs with switches may be unreasonable in many environments, but placing all servers on a switch instead of a hub will improve both performance and security.

Other network-based tools that can detect a host with a network interface card (NIC) in promiscuous mode, such as AntiSniff (Windows) and sentinel (UNIX). These tools work by performing a number of tests to detect the promiscuous host; they then check the network host’s operating systems, domain name system (DNS) activity, and network and machine latency.

Sniffers can be defeated using cryptography. Use of secure IP (IPsec) and Secure Shell (SSH) for TCP/IP applications can provide privacy and integrity to all

communication and applications. Information on IPsec is available on www.ipsec-howto.org/x202.html, and SSH is available from SSH Communications Security (www.ssh.com).

25.4.2 Attacks on the Physical Plant. The most common medium employed today on LANs is copper-based, unshielded twisted pair (UTP) cable. All copper media, including UTP and coaxial cable, emanate a magnetic field because of the changing current on the wire. Van Eck monitoring devices can pick up these emanations remotely and reproduce the frames on the wire or keystrokes at a machine. As far-fetched as this might sound, the vulnerability is very real. The U.S. Government and military have a set of standards to reduce and limit electromagnetic radiation (EMR) called TEMPEST, and the National Security Agency (NSA) has a list of products that are TEMPEST-compliant. Indeed, this vulnerability may not be a major problem in most organizational networks, but there is some set of networks where this is a concern.

An alternative to encasing workstations in Faraday cages (i.e., copper mesh layers surrounding all components) is to generate random electronic noise that masks meaningful radiated data transmissions.³

One way to reduce or eliminate EMR is to reduce or eliminate the amount of copper media on the network. Optical fiber, for example, has no EMR because there is no electricity on the line. It does not eliminate the EMR at the desktop itself, but it does prevent its entry into all interconnecting fiber cables.

Users also can be the source of some types of denial-of-service (DoS) attacks, either purposely or accidentally. Consider coaxial cable Ethernet networks (10BASE-5 or 10BASE-2) where nodes are attached to a common LAN medium. In both cases, the coaxial cable has a terminating resistor at the end of the wire to eliminate reflection of the signal. If the resistor is removed, it allows extra noise on the wire that can block all traffic on the network. End-of-cable resistors should be beyond the reach of users if at all possible.

Similar DoS attacks may occur whenever users modify the wiring scheme of the network. Removal of terminating resistors is only one action that can cause problems. Hubs in common areas might be unplugged or have network connectors removed. A token ring hub-to-hub connection can be detached, breaking the integrity of the ring and thus preventing LAN hosts from communicating with other hosts and denying service to users.

It is important that the physical network should be secured to the greatest extent possible. LAN managers should educate users to avoid the accidental problems that might occur and even how to recognize nefarious attacks.

25.4.3 Modems, Dial-Up Servers, and Telephone Lines. Modems anywhere on the LAN are a potential danger, particularly those that are connected directly to a user's system, with or without official sanction. Modems can provide a back door into the LAN, possibly bypassing the firewall, strong authentication, proxy server, and any other network security. Although less common in today's LAN architectures, dial-up modems are still used to dial into routers/bridges during network troubleshooting exercises. Care, as discussed in this section, should still be taken if dial-up modems are in use to access LAN devices.

In general, all modems should be concentrated at the network's dial-up server. Individual user systems should, in most cases, be banned from having modems on the network. This is a difficult rule to enforce, however, because laptops and an increasing number of desktop systems include preinstalled modems, and a user can always connect

25 · 6 LOCAL AREA NETWORKS

an external modem to the serial port of any system. This is an example of why security managers have to integrate policies into the culture of an organization. Otherwise, users will find a way around what they perceive to be prohibitive and onerous policies, and modems are one way to circumvent the corporate firewall.

Modems in auto-answer mode are particularly dangerous. Although most companies do not advertise their dial-in telephone numbers, these numbers do not remain secret for very long from someone who wants to find them. Anyone with a telephone directory can easily start mapping an organization's block of corporate telephone numbers. For example, if the main number is 802-555-3700, attackers have a place to start. When attackers call the main number and ask the receptionist for the organization's fax number, they obtain even more information. Using war-dialer software, attackers can scan an entire block of telephone numbers (e.g., 555-3700 through 555-3799) and obtain a list of which numbers are active, which respond with a tone, and what the tone represents (e.g., fax, modem, etc.). If a user has an auto-answer modem on a computer, attackers may gain access to the user's system without so much as a password. Security managers should work with their local telephone companies to obtain telephone numbers for modem lines that are not in the organization's telephone block.

The dial-up server, then, is the place to concentrate the modems and the authentication of dial-up users. There are several strategies for authentication at the dial-up server, the strongest being some form of two-factor authentication, such as a combination of passwords and a token. Another strong protection mechanism is to implement a dial-back mechanism, so that once a bona fide user logs in, the system hangs up and calls back to a preconfigured telephone number. This is a very effective scheme that works well with fixed-location telecommuters but not with roaming employees. In addition, attackers have been known to tamper with the central switch of a telephone company to call-forward from an assigned number to the attacker's own modem.

When a user requires two separate logons, one to the dial-up server and then one to a domain server, security restrictions should control what the caller is allowed to do after passing the first test. One of the authors of this chapter worked with a company that had a shared secret (an oxymoron) telephone number for its modem bank and then a single shared username and password for all the users to authenticate to the dial-up server. To access files and shared network resources, the user then had to authenticate to the domain controller. But after passing the identification and authentication for the first server, an attacker was on the organization's LAN and had complete, unfettered access to the Internet and an identity that implicated the company in any possible malfeasance.

Some guidelines for securing dial-up servers include:

- Maintain and monitor telephone logs.
- Configure all software and modems so that a user logout forces the modem to disconnect, and a modem disconnect forces a user logout.
- Configure the modems so that they return to their default configuration after every connection.
- Implement a dial-back mechanism, where possible.
- Use two-factor authentication for roaming users.
- Periodically scan internal telephone numbers for unauthorized modems.
- Prevent the display of any banner message when the user connects to the modem, and certainly do not display any sort of *welcome* message.

- Train the organization help desk in social engineering techniques, and prohibit them from giving out modem telephone numbers, user names, or other sensitive information that could help attackers.

25.4.4 Wireless LAN Issues. Wireless LANs (WLANs) have vulnerabilities their wired counterparts do not. The most obvious difference between wired and wireless networks is the medium itself. Although copper-based LANs emit a small amount of radiation that can be intercepted, the entire basis of wireless LANs is transmitting data using relatively strong radiation in some form.

There are WLANs based on infrared signals that cannot penetrate building walls and so achieve some degree of security due to the limited propagation of those signals. Such LANs typically are found in networks requiring high levels of security. However, most WLANs today use radio transmission techniques. In these networks, anyone on a nearby street can use a listening device to intercept data and even capture the network identifiers required to connect to the LAN. The practical range of interception is governed by the inverse-square law for the signal strength (it declines as the square of the distance from the source) and by the sensitivity and signal-to-noise characteristics of the receivers.

Fortunately, there is a certain measure of security within the physical layer itself. The Institute of Electrical and Electronics Engineers (IEEE) 802.11-based LANs employ either direct-sequence spread spectrum (DSSS) or frequency-hopping spread spectrum (FHSS) techniques. As always, depending on range and noise levels, it is possible to eavesdrop. However, interpreting the signals is made more difficult by how DSSS and FHSS work.

To make sense of the transmissions, the receiver must know either the *chipping code* used in a DSSS network or the *frequency-hopping pattern* in an FHSS implementation. Without such information, the signal will appear to be nothing more than background noise in the industrial, scientific, and medical (ISM) radio bands to the illicit receiver. It is not an insurmountable problem for the would-be eavesdropper, but the work factor is greatly increased when compared to narrowband radio techniques. The spread spectrum approach also offers more reliability in the face of interference from denial of service (i.e., intentional jamming), as the signal is spread over a broad range of frequencies. Some vendor equipment also comes with software components that allow for tuning around interference.

For example, the IEEE 802.11g amendment uses the newer orthogonal frequency division multiplexing (OFDM) from 802.11a for higher data speeds, yet is backward compatible with 802.11b using DSSS, which was already using the same ISM frequency band. DSSS data rates of 1, 2, 5.5, and 11 Mbps are supported, as are OFDM data rates of 6, 9, 12, 18, 24, 48, and 54 Mbps. IEEE requires only mandatory data rates of OFDM using 6, 12, and 24 Mbps, regardless whether it is 802.11a or 802.11g OFDM.⁴

For greater privacy than that provided by the physical layer alone, the 802.11 standard includes an optional encryption method called Wired Equivalent Privacy (WEP). This technique is truly optional so not all vendors support the standard. WEP uses a 40-bit form of the RC4 algorithm by default, although some products support stronger, 128-bit versions. It is a good idea to choose a product that offers more than just the 40-bit version, as a 40-bit keyspace does not provide great security given today's computing power.

Because WEP does not offer strong encryption and does not describe a standard key-exchange mechanism, many vendors have implemented layer three tunneling methods, such as those found in virtual private networks (VPNs), to provide greater privacy. These

25 · 8 LOCAL AREA NETWORKS

VPN-based approaches generally employ other encryption processes (e.g., Microsoft Point-to-Point Encryption) as used in the Point-to-Point Tunneling Protocol (PPTP) that use longer keys than WEP and often support Public Key Infrastructure (PKI) or other key-exchange mechanisms. Some implementations also provide authentication through standards such as Remote Access Dial-In User Service (RADIUS) for more flexible client management. The major problem is that these approaches are not all interoperable and are not necessarily multiprotocol capable.

WEP also can be used for authentication to prevent unauthorized access to the WLAN itself. Such authentication adds another layer of protection to the username and password combination employed by typical server software. Before gaining access to information resources on the server, a client first must gain access to the physical medium. Using the shared key scheme, a wireless device must possess the same encryption key as the LAN's access point, the device enabling wireless connectivity to the wired portion of the LAN. Any data transmitted must be encrypted with the key, or the frame will be ignored. Many wireless access products also have the capability to create access control lists based on MAC addresses to filter LAN connections.

IEEE 802.11i-2004 or 802.11i security standard, implemented as Wi-Fi Protected Access II (WPA2), is an amendment to the original IEEE 802.11. WPA2 was originally developed by the Wi-Fi Alliance (www.wi-fi.org). This standard specifies security mechanisms for wireless networks. It replaced the short Authentication and Privacy clause of the original IEEE 802.11 standard with a detailed Security clause. In the process it deprecated the original WEP encryption method. The amendment was later incorporated into the published IEEE 802.11-2007 standard.

In summary, network managers should consider these security items when evaluating wireless network components:

Physical Layer Schemes

- **Infrared.** Cannot penetrate walls and is good for high-security applications.
- **FHSS.** Signal hopping provides good level of security but complexity of technique limits bandwidth.
- **DSSS.** Low “spreading ratio” can increase available bandwidth but also the possibility of interception and jamming.
- **OFDM.** Used for higher data rates in newer WLANs but may be more sensitive to noise and jamming.

Encryption Options

- **WEP.** Deprecated in 2004, commonly employed 40-, 64-, or 128-bit keys with the Rivest Cipher 4 (RC4) algorithm.
- **Wi-Fi Protected Access II.** A more secure alternative to WEP, employing the Advanced Encryption Standard (AES) Counter-Mode/CBC-MAC Protocol (CCMP).⁵
- **Alternative encryption methods.** Often more secure than WEP and WPA2 but not always interoperable.

Authentication Methods

- **Wired Equivalent Privacy.** Uses pre-shared key (PSK) mode, which requires clients to have the same encryption key as the LAN access point, which introduces key management issues.
- **Wi-Fi Protected Access II.** WPA2 supports IEEE 802.1X/EAP authentication or PSK technology.

- **Access control list.** Allows only certain clients to gain physical access to the LAN, based on the MAC address; this adds complexity to client management.
- **Server-based authentication.** Flexible user authentication with RADIUS for an additional layer of protection from illicit connections.

For more information about security for wireless networks, see Chapter 33 in this *Handbook*.

25.5 NETWORK OPERATING SYSTEM ISSUES. In the early 1990s, it was common to find desktop systems running the Windows operating system *and* the Novell NetWare network operating system (NOS). Desktop applications ran over Windows, and NetWare was used only to move files to and from the shared file space, or to print documents.

Today, the distinction among the desktop operating system, server operating system, and NOS has disappeared. Operating systems such as Linux, MacOS, UNIX, and Windows all provide desktop application suites with networking capabilities, including communications protocols such as TCP/IP. There are some general security considerations for all LANs regardless of the specific operating system:

- Use whatever capabilities are provided by the operating system to employ strong passwords.
- Create password policies that force strong passwords. Change passwords periodically and do not allow reuse. Periodically audit passwords using password-cracking tools such as L0phtCrack (Windows) or crack (UNIX). Ensure that the administrator and root accounts are given passwords that are not widely distributed or guessed.
- Disable (or uninstall) any services that are not being used.
- Keep the operating system and application software up to date, and with the latest security patches installed.
- Carefully manage access control lists for files and other system/network resources.
- Strictly define users, groups, and network/domain trusts.
- Tightly secure any running applications.
- Log on as administrator or root only when necessary; otherwise log on as a regular user.
- Allow operators and administrators to log on only locally at server systems.
- Limit use of guest, demo, or anonymous accounts.
- Where feasible, put boot and system files as well as application files and data on different partitions, hard drives, or input/output (I/O) controllers.
- Regularly audit server systems.
- Monitor log files.
- Remove floppy, CD, DVD, and thumb drives from servers after the system has a stable configuration.
- Implement best industry practices when securing the operating system.
- Use vulnerability assessment tools on a regular basis to scan servers.
- Use intrusion detection tools to monitor potential attacks on the LAN that are launched from the internal network.

25 · 10 LOCAL AREA NETWORKS

- If using the Simple Network Management Protocol (SNMP) for network administration, carefully choose community names and block external access to the SNMP service. Make management information bases (MIBs) read-only, where possible.
- Avoid use of the DNS HINFO (host info) resource record to identify the central processing unit type and the installed operating system.

Specific operating system vulnerabilities are beyond the scope of this chapter; entire books and Websites are devoted to securing some of these individual operating systems. At a minimum, network managers must monitor their operating system vendor's Website and all other sites that cover the NOS's security. The sections that follow provide some general observations and comments about the various network operating systems.

25.5.1 Windows 9x. All of the Windows operating systems (including NT and 2000) support peer-to-peer resource sharing and are vulnerable to exploitation of NetBIOS file and print sharing. In particular, when file and print sharing is enabled, the service is, by default, bound to TCP/IP. Although this does not cause an additional exposure to systems on the local network (since shares can be seen by other nodes on the LAN anyway), it does provide a potential vulnerability for hosts connected to the Internet. File and print sharing can be unbound from TCP/IP using Start, Control Panel, and Network.

Windows 9x (including Windows 95, Windows 98, and Windows ME) systems also have a vulnerability in the way authentication is performed when a user wishes to access a remote share. Windows uses the challenge-handshake authentication protocol (CHAP) for all passwords that need to be sent over the network, so passwords never appear in plaintext on the LAN. However, because Windows 9x uses the *same* challenge during a given 15-minute period, an intruder with a physical access to the LAN and to a sniffer could effect a replay attack by resending a duplicate authentication request and remapping a share on the Windows 9x system. This example illustrates the critical role of physical security in preventing compromise of LANs.

One of the classic Trojan horse programs for Windows 9x is Back Orifice (BO). Advertised as a remote Win9x administrator tool, it can be used by a nefarious user to take total control of someone else's system, including the capability to modify the registry, reboot the system, transfer files, view cached passwords, spawn processes, and create shares. SubSeven and NetBus are other tools that can be used to take control of a remote Windows system. Some commercial virus scanners can detect these programs on individual systems, and several workstation firewalls exclude communications characteristic of these Trojans.

Windows 9x has no particular logon security mechanism. Although every user might be forced to log on to a system, any user can log in with any username and any password to get at least basic access. Several password-cracking programs are available through the Internet to break Windows' .PWL password files, which are accessible once a user has access to the network. If a password-protected screen saver is preventing an attacker from logging in, there is an easy way around this as well: Simply reboot the computer. However, third-party security programs include nonbreakable secure logins and secure screen savers; many include bootlock functions that prevent any access whatever unless a valid password is entered. Current examples of such software can be located easily using buyers' guides such as the annual listing from the Computer Security Institute.⁶

25.5.2 Windows NT/2000, XP, Vista, Win7, and Win8. From a security perspective, Windows 2000 Millennium Edition (ME) is not significantly stronger than Windows 9x. Network administrators should periodically scan the network's public shares to ensure that they are appropriate. Windows NT Server, NT Workstation, and 2000 Server editions are built for security, and network services and have the software architecture to support these services. However, a security vulnerability announcement related to these operating systems seems to come out almost weekly. Many of the hacking tools available for Win9x also are available for Windows NT and 2000; Back Orifice 2000 (BO2K), for example, is an NT/2000 version of BO and NetBus also can take control of an NT/2000 host.

Scripting holes in Internet Explorer (IE) and Office 2000 make all Windows systems susceptible to a variety of new virus and worm attacks. Although the early viruses, such as Melissa and I LOVE YOU, required users to open e-mail attachments, that is no longer so. Microsoft Outlook and Outlook Express will execute Hypertext Markup Language (HTML) and script code in the body of an e-mail by default. Several ActiveX components also will execute from an e-mail containing HTML and script code; examples of such controls include Scriptlet.typelib (ships with IE 4.x and 5.x) and the UA control (Office 2000). The best protection against these types of vulnerabilities is to define Outlook and Outlook Express to read e-mail in the "Restricted Sites Zone" and disable all Active Scripting and ActiveX related settings in that zone. This vulnerability affects all Windows systems with Office 2000 or Internet Explorer 4.x/5.x installed, even if IE is not used.

Securing Windows NT/2000 systems is well beyond the scope of this chapter, but some of the precautions, in addition to those listed already, follow.

- Format the drive using NTFS rather than FAT.
- Use long file names and disable the DOS 8.3 naming format.
- Disable the Everyone group.
- Rename the administrator account.
- Turn auditing on. (It is off by default.)

All NT-based systems have been given the C2 security rating by the National Computer Security Center, which includes Windows NT 3.5 and 4.0 and Windows 2000 SQL Server version 8.0. This means that when these versions of Windows are installed correctly, they meet evaluation criteria set forth in the National Computer Security Center (NCSC) *Orange Book* of security specifications. C2 certification is not applied to the operating system itself; rather, it is applied to a particular installation. Microsoft provides tools to audit a site so administrator(s) can deploy the correct hardware and software configurations to achieve this level of security in a network.

Windows 2000 introduced a new feature that administrators might want to employ. Windows NT introduced the ability to compress and decompress files on the fly. Windows 2000 introduces the capability to encrypt and decrypt files on the fly. The Encrypting File System (EFS) uses public key cryptography and the Data Encryption Standard (DES) to encrypt files on the hard drive. EFS includes an optional capability for a recovery mechanism in case of key loss. Organizations using EFS on critical systems should consider employing this mechanism to protect against loss or destruction of the private key.

Windows XP, which has sold well over 400 million copies and still enjoys the second largest installed base of any Microsoft OS next to Win7, introduced a number of

25 · 12 LOCAL AREA NETWORKS

security-oriented features. The major improvement was the inclusion of a firewall capability in both the Home Edition and Professional versions. Professional goes a couple of steps further by offering EFS file encryption, Kerberos,⁷ smart card support, and a new software restriction feature allowing administrators to mitigate the impact of viruses and Trojan horses. XP also supports raw sockets, which in itself is not unusual—UNIX and Linux do as well. This feature is intended to increase the functionality of Internet services, but in Microsoft's implementation, it is available to any user, no matter what privilege level. Thus hackers can possibly gain control of a computer running XP and use it to initiate DoS attacks by commanding the OS to generate a flood of traffic.

Although Microsoft's Windows Vista was released with much fanfare—and after a number of delays—it has not been as widely implemented as might have been due to concerns about security and stability of the platform, not to mention a perception that many of the security features create a great deal of inconvenience in the user experience (e.g., User Account Control, to be described, and the Digital Rights Management implementation). Regardless, a prime mover of Vista development was Microsoft's Trustworthy Computing initiative, and as such, a number of new security capabilities were added.

Features include User Account Control (UAC), Bitlocker Drive Encryption, Windows Defender, Data Execution Prevention, Application isolation, Windows Service Hardening, Network Access Protection, and a variety of others. UAC is the most visible from the user perspective, requiring user intervention before allowing any action that requires administrative-level privileges. These include⁸:

- Right-clicking an application's icon and clicking "Run as administrator"
- Changes to files or folders in %SystemRoot% or %ProgramFiles%
- Installing and uninstalling applications
- Installing device drivers
- Installing ActiveX controls
- Changing settings for Windows Firewall
- Changing UAC settings
- Configuring Windows Update
- Adding or removing user accounts
- Changing a user's account type
- Configuring Parental Controls
- Running Task Scheduler
- Restoring backed-up system files
- Viewing or changing another user's folders and files

As an interesting historical aside, the National Security Agency assisted Microsoft in the development of Vista. As reported in the *Washington Post* in January 2007:

For the first time, the giant software maker is acknowledging the help of the secretive agency, better known for eavesdropping on foreign officials and, more recently, U.S. citizens as part of the Bush administration's effort to combat terrorism. The agency said it has helped in the development of the security of Microsoft's new operating system—the brains of a computer—to protect it from worms, Trojan horses and other insidious computer attackers. ...

The NSA declined to comment on its security work with other software firms, but Sager said Microsoft is the only one "with this kind of relationship at this point where there's an acknowledgment publicly."

The NSA, which provided its service free, said it was Microsoft's idea to acknowledge the spy agency's role. ...

"I kind of call it a Good Housekeeping seal" of approval, said Michael Cherry, a former Windows program manager who now analyzes the product for Directions on Microsoft, a firm that tracks the software maker.

Cherry says the NSA's involvement can help counter the perception that Windows is not entirely secure and help create a perception that Microsoft has solved the security problems that have plagued it in the past. "Microsoft also wants to make the case that [the new Windows] is more secure than its earlier versions," he said.⁹

It is left as an exercise for the reader to decide whether having a spy agency working on a premier OS is a good thing or not.

One of the most important capabilities for the network security manager is to audit the Windows server systems to protect their integrity. These tools are part of the base operating system or the Windows NT Resource Kit:

- *netstat* examines open ports.
- *Event Viewer* examines application, security, and system logs.
- *net start*, *net user*, *net group*, *net local group* display running services, users, groups, and local groups.
- *dumpel* converts Event Viewer logs to simple text files.
- *NetMon* displays network traffic.
- *netsvc* displays local and remote running services and drivers.
- *addusers* displays users and groups.
- *findgrp* displays local and domain groups for a user.
- *local* and *global* show all members of specific local or global groups.
- *dommon* displays trusted domains.
- *xcacls* examines the file Access Control Lists (ACL).
- *perms* examines the ACLs associated with a user.
- *sysdiff* displays changes in the Registry and file system.
- *regdmp* creates an ASCII version of the Registry.
- *ralist* lists a domain's Remote Access Servers (RAS).
- *rasusers* lists users authorized for dial-in access.

According to Tech Review Source ([www.techreviewsource.com /Windows-7/windows-7-security-features#.UL-S3WdN_f0](http://www.techreviewsource.com/Windows-7/windows-7-security-features#.UL-S3WdN_f0)), Windows 7 was the most secure OS Microsoft had released to date. Security features include the new Action Center, improved UAC, Parental Controls, Internet Explorer 8 Security, Windows Defender, and Microsoft Security Essentials. Windows 8 added many changes to the operating system but they were primarily in the user interface and user experience; Win8 capitalized on Win7's newer security capabilities.

25.5.3 UNIX. UNIX is the oldest operating system still in widespread (and growing) use today. Readers needing guidance for Novell Netware should refer to Chapter 18 in the fourth edition of this *Handbook*. Originally developed in 1969 at AT&T Bell Laboratories, UNIX became the first operating system to integrate network communications when TCP/IP was bundled into Berkeley Software Development

25 · 14 LOCAL AREA NETWORKS

(BSD) 4.2 UNIX in 1984. UNIX had traditionally been reserved for server systems and hardcore computer users. With the development of the X-Windows interface for UNIX and the wide deployment of Linux since the mid-1990s, UNIX and its variants represent the only significant competition to Windows in the desktop and server environment.

Like TCP/IP and the Internet itself, UNIX was developed for functionality and use within a trusted user community. As such, while UNIX has many powerful tools, it does not have a cohesive security architecture, nor is it an inherently secure operating system.

UNIX has most of the basic operating system protections: passwords, access control lists, groups, user privilege levels, and so on. But UNIX also comes with a large variety of services (daemons) enabled by default, including *File Transfer Protocol (FTP)*, *Telnet*, *finger*, *echo*, *chargen*, *daytime*, *Remote Procedure Call (RPC)*, *BIND*, and more. In addition, nearly every UNIX daemon has had some sort of security vulnerability reported at one time or another, with buffer overflows being quite prevalent.

There are many things that an administrator should consider when securing a UNIX/Linux system. In addition to the general steps just listed, the security manager might also:

- Disable (or remove) any unused services, particularly *finger*, the BIND name daemon (*named*), *RPC*, *sendmail*, Trivial FTP (tftp), Post Office Protocol (POP), Internet Message Access Protocol (IMAP), *sadmind*, *mountd*, and Network File System (NFS).
- Install the latest version and security patch of all installed software.
- Take great care when configuring access control lists and other sharing.
- Prevent running *Sendmail* in daemon mode (turn off the -bd switch) on machines that are neither mail servers nor mail relays.
- Limit use of the “r” remote access protocols.
- Use shadow password files.
- Implement TCP Wrappers to control access to services.
- Consider using encrypted communication protocols, such as Secure Shell (SSH) or Secure Sockets Layer (SSL), for remote access. Prevent transmission of cleartext passwords over the Internet.

One of the most important capabilities for the network/security manager is to audit the Windows server systems to protect their integrity. These tools are part of the base operating system or the Windows NT Resource Kit:

- *netstat* examines open ports.
- *lsof* displays hidden file space and network connections.
- *tcpdump* displays network traffic.
- *who* displays users that are logged on and the *utmp* log file.
- *last* displays login history, and the *wtmp* log file.
- *lastb* display a history of bad logins (and the *btmp* log file).
- *syslogd* is a central server facility for managing and logging system messages.
- *TCPWrapper* monitors and manages incoming service requests.

25.5.4 MacOS. The Macintosh operating systems have mostly given way to other platforms. That said, they are still worth mentioning, as Apple's market share across the board has been buoyed somewhat in recent years by its strength in mobile and tablet devices. The Macintosh was the first desktop operating system that included networking and resource sharing via AppleTalk as integral elements. But like UNIX and TCP/IP before it, the MacOS is designed for convenience and usability but not for security.

Because of its peer-to-peer nature, MacOS has traditionally had a number of potential exposures. Although Windows and UNIX also could operate in a peer-to-peer mode, a novice user generally would not know how to share resources and thereby might not inadvertently open holes.

For example, a nefarious Mac network user could quickly see what servers and shares were available on the network by using the original *Chooser* accessory. In desktop use, Macs had relatively little security. Password protection was provided by default only with some laptop systems, and not even a password-protected screen saver came standard with the system. In short, there was very little standing between a determined attacker and a Mac computer. Third-party software was required to provide password protection against access to the system and files, or for data protection with disk encryption.

Mac-based viruses and worms continue to be much less prevalent than their Windows counterparts, but Macs are not totally immune. First, those viruses that depend on Microsoft Office Suite software will work because the Mac versions of Word and Excel employ macros. Second, Internet-based attacks aimed at TCP/IP—such as the Ping-of-Death, Teardrop, and SMURF—can still affect a Mac server. There are more choices for add-on security than in the past, with packages like Norton™ Antivirus for Mac® and Norton™ Internet Security for Mac® being similar to their counterparts for other operating systems.

The Mac OS has undergone a fundamental transformation since the last “classic” release of OS 9 back in 1999. With the advent of OS X, Apple introduced its first UNIX-based platform, which has been preloaded on all Macintosh computers since 2002.

Version 10.5 (Leopard) was released in 2007 and added a number of security enhancements to address traditional platform weaknesses, including:

- Secure guest account
- Application Layer firewall
- Application signing
- Sandboxes
- Full disk encryption
- Library randomization

Apple's intention was to provide for greater pre-emption of attacks as well as resiliency to them, and the company has continued its development of better security throughout OS X's lifecycle. Currently on version 10.8 (Mountain Lion), which was released in 2012, the platform includes many of the same features as previous iterations, with improved administrative controls and privacy options.

One of the biggest security challenges is conceptually not unique to Macintosh, but with the increased integration of Apple's iCloud services in OS X (not to mention iOS in the mobile space), there is a greater risk of files being moved from local to network

25 · 16 LOCAL AREA NETWORKS

storage. Users expect access to data from any device, anywhere at any time, and that convenience makes all lost or stolen laptops, tablets, and phones significant risks.

While the MacOS's fortunes have waxed and waned and waxed again, there still are fewer security incidents reported because the greater popularity of other platforms make it easier to learn about them, because there are more potential targets, and because one single attack can affect more systems. Put another way, there are fewer attacks on Macs because the hacker community is not so familiar with them, and there are fewer attractive targets worth the opportunity cost. Still, it is just as important to keep the version of MacOS up to date as with other operating systems.

25.6 CONCLUSION. A good administrator can secure almost any NOS, although no NOS is secure initially. The network administrator needs continuous vigilance and monitoring, while recognizing that the operating system is only a part of the overall security plan for the LAN and network services. Most network administrators, due to the nature of their job and training, focus exclusively on the computers attached to the LAN and to the LAN's operating system and software. Unfortunately, this approach is too narrow in its scope. Personal firewall software also might be employed to protect individual systems against attack, but almost all of these products are oriented toward IP-based attacks and miss attacks that employ the NOS's native operating system.

Routers, network firewalls, and proxy servers are essential for protecting LAN systems from attack by an external source. The network administrator also must provide tools to protect servers and workstations from other users on the LAN.

26.1 INTRODUCTION. Once considered sufficient to protect an entire organization from external threats, the firewall is still perhaps the most recognized and deployed network-security devices for Internet-connected operations. However, earlier firewall generations made security decisions with little contextual support other than the origin and destination of the packets traversing a particular allowed path.

As communications capabilities and functionality demands increased, so too did the firewall's need to inspect and enforce allowed paths using more complex protocols and require ever-increasing throughput. This evolution transformed the firewall into a true gateway security device (GSD)—able to provide allowed path enforcement using a combination of techniques which once required additional security devices to accomplish.

Properly selected and deployed GSDs are one security layer designed to handle these increasingly complex scenarios. The GSD is effective only with a full understanding of the capabilities and limitations—both operational and failure conditions—of consolidating multiple security functions into a single device. By providing allowed path enforcement more intelligently and accurately, combined with the added rigor of genuinely understanding expected network flows, GSDs provide sufficient additional defense-in-depth layers throughout the organization.

Although this chapter focuses on the GSD as a combined security device, the concepts covered are useful for understanding and evaluating the functionality of individual network-security devices. Every organization must make risk and performance decisions by weighing this approach against maintaining independent devices that focus on a particular security function.

26.1.1 Business Requirements Outpacing Security. Technological advancement continues to transform an enterprise's ability to manage the data life cycle. The pervasiveness of mobile devices and move toward cloud-computing resources that are no longer solely controlled or consumed by the organization continues to redefine the perimeter. Users are increasing demands for unfettered access to corporate data from anywhere on any device (including those not controlled by the organization).

This dynamic environment increases the need for layered security architectures with deeper awareness of content and context.

26.1.2 Demand-Driven Processing. Enterprises not possessing the requisite internal human or technological expertise to achieve the organization's goals for information technology (IT) have long looked to outsourced solutions to meet their needs. Software as a Service (SaaS) provides offerings such as productivity applications, collaboration, and email (e.g., Microsoft Office365) and customer relationship management (CRM) (e.g., salesforce.com). Infrastructure- and Platform-as-a-Service (IAAS and PAAS, respectively) provide on-demand storage and computing (e.g., Amazon Web Services—S3/EC2 or Rackspace Open Cloud). Outsourced offerings continue to mature and redefine how enterprises develop, manage, and present their information.

Virtualization technology continues to provide opportunities to use internal processing capabilities more efficiently. Although providing better performance, it can also diminish security in that existing offerings are not necessarily as mature as dedicated security infrastructure. When internal and Internet facing systems must operate on the same virtual architecture, this creates additional risk as systems now interact at the hypervisor and virtual switch (vSwitch) level where traditional network-security devices are unable to inspect and enforce traffic at this level.

See Chapter 68 in this *Handbook* for more details about security and outsourcing.

26.1.3 Ubiquitous Mobility. Today's business climate demands the ability for employees to work from anywhere, and this need for mobility and flexibility continues a significant shift in how organizations define and protect their perimeters. Employees may use a variety of systems whether at work, home, or on the road. The level of access and functionality required extends well beyond email into enterprise applications and data. As functional mobility stretches from company-owned to personal devices, organizations must have a method to ensure a compromised mobile device does not weaken the existing internal or outsourced security controls.

26.1.4 Regulatory and Industry Compliance. Federal regulatory requirements continue to have a significant impact on how organizations manage risk through data protection, retention, and privacy activities—many having significant auditing and reporting requirements.

- The Sarbanes-Oxley Act (SOX) focuses on controls and procedures designed to preserve the integrity of publically traded organizations' financial reporting.
- The Gramm-Leach-Bliley Act (GLBA)—specific to financial institutions—concentrates on the protection of customer data and privacy.
- The Health Information Portability and Accountability Act (HIPAA) requires protection of individually identifiable health information such as personally identifiable information (PII) and protected health information (PHI).

Industry-specific requirements continue to appear and evolve in an effort to address the minimum security requirements to operate with or within a specific industry. The Payment Card Industry Data Security Standard (PCI DSS) establishes baseline requirements for the protection of cardholder data during processing, transmission, and storage. PCI DSS requires organizations to determine their level of involvement

26 · 4 GATEWAY SECURITY DEVICES

with the cardholder data. Once established, this determines which requirements are necessary to demonstrate compliance with the standard.

Each critical infrastructure sector—as defined in the United States by the Department of Homeland Security—has a Sector-Specific Plan (SSP), which provides representative organizations and agencies with the risk-management tools and strategies specific to the protection of each industry. One of the more mature programs is North American Electric Reliability Corporation (NERC) Critical Infrastructure Protection (CIP). NERC CIP addresses multiple physical and digital security elements of the North American power system, including gateway protection through the establishment of an electronic security perimeter.

See Chapter 64 of this *Handbook* for more details on GLBA, SOX, and PCI DSS.

26.2 BASIC CONCEPTS AND TERMINOLOGY. Greater demands for mobility, new models for business interaction, and leveraging Internet-based processing capabilities continue to force the evolution of traditional perimeter protections.

26.2.1 General Capabilities. With the substantial processing requirements of specialized network security systems (e.g., IPS or anti-spam), organizations traditionally architected security infrastructures that leveraged dedicated solutions/devices for each function. However, current generation GSD processing capabilities provide the opportunity to combine many of these once dedicated systems into a single device.

26.2.2 Unified Threat Management. Unified threat management (UTM) combines elements such as anti-malware, anti-spam, IDS/IPS, VPN, application proxy, and content filtering—transforming the firewall into the original iteration of the GSD. These added capabilities allow the UTM to provide greater control and inspection at the application layer. However, typically there was only marginal management and performance integration between feature sets.

26.2.3 Next-Generation Firewall. The next-generation firewall (NGFW) is the latest evolution in stated capabilities that complements and surpasses those of the UTM. Instead of just bolting multiple security technologies on top of one another, the NGFW provides tighter integration of each level of security. These new capabilities include greater protocol awareness and more granular allowed path enforcement. The NGFW is able to profile protocols regardless of port chosen. This increases the ability to detect deceptive behavior such as encrypted payloads over protocols that would not normally use encryption. This generation of GSD also has the ability to adjust policy dynamically—extending protection to other parts of the security infrastructure.

26.2.4 Web Application Firewalls. GSDs provide additional capabilities to inspect and enforce allowed paths for Web-based communications. However, the complexity of the current and next-generation Web protocols may outpace the security provided by this device. The Web application firewall (WAF) provides more robust HTTP protocol inspection capabilities. The WAF provides customizable rules to protect against common payload-based attacks such as SQL injection, XSS (cross-site scripting), and command injection. This platform can also serve as a virtual patch for Web applications—legacy (no patches possible) or ones awaiting unreleased patches.

26.2.5 Firewall Architectures Changing. As security vendors work to keep pace with these changes with more functionality and higher performance, it is the

customer's responsibility to understand the advantages and disadvantages each proposed protection solution. Such analysis provides the necessary insight for the organization to deploy the most appropriate architecture to meet the necessary security and performance requirements.

26.2.6 Packet Filtering. Routing devices gave rise to first-generation firewalled capabilities. Packet filtering is a set of explicit rules describing the allowed paths network traffic may travel. The rules, in the form of an access control list (ACL), independently evaluate one or more portions of each packet's header to make the allowed path decision.

The packet filter acts on each packet as an individual entity without respect of the packet(s) that come before or after. Although this method provides the security with the least overhead of other firewall architectures, it is vulnerable to several network and transport layer attacks.

Internet Protocol (IP) *spoofing* is specially crafting a packet in an effort to deceive the router into accepting traffic that appears legitimate. The attacker will configure a packet to look like it originated from the internal network even though it is coming into the external interface. A *Land* attack sends a spoofed TCP SYN packet to a host with the source and destination IP and port being equal and can cause a denial of service on a vulnerable network stack. The *Teardrop* attack intentionally fragments a packet and manipulates the fragment offset where the preceding fragment's offset overlaps with the offset of the next fragment. When the receiving system reassembles the overlapping fragments, the network stack will crash, causing a denial of service.

Although both the Land and Teardrop attacks require a vulnerable end-device, initial packet filters did not have contextual understanding to stop such attacks. Mitigation for the Teardrop attack includes implementing packet reassembly—recombining the fragments into the original packet to ensure the recombined packet does not violate basic IP packet specifications—before forwarding to its next hop.

For details of these and other denial-of-service attacks, see Chapter 18 in this *Handbook*.

Current generations GSDs use stateful inspection (covered next) in an effort to overcome many of the limitations of packet filtering. However, many nonsecurity-related devices use packet filters to provide basic protection of their administrative interfaces and monitoring functions.

26.2.7 Stateful Inspection. Stateful inspection identifies and tracks additional parameters within each packet, adding context by representing flows along allowed paths as network connections instead of individual packets. Even though IP and User Datagram Protocol (UDP) are connectionless protocols, the firewall creates a virtual connection to emulate its connection-oriented counterparts. Although the specific parameters tracked in the state table vary across GSD vendors, the table resides in memory for more efficient processing.

Since a packet filter inspects packets individually, it does not affect firewalls in a load-balanced or fail-over architecture. However, to ensure sustained connections in high availability architectures, stateful inspection must establish and maintain a synchronized copy of the state table in each of its high availability members. Although some vendors still maintain that a direct serial connection is the most reliable connection method, highly available solutions are unlikely to be in a physical proximity necessary for serial connection and typically take advantage of existing network connections to maintain the state synchronization.

26 · 6 GATEWAY SECURITY DEVICES

26.2.8 Application Layer Gateway. As threats became more sophisticated across existing allowed paths, firewalls added application-layer gateway (ALG) protection. Each application-specific proxy (e.g., HTTP, RPC, FTP, etc.) acts as the allowed path broker for the connection, creating a separate, backend connection to the other host. Although the full connection is actually two independent sessions, this duality is transparent to the requester and the server. Being a brokered connection adds an additional layer of defense by re-writing potentially malformed requests, validating/enforcing protocol compliance, and not allowing direct communication between client and server.

The detailed payload analysis increases the amount of time the firewall spends evaluating each packet potentially reducing throughput for other network traffic and increasing the need for sufficient processing resource. The ALG may also create issues such as poor performance for protocols requiring minimal overhead in addition to unexpected compatibility issues due to vendor-specific protocol implementations. Active review and management will help to minimize the ALG's impact on operations.

26.2.9 Current Gateway Security Devices. The firewall evolved yet again as attacks continued to increase in complexity and scale. Stateful filtering and application layer gateway functionality being effective at protecting against specific known attack vectors. However, the sophistication of the newer generation attacks quickly revealed those two features were unable to provide the necessary level of protection. The additional capabilities integrated into the firewall gave rise to the GSD.

The initial iteration of GSD is known as unified threat management (UTM). UTM is the consolidation of the firewall with multiple additional security platforms (e.g., network intrusion-prevention systems, content filter, anti-spam, etc.) into a single device. UTM vendors that only had a strong presence in one or two of the protection measures had to either integrate a third-party security product or build their own offering to fill out the full protection suite. This was also an opportunity to consolidate management and monitoring capabilities to create a unified platform. However, the UTM would prove somewhat inefficient, as each packet travels serially through the different security engines, severely impacting performance as the number of protections enabled increases.

The most current generation of GSDs—known as next generation firewalls (NGFWs)—provide greater application detection, awareness, and enforcement in addition to tighter integration of all security layers. Increasing the processing and inspection capabilities alone were not enough to meet the demands of the current generation application protocols. These protocols are more complex in form and function, even though they may follow the traditional allowed path such as HTTP. The NGFW must also be able to decode and understand the application's inner workings regardless of port and enforce on all or subsets of the protocol. NGFWs process packets through selected security engines in parallel to increase performance and focus the protection needs to the specific type of traffic detected.

26.2.10 Host Environment Context. Although this chapter focuses on gateway security devices from a network perspective, comparable host-based protections warrant coverage, as they are an important defense-in-depth component and have certain capabilities that the network-based GSDs cannot provide. With mobility and ubiquitous information access being central themes surrounding today's personal and business environments, the host-level protection is an ever-present fixture. The host's

movement from relying on the network security measures to local context and environmentally aware security measures will provide more robust and flexible security wherever the host goes.

Host-based security—aside from basic firewalling—has additional complexity and considerations due to the protection requirements of the additional elements (software, services, etc.) running. The host's ability to understand its local environment allows for more granular protection and visibility. Instead of focusing purely on port-based network access, the increase environmental context defines what applications and services can: access or receive network traffic, access or change other services, or execute code in a virtual machine (VM) to verify expected behavior(s).

26.2.11 Firewall Platforms. GSDs continue to advance in form, function, and contextual understanding to provide allowed path enforcement at all layers of the network stack. Malicious actors continue to develop increasingly targeted and effective code that travels on an otherwise allowed path. These more detailed network inspection requirements dictate that every organization select the most appropriate platform to meet its security and performance needs.

26.2.12 Routing Devices. As the need to transmit data within a network and beyond increased, routing devices were adapted to provide native and then modular security services.

26.2.12.1 Access Control Lists. Routing device ACLs typically provide rudimentary allowed path enforcement with minimal performance impact. ACLs permit or deny individual network packets based on a combination of parameters from the header such as source and destination IP addresses and/or TCP/UDP port.

Routing device-based security services matured to provide enhanced capabilities based on their contextual understanding of the network. Routing devices can support several stateful inspection techniques, the most rudimentary being the ability to track connections based solely on the acknowledgement (ACK) flags of an established connection. However, this method is more susceptible to spoofed packets directed at the intended target than traditional stateful inspection based on a table of established connections. Routing platforms can also provide anti-spoofing capabilities based on network topology. When enabled, the routing device will make forwarding decisions based on its understanding of connected and learned routes and only allow source IPs to originate from the appropriate interface.

26.2.12.2 Hardware Modules. With bandwidth increasing into the tens to hundreds of Gigabits per second (and beyond), routing device manufacturers needed to offload the security functions to a dedicated vendor-specific module (or line card). The module provides logical protection for one or more allowed paths while using the backplane to achieve higher data rates and provide protection based on one or more of the firewall architectures described above. Some routing vendors also support modules—similar to a blade server—allowing other security vendors to integrate their technology deeper into the routing infrastructure.

26.2.13 Appliances. The GSD appliance emerged as a way to shed complex security decisions from routing devices onto a dedicated security platform. Appliance form factors, capabilities, and limitations vary among GSD vendors with the GSD application integrating into the chosen hardware platform.

26 · 8 GATEWAY SECURITY DEVICES

26.2.13.1 Proprietary. A proprietary hardware-based GSD appliance manufacturer is able to establish and retain tight controls over all aspects of the platform. The hardware is purpose-built to interoperate with the GSD software and provides different levels of performance and functionality. High-performance components such as application-specific instruction sets are typically proprietary. However, the vendor will balance the cost effectiveness of the platform by choosing commercial-off-the-shelf (COTS) hardware for the utility components (e.g., network interfaces and RAM). The accompanying proprietary, hardware-specific operating system (OS) allows the vendor to maintain tight controls on interoperability, configuration, and software revisions.

26.2.13.2 Hardware Independent. Hardware independent GSD appliances transfer responsibility to the customer to procure hardware that meets a specific set of requirements while allowing the GSD vendor to retain responsibility for developing the GSD application and/or OS. The GSD uses either a customized version of an OS (typically Linux or Berkeley Software Distribution [BSD]) or installs directly onto a customer-provided base OS.

A GSD application installed on a proprietary (or premodified) OS reduces native security exposures through vendor custom hardening of OS mechanisms to remove nonessential features and functionality while maintaining the tight controls described in the section above.

The GSD application may also be able to install on specific versions of the customer's native OS choice, providing the customer the most flexibility in choosing a GSD appliance. The GSD application will make some hardening changes but leaves much of the operating system management to the customer. This increases the risk of insecure and/or underperforming implementations due to the GSD vendor not fully controlling OS configurations, patches, and interoperability.

26.2.13.3 Soft Appliance. The soft appliance augments the hardware independent/proprietary OS GSD into a bootable platform that can run on consumer-grade equipment. This platform is more suited for point-in-time protection needs, such as main GSD device failure, fast-turn deployments, and testing. Before deploying a soft appliance, the customer must temper the potential “flexibility” of this solution with other considerations such as manageability (configuration, logging, etc.), scalability, and required functionality.

26.2.13.4 Embedded Appliance. In addition to high-end, scalable devices, GSD vendors also recognized the opportunity to service other markets such as providing specialized capabilities on platforms scaled to meet the needs of consumers and small-to-medium businesses (SMBs).

SMBs are less likely to have sufficient funding or dedicated security staff to purchase, manage, and monitor multiple security devices. The SMB-grade GSDs provide a more economical all-in-one device, due to its smaller form factor, simplified user interface, and lower performance requirements. In addition to providing the standard wired and/or wireless connectivity options, the device typically provides a full complement of UTM security functionality.

26.2.14 Virtualization. GSD vendors now provide solutions ranging from leveraging the virtual environment to provide independent network security capabilities to embedding granular protections at the hypervisor level. Instead of requiring

a full installation, some GSD vendors will provide a preinstalled virtual appliance that minimizes total deployment time. It is important to ensure that the virtualized GSD maintains its priority in obtaining and sustaining resources from the VM instance.

A VM-capable GSD acts as an independent network security entity. Instead of having dedicated hardware, the GSD leverages the hypervisor's hardware abstraction layer to gain access to the necessary resources. This implementation provides hardware appliance-like capabilities to control the allowed paths based on what networks route through the GSD VM instance.

A VM-embedded GSD virtual appliance integrates with the hypervisor to gain low-level access to the entire VM host/cluster. The GSD now has visibility into previously inaccessible communication paths and is able to conduct allowed path enforcement for both inter- and intra-VM communications.

26.2.15 Host-Based Agents. As mobile devices demand greater internal network access—including data to be stored local to the device—so did the requirement for those host-based protections to be able to minimize the additional risk of allowing such access. Antivirus capabilities, although arguably only marginally effective against new and emerging threats, still maintain a necessary presence to filter known attacks vectors. Firewalling capabilities at the network and application level reduce the host's network-facing threat profile. The Host Intrusion Prevention System (HIPS) provides protection against known and potentially unknown threats because of its ability to inspect up to the application layer.

When network-security devices fail to detect a threat, host-based protection has additional measures to detect local anomalous behavior due to its increased contextual awareness of how the host—the applications and the operating system—should behave, thus allowing the host an advantage in detecting emerging threats. However, organizations should not underestimate the administrative overhead necessary to manage and monitor this protection.

See Chapter 27 of this *Handbook* for more details on host-based protections.

26.3 NETWORK-SECURITY MECHANISMS. Network security, once synonymous with the firewall, continues its growth in both scope and depth. Government and organizations are requiring security to be baked into the systems and solutions they produce or purchase.

It is entirely possible for an attack to originate from a system not coinciding with a direct perimeter attack. These attack vectors include likely exposures, such as an employee mobile device infected with malicious code while traveling; the new USB flash drive an employee receives at a conference; or a vendor providing legitimate support that plugs his/her laptop into the internal network.

Those who are selecting network security systems must be able to decipher the hyperbole from reality to ensure the device(s) deployed realistically address(es) the specific risks pertinent to the organization. Gateway security devices maintain their basic allowed path control heritage but now are far more advanced in their ability to integrate protection within the payload and beyond.

26.3.1 Allowed Paths. Network-security devices provide allowed-path protections to ensure network traffic only flows in expected and intended ways. Unfortunately, this base level of enforcement is insufficient because application-layer attacks (e.g., client-side browser exploits) leverage these traditional allowed paths. Regulatory and compliance security requirements are also driving the deployment of more

26 · 10 GATEWAY SECURITY DEVICES

capable allowed-path enforcement mechanisms deeper into the internal network to protect intellectual property, customer/partner data, and industrial control systems (ICSs).

To manage allowed-path risk effectively, organizations must define and baseline their expected traffic flows both internally and externally. The baseline is vitally important when the only indication of compromise may be an unusual—though apparently benign—interaction between systems that do not typically interact with one another.

26.3.2 Tunneling. Tunneled access into the internal network for the purposes of remote access, information sharing, and commerce is essential for most organizations. These tunnels, typically in the form of a virtual private network (VPN), use encryption to protect the confidentiality of the transferred data. If the GSD does not terminate the tunnel, it typically only provides network and transport layer allowed path enforcement through to the termination endpoint. This scenario fragments the inspection of the encapsulated traffic, requiring the termination endpoint itself or another security device post-decryption to provide additional protection through allowed path enforcement and application layer inspection.

See Chapter 32 for more information on GSD VPN capabilities

26.3.3 Anti-Spoofing. One of the most readily exploited vulnerabilities of the IP protocol is *spoofing*. Due to this inherent weakness in the IPv4 protocol, a host's network stack is capable of producing packets that can appear to originate from any IP address and/or port chosen. This attack is an effort to deceive the receiving host and/or any network protection in between into believing the originating host is following an allowed path. Due to the simplicity of executing spoofing attacks, GSD vendors developed and implemented several effective methods to thwart these types of attacks. The network topology is a key element in the GSD's ability to determine what traffic should be originated from each of its physical and/or logical interfaces.

One common anti-spoofing method is explicit definition of the network topology on a per-interface basis. This provides an efficient method for the GSD to determine whether the packet's source IP address entering an interface matches what the GSD expects to be the source network. If not, the packet fails to meet the criteria and is dropped. Although simple and effective, the disadvantage is the manual management of the per-interface network definitions.

Another method is to learn the network topology by leveraging the routing table to make the same type of per-interface anti-spoofing decisions. The firewall goes through the same process of evaluating if the packet's source IP matches what should be originating from that interface. However, this does not require ongoing manual intervention when network changes occur, as the routing engine updates this information. Although this method creates less administrative overhead, two disadvantages include problems if the network uses asymmetric routing and/or falls prey to a route poisoning attack.

Both of these anti-spoofing measures are highly effective when evaluating whether network traffic is originating from the appropriate interface. However, the focus remains solely on preventing internal network address compromise. Since not all of the IP networks in existence are actually allocated and/or in use, these “bogon” networks are another method used to launch spoofing attacks. Since “bogon” network traffic is originating on the external interface, the GSD would not block this based on common anti-spoofing rules. Updated lists are readily available allowing the security administrator to enforce “bogon” protections. Some GSDs have a feature that automatically updates the list on a recurring basis, providing automated protection.

26.3.4 Network Address Translation. Network address translation (NAT) is a mechanism that maps internal (typically private RFC 1918) network addresses to one or more publicly routable IP addresses. This is an essential function in IPv4 due to the increasing shortage of publically routable address. Due to its ability to mask the internal network addressing, NAT quickly became thought of as a security mechanism. Realistically, NAT only ensures network traffic maintains their translations—but it has no inherent security capabilities such as payload inspection.

To ensure sustained connections in high availability architectures, NAT must establish and maintain a synchronized copy of the translation table with each high availability member. This mechanism follows the same serial or network connection used to maintain the state table.

26.3.5 Intrusion Detection. GSDs inherently provide detective controls at multiple layers. These distinct controls (e.g., firewall, intrusion detection/prevention system, etc.) provide greater visibility into the types and scopes of potential incidents when properly configured and monitored. The logging and alerting capabilities associated with each control are important and necessary mechanisms for security personnel to use to understand the current state of the perimeter. With this information, it is possible to develop actionable intelligence to detect and act on anomalous and/or malicious behavior before, during, and after an incident.

Responding to alerts and reviewing all of the information generated by the GSD can be extraordinarily time consuming. However, it is important that the security administrator take the necessary steps to ensure timely and accurate log reviews. Without such reviews, it is easy to overlook issues such as pre- and post-attack-related traffic and system misconfigurations. Logs also provide an excellent opportunity for GSD tuning, including rule-base optimization and reducing false positives (postverification).

Properly planned and configured alerting and logging mechanisms are essential. When done poorly, these mechanisms can overload the support staff with unnecessary or extraneous information, making them less efficient and effective at addressing actual security issues.

26.3.6 Intrusion Prevention/Response. Although logs and alerts are useful for detecting and investigating security incidents, these mechanisms are passive and cannot provide threat protection. Firewalls evolved to include automated active mechanisms to respond to security events and provide active protection.

See Chapter 27 of this *Handbook* for more details on intrusion detection and prevention.

26.3.6.1 Connection Termination. The essence of perimeter defense is to protect the internal network by blocking connection attempts that do not follow the established allowed path policy. One method for TCP-based protocols is to respond to the initiator (and sometimes the intended recipient) with a reset (RST) packet, severing the connection. The most common method—which works for connection-oriented and connectionless protocols—is to drop the packet without a response. As firewalls evolved into richer functioning GSDs, this protection grew to include blocking based on malicious activity occurring at the application layer.

Inversely, attackers can use connection termination as a method to determine where and what type of network-security devices are in use. This context may provide them additional insight on potential methods to bypass and/or adversely impact the security

platform. Though this situation is unavoidable no matter what termination mechanism is employed, it is another reason to apply defenses in layers.

26.3.6.2 Adaptive Threat Mitigation. Although the GSD's policy provides the main enforcement mechanism, vendors quickly realized that this was insufficient, as attackers continually develop additional methods to thwart these protections. GSDs include several enhanced capabilities that allow the device to adapt to specific threat conditions and provide targeted prevention.

Since attackers employ methods to change attack sources to avoid detection, and it is not always practical to follow a rigid whitelisting (least privilege) strategy, organizations typically opt to use blacklists as an additional level of protection. Some GSDs use dynamic object groups to update these lists on a predetermined schedule helping minimize administrative overhead.

The use of thresholds provides the GSD a more efficient method to address consistent attacks that would otherwise follow the same policy-based evaluation for every attempt. One common threshold type is event quantity/type over a given set of time (e.g., total number of packets per second or x number of packets per second across multiple destination IP addresses). Once breached, the GSD will typically automatically block all traffic from the origin IP address for a predetermined time period. This type of adaptive technique requires additional processing resources and requires tuning to ensure this does not impact legitimate network flows.

Being primarily perimeter devices, GSDs typically have minimal visibility into the internal, trusted network. However, modern security infrastructures can leverage multiple threat detection methods across the network to provide more comprehensive protection. Once detected, the device can leverage the security management infrastructure to update other security device policies—automatically providing additional protection or containment. This capability is also integrating with host-based protections to drive protection deeper into the network. If a host detects a threat while on an untrusted network, the infrastructure would learn about this and adapt network protections before the device connects to an internal network.

26.3.6.3 System-Level Actions. As an added layer of defense, gateway security devices typically have built-in mechanisms to detect and respond to threats against the platform itself. Following an implicit deny model, the expected behavior is to fail secure (e.g., shutdown the firewall) and not pass traffic. However, as this automatic response affects the functionality of the security device, it is important for the administrator to understand and test this functionality prior to deployment to ensure this response behavior is consistent with the protection and availability needs of the organization.

26.3.6.4 Application Inspection. The ability to protect allowed paths based on IP and/or port combinations provides marginal benefit when matched against the growing protocol complexity and configurability. As GSDs evolved, so did the ability to evaluate and enforce allowed paths based on the application layer. This capability ranges from basic protocol evaluations such as an RFC conformance check to full application layer gateways. Depending on the type of application layer protocol, a dedicated device may be necessary in high capacity, security, and/or reliability environments.

WAFs. Web application firewalls (WAFs) provide targeted enforcement within an HTTP(S) allowed path. WAFs can more readily detect and prevent common Web server attacks such as XSS and SQL injection and typically have added capabilities to protect

more complex Web 2.0 (e.g., AJAX) and Web services (e.g., SOAP or JSON) protocols. It is also possible to protect otherwise vulnerable Web servers from exploits by writing protection rules that detect and nullify the application layer attack traffic. The WAFs granular rule development is also better suited to protect custom Web applications.

Proxy Servers. The forwarding proxy enforces outgoing Internet connections by intercepting and controlling access based on criteria such as user ID, time of day, and/or whitelist/blacklist. Depending on the type and configuration, the forwarding proxy can either broker the outbound connection and make requests on behalf of the client or just enforce the particular allowed path. Classic forwarding proxies requires client-side configuration to enforced Internet-bound communications. A transparent proxy is a forwarding proxy that operates as a “bump-on-the-wire”—sitting in-line or off a span port—and typically does not require client-side configuration.

Conversely, a reverse proxy provides protection to inbound allowed paths. The inbound connection terminates at the proxy, and the proxy itself establishes the second half of the connection directly with the application server. Being a brokered connection, this adds an additional layer of defense for inbound traffic by rewriting potentially malformed requests and/or not allowing direct communication to the application server.

Application Identity. In addition to source and destination IP address, network firewalls typically rely on the destination port to make a final allowed path determination for common protocols (e.g., HTTP—TCP port 80). However, it is trivial to evade upper layer inspection (e.g., proxy or WAF) by changing the destination port to something that bypasses the application layer inspection but still follows an allowed path. Current generation security devices must be able to profile all network traffic based on application type instead of destination port.

Application identification must be able to dissect the traffic and understand the subsystems/protocols embedded within the main communication flow. For example, Skype not only inherently provides video conferencing but also file transfer and chat services. With add-ons, functionality can extend to remote desktop sharing/control. By having this detailed level of application understanding, it is possible for granular enforcement of one or more protocol subsets. This profiling also includes determining common protocols on unexpected ports and encrypted traffic over a common clear-text protocol—whether encrypted or not.

26.3.7 Encryption. Confidentiality protection for sensitive data-in-motion continues to grow due to the need to minimize the risk of compromising personal/personnel data and/or intellectual property. This creates a distinct need to provide allowed path enforcement when using encryption services to or through the GSD. Due to the computationally complexity, encryption protocols can significantly reduce GSD throughput without offloading encryption services to an add-on, on-board device, or dedicated external devices to meet the encryption needs.

See Chapter 7 of this *Handbook* for more details on encryption.

Inspection. The integration of encryption into network and application flows in essential to protect the confidentiality of the data-in-motion. Although not necessarily malicious, these encrypted sessions reduce the effectiveness of any network-security device(s) attempting to inspect the protected payloads. In addition to the typical VPN and HTTPS Web traffic, the GSD must also be able to identify encrypted communications regardless of port or service. The two main methods for inspecting encrypted traffic are direct termination and on-the-fly decryption.

In the first method, the GSD terminates the encrypted connection. This provides an opportunity to inspect the once tunneled communication. Once inspected and if

permitted, the GSD may pass the remained of the communication decrypted or re-encrypt the session to maintain the confidentiality protection to the endpoint.

In the second method, the GSD will use escrowed encryption keys to decrypt network flows passively. Besides meeting the additional performance requirements to conduct passive decryption, another possible weakness is the inability to provide fully synchronous responses to detected threat—potentially allowing some malicious traffic across an allowed path before the enforcement occurs.

VPN. A virtual private network (VPN) is an encapsulated network overlaying an existing set of physical and logical networks. A common VPN implementation is for a remote client connection—allowing an authorized user to access the internal network through an encrypted tunnel. Once established, VPN clients can access internal networks and/or systems while protecting the confidentiality of the connection. Site-to-site VPNs allow authorized remote locations to gain direct internal network access for multiple users over a single connection.

Since there is little to no control when mobile systems leave the confines of the internal network, the fidelity of the mobile device is a concern. The risk of compromise at every level—from physical to operating system to applications and beyond—can expose the internal network to increased risk during a VPN session. Without terminating VPN sessions directly on the GSD, it is still possible to increase visibility and additional allowed path enforcement once the unencrypted traffic leaves the VPN termination device—see the Deployment section for additional details and considerations.

See Chapter 32 of this *Handbook* for more details on VPNs.

Acceleration. Using Secure Sockets Layer (SSL) and Transport Layer Security (TLS) to protect Web-based traffic or IPsec to protect VPN traffic creates a potential barrier to comprehensive allowed path enforcement. Since the encrypted traffic potentially fragments allowed path enforcements, GSDs evolved to be capable of terminating these connections to add an additional layer of inspection. However, encryption/decryption is mathematically intensive and requires sufficient processing resources to ensure these processes do not impact GSD throughput. When it is necessary for the GSD to terminate or inspect encrypted traffic, the use of a hardware encryption module is a common method to off-load this processing burden and minimize impact to other traffic flowing through the GSD.

26.3.8 Identity-Based Enforcement. By integrating with enterprise directory services using mechanisms such as Lightweight Directory Access Protocol (LDAP) or Remote Access Dial-In User Service (RADIUS), GSDs are able to make identity-based decisions. Instead of allowing or denying access to an allowed path by source IP, the GSD can authorize access per user or based on group membership and include this authorization data in logs. This additional detail enhances reporting and auditing capabilities, providing more specific information about a particular connection well beyond just the IP address or DNS name of the host requesting allowed path traversal.

26.3.9 Complex Protocol Engines. Complex protocols, including those used to deliver feature rich Web applications, IP telephony, or specialized protocols, such as those used by industrial control systems (ICSs), are an intrinsic necessity for many organizations. Due to the ever-increasing need to share information and access regardless of mobile device form factor or location, these complex protocols are traversing the GSD. Even with successful detection of an application in-use, it is a continual

development race for the GSD to be able to understand and enforce the intricacies of each protocol.

Today's Web-based applications continually develop new functionality to meet customer demand. Social media Websites offer viable business models and may necessitate some or all users within an organization to access this service to conduct business. Due to ever-present personal elements (e.g., chat/comments, games, etc.), the GSDs must be able to dissect the connection and selectively permit some or all of the functionality offered by the host application.

IP telephony protocols such as session initiation protocol (SIP) and real-time protocol (RTP) are typically intolerant to latency and jitter—which are introducible by GSDs. ICS protocols introduce vendor-specific protocol dependencies/intricacies and are even less tolerant to network variations. The loss or slowness of ICS communications can be as severe as damage to equipment or death when impacting safety systems.

Although an internal or external network perimeter is a logical point of inspection, the GSD is not necessarily the appropriate device to conduct such detailed protocol inspections. Instead, these situations may warrant additional security layers using specialized devices for the application layer or specialty protocol enforcement.

26.3.10 Content Control and Data Leakage Prevention. Organizational policies establish the behavioral expectations of its employees. The Acceptable Use Policy (or similarly named) typically covers matters specific to use of technology resources; however, the policy itself cannot provide active protection. Content filtering (CF) bridges the gap between technical and nontechnical policy enforcement. This enforcement typically focuses on internal users attempting to access information resources outside of the organization. By filtering heavily used protocols such as HTTP and SMTP, the organization can minimize user access to information not fitting the organization's definition of business use.

This technology has several methods for inspecting, classifying, and filtering content. Inspection takes multiple forms, including residing in-line, out-of-band to monitor passing traffic without impacting the physical connection, or in conjunction with proxy redirection. Classification occurs through multiple methods, including vendor-defined categories, blacklists, and/or reputation scoring based on IP address and/or DNS name. This also allows the organization to choose to use a subset of the provide policy and/or selectively develop a whitelist to provide more granular enforcement. The filtering feature logs and/or severs the connections allowing the organization to customize its response to detected policy violations, including redirection to a "not for business use" Web page and/or automatic administrative and/or managerial notification of repeated violations.

See Chapter 31 of this *Handbook* for more details on content filtering.

26.3.10.1 Information Classification and Enforcement. An overlooked but important aspect of information assurance is the proper classification of information/data into categories. This allows the organization to determine the risk reduction efforts necessary to protect each information level/type. Similar to the classification process used by governments, identifying the sensitive information increases the ability to enforce not only who has access to the information but also where and how this information can be transferred.

Digital rights management (DRM) and data loss prevention (DLP) are two current generation technologies for addressing these information-specific risks. DRM

26 · 16 GATEWAY SECURITY DEVICES

focuses on the definition and enforcement of data-at-rest—typically at the information repository level. GSDs may include DLP protections such as enforcing data-in-motion protections, including denying the transfer of files based on content/designation and/or requiring encryption for sensitive data.

26.3.10.2 Anti-malware. A contemporary attack vector is to target a commonly used Website/service and inject malware. Although the content filter may make an initial decision to allow the connection based on the specific site name, it may also have the added capability to intercept and block the malicious content before it ever reaches the host. This functionality makes it possible to evaluate different types of traffic such as SMTP attachments and HTTP downloads. Although this type of application layer protection can dramatically reduce the GSD throughput, it is possible to redirect the scanning to an additional module within the GSD with dedicated processing power or to a dedicated network anti-malware appliance.

26.3.10.3 Active Content. Active code used on HTTP connections—such as Silverlight, Java, AJAX, and Flash—provides a foundation for a rich Web experience but also increases security risk due to their application-focused functionality. Malicious email attachments—such as documents with embedded code—are common components of phishing and spam campaigns.

In conjunction with host-based protections, the GSD can decrease the risk of active code by preventing specific types from ever reaching the endpoint and/or scanning the active code in a sandbox prior to allowing the active code to traverse the allowed path.

See Chapter 17 of this *Handbook* for more details on mobile code.

26.3.10.4 Caching. Although the aggregate cost of bandwidth continues to fall, organizations continue to look for opportunities to manage these frequently congested circuits more efficiently. Proxy servers typically integrate caching mechanisms to store frequently used Internet content locally, increasing local throughput by reducing Internet-bound traffic. The GSD may also be able to provide similar caching services, given sufficient storage capacity and processing resources.

26.3.11 IPv6. The allocation of the last remaining available IPv4 address blocks to Regional Internet Registries (RIR) occurred in 2011—indicating the world is “out of IPv4 addresses.” Although one may argue that statement is overly dramatic, mass migration to IPv6 is still occurring at a slower pace than one may expect, even though IPv6 was developed in the late 1990s. While organizations continue to develop their individual transition plans, it is likely that IPv6 is already in their environment. Many modern operating systems and devices have dual IPv4 and IPv6 network stacks, with some enabled by default. IPv6 and its associated transition technologies have specific security implications that the GSD must understand and enforce.

26.3.11.1 Perimeter Security Concerns.

Addressing. IPv6 is more flexible in its approach to dynamic addressing. Instead of solely relying on DHCP, an IPv6 device can address itself through stateless address autoconfiguration (SLAAC). The host uses a unique identifier (typically its own Message Authentication Code (MAC) address) in addition to the Neighbor Discovery (ND) protocol to complete the automatic addressing. Since there is no authentication

requirement, the GSD must prevent external devices from attempting to act as an internal router during the addressing process.

The significant increase of available addresses in any particular IPv6 network makes it infeasible to discover devices and network topology using traditional port scanning methodologies. By using the multicast listener discovery (MLD) protocol, an attacker can send a probe to the link-local multicast address (ff02::1) and listen for responses. The GSD must block this capability at the perimeter to prevent external devices from attempting to discover internal hosts and topologies.

Tunneling. Without ubiquitous end-to-end IPv6 connectivity, there are several IPv6 transition technologies (such as 6to4 and Teredo) that allow IPv6 capable systems to tunnel communication over legacy IPv4 networks. As with other tunneled traffic, to be effective, the GSD must not only be able to enforce the appropriate allowed path for the tunneled traffic but also inspect the encapsulated IPv6 packet.

IPv6 also has native support for IPsec (both AH and ESP). Configuration and use of IPsec in an IPv6 environment requires the same discipline in choosing and configuring cryptographic options as IPv4. It is also possible to use IPv4 IPsec to protect IPv6 transition technology tunnels as unencrypted tunnel sessions would otherwise be vulnerable to interception and/or manipulation.

Global Connectivity. Network address translation (NAT) is an essential element for IPv4 Internet connectivity due to the relatively “small” number of publically routable addresses. The size of the IPv6 address space (2^{128} addresses) provides for global IP interconnectivity without the need (or definition) of a NAT replacement. IPv6 devices will now communicate natively across the Internet—changing perimeter dynamics yet again. With IPv6 enabled, it is essential for GSD to enforce strict ingress *and* egress filtering.

Mobility. Mobile IPv6 (MIPv6) allows hosts to maintain access to the home network while physically roaming to other locations and uncontrolled networks. A user would be able to leave the office network and travel from one appointment to another without losing connectivity to the internal network. Since the device can move network to network without dropping the internal connection, MIPv6 also creates potential issues with stateful inspection if the GSD does not understand the protocol. If the organization chooses not to support MIPv6, the GSD should filter Type 2 Routing Header (RH2) packets.

26.3.12 Additional Considerations

26.3.12.1 Host Protection. Although firewalls and GSDs play a crucial role in protecting the overall network infrastructure, it is neither cost feasible nor possible to deploy these devices at all points inside the network. Individual hosts must have a way to protect themselves from threats independent of network-security devices. Unlike the network, a host has a contextual understanding of what the system can, is, and/or should be doing. Beyond the simple allow and deny functionality, contextual security measures can detect unexpected system configuration changes such as service changes or an application behaving in an unexpected manner.

When a host leaves the internal network, it becomes an extension of the network protection profile. By providing adequate local protections at the network and application levels, the mobile endpoint helps to mitigate potential issues upon reconnecting to the internal network. It is also crucial to determine the level of protection necessary and how each of these additional levels of security will affect system performance, management, and end-user impact.

26 · 18 GATEWAY SECURITY DEVICES

26.3.12.2 Network. Hosts need to be able to determine the types and appropriateness of inbound and outbound traffic. These network restrictions may vary from the internal network to uncontrolled networks. In certain circumstances, all network traffic may be suspect and scrutinized further. For example, when on the internal network, the host allows most inbound and outbound traffic. If the host were on an uncontrolled network, it would not allow any nonestablished network flows. Simple host-based network protections are not enough; additional host protection mechanisms such as intrusion prevention can detect and stop network and application-based attacks.

26.3.12.3 Applications Access. The host's contextual awareness also helps dictate the ability for applications to execute as well as send and/or receive data. The goal is to ensure only the appropriate applications and/or services have network access. The host protection policy may allow applications to establish outbound connections, but never listen (nor accept nonestablished inbound packets). For example, an HTTP server uses a daemon to listen for connection attempts. The HTTP client will attempt to make a connection to the HTTP server daemon. By using a host protection mechanism, it would be possible to prevent one or both of these actions.

26.3.12.4 Hybrid Protections. The host intrusion prevention system (HIPS) functions similarly to a network intrusion prevention system (NIPS) by detecting known attack patterns and/or anomalous behaviors. Hybrid host protections build on the host's contextual awareness and provide the ability to monitor other unusual application level activity such as changes to binaries, service manipulation, and spawned listeners.

26.4 DEPLOYMENT

26.4.1 Zoned Architecture. In a contemporary interpretation of the screened subnet architecture, zones define different types and/or sensitivities of networks, applications, and/or services. This provides the ability to manage allowed paths at the macro level (per zone) in addition to the traditional allowed paths (specific hosts or services). As requirements drive security deeper into the network, the zoning concept is equally effective when used to manage and protect internal and external networks.

26.4.1.1 Perimeter Zones. The border router maintains the architecture's first line of defense against external attacks. The ACL(s) on this router should mirror the basic allowed-path configuration of the external (untrusted) firewall interface and provides several important benefits.

The GSD is able to operate at optimal efficiency, since traffic rejected based on border router's packet-filtering rules normally would never reach the firewall. This permits the firewall to focus, in terms of load, on protocol inspection. If, for example, the firewall receives a packet that should never have made it passed the border router's ACL, the firewall can assume that the router is not behaving normally. The firewall is then free to respond appropriately, with such actions as terminating all connections from a specific host.

26.4.1.2 External Service Zones. The necessity for mobility and accessibility places significant demands on Internet-facing systems in addition to increasing the administrative overhead of managing external access. The sections below provide only a sampling of possible external service zone architectures.

Utility. Instead of lumping systems such as Web, DNS, and email onto a single network, there may be an advantage by implementing zones. Utility servers such as DNS and email could logically be on the same network. Web servers typically demand greater bandwidth, and by using this concept, can protect the entire zone with a simple inbound access rule.

Extranet. Extranet systems create additional complexity since they provide the user interface, while internal systems may provide the relevant content. Zoning provides more flexibility by allowing external connections to reach the Extranet servers while providing those same servers access to internal resources.

VPN. VPN networks are also an opportunity to use zoning. Since the VPN connection device must be Internet facing, this requires two different networks connected to the firewall. The external, Internet-facing (VPN untrusted) interface would only allow a few protocols for inbound and outbound encrypted traffic. The second network (VPN trusted) is for unencrypted network traffic moving to and from the internal network. This architecture also provides extra internal network protection in the event of a compromise of the VPN device as well as creating a traffic inspection point that is unimpeded by encryption.

26.4.1.3 Internal Service Zones. With the increasing prevalence of non-company-owned assets and more complex data flows, organizations continue to look for better methods to protect internal networks. The sections below provide only a sampling of possible internal service zone architectures.

Administrative and Monitoring Systems. Organizations typically limit direct access to network and security devices. By requiring all administrative and monitoring traffic to originate from a specific host and/or network, a zone can effectively reduce each device's threat profile. This zone would not only allow minimal noninitiated inbound traffic but would also limit outbound connections to the managed and monitored systems.

High-Value Systems. Organizations relying heavily on intellectual property and/or other protect data types (e.g., personal and financial information) have an intrinsic need to provide higher level protections to protect their investments. Zoning provides an additional layer of protection by minimizing unnecessary information flows to/from these high-value systems.

Industrial Control Systems. Incidents such as Stuxnet and Night Dragon are stark reminders that even though certain system types are considered extremely complex and less accessible, it is only a matter of time before successful compromise is possible. Manufacturing organizations with significant investments in industrial control and supervisory control and data acquisition (SCADA) systems can (or have requirements to) isolate these environments as an additional layer of protection and/or compliance.

26.4.2 GSD Positioning. The increased use of encrypted protocols such as SSL/TLS and IPsec can blind network protections. Certain GSDs have the ability to terminate encrypted sessions, though the increased processing and bandwidth requirements may exceed the limits of the device. If concerned, the security architecture should deploy appropriate countermeasures at strategic locations that avoid encrypted traffic. This way, the GSD can focus on its primary role of detecting and preventing malicious activity.

26.4.2.1 Inline. Placing the GSD inline creates a choke point for active enforcement on all network traffic that flows through it. When a malicious packet enters

26 · 20 GATEWAY SECURITY DEVICES

the GSD, protocol analysis will detect the anomaly and will not allow it to flow out the other interface. Although bandwidth limitations are a typical concern, improperly configured inline devices may also present a denial-of-service condition. With proper infrastructure planning and deployment, it is possible to minimize these risks.

26.4.2.2 Controlling Encrypted Traffic. Since mobile devices frequently venture outside of the controlled network, one logical place to evaluate traffic is on the unencrypted side of the connection. This may be on the backside of a SSL terminator (in some cases on the server itself) or on the unencrypted side of a VPN connection. The second option is to use the GSD to inspect (e.g., termination and/or passive decryption) the traffic before forwarding the traffic onto its final destination. This level of functionality requires substantial processing resources but may be a necessity if the security layers downstream are insufficient.

26.5 MANAGEMENT AND MONITORING STRATEGIES. Regardless of vendor claims, network-security devices are never a plug-and-play endeavor. It is essential to take additional steps to define the security requirements for managing and monitoring GSD components. This approach helps ensure a well-rounded security posture.

26.5.1 Monitoring. Firewalls and GSDs provide complex functionality; monitoring such systems must go beyond just verifying system availability and cover device health, availability, and integrity.

26.5.1.1 Health. Metrics such as processor utilization, available RAM, and number of connections all have an impact on overall functionality. A centralized management console may provide the ability to monitor and alert on these metrics. If this functionality is unavailable, it may be necessary to use monitoring protocols such as Simple Network Management Protocol (SNMP) and/or Remote Monitoring (RMON) to gather these statistics. The GSD must tightly restrict the systems able to poll using these methods because of the inherent insecurities of the aforementioned monitoring protocols. By trending these metrics, it may be possible to determine when it is time to increase bandwidth or purchase systems that are capable of meeting the new throughput or processing needs.

26.5.1.2 Availability. When GSDs are unavailable, the network functionality can dramatically diminish. A simple test of system availability is using ICMP to “ping” one or more interfaces to ensure the device itself is responding. However, this approach can be deceptive. Just because the device itself responds, does not mean it is properly forwarding traffic. It is also advisable to send probes (e.g., ICMP, traceroute, or other queries) to something on the other side of each interface to ensure the other device is actually receiving the packets to ensure valid results. This approach provides a better overall picture of the GSD availability.

26.5.1.3 Integrity. The ability to trust network security systems components is vital. The possibility of a root kit compromising a firewall or GSD is now a reality. These systems must have the ability to protect against modification of system components such as ceasing operation and/or alerting the change. If this embedded functionality were unavailable, it is possible to write a script to generate cryptographic hashes of critical system components and verify against a known trusted version.

26.5.2 Policy. The GSD policy is the core definition for providing and protecting allowed paths. Most security systems process packets starting at the beginning of the policy and continue until there is either a match or reaching the end of the rule base (which should be an explicit “deny any”). As discussed later in this chapter, there are situations where rules may process before or after the main rule base.

Centralized management consoles provide intuitive GUIs to configure and easily manage one or more firewall and GSD policies. Certain platforms also provide the ability to manage policies directly from the device.

26.5.2.1 Defining Allowed Paths. Allowed paths identify specific protocols used to implement communication. In a typical Internet environment, business services require allowed paths such as HTTP(S), SMTP, and DNS. These requirements will vary, but for an environment, each allowed path should directly relate to the required service.

Starting from an implicit or explicit (depending on the platform) “deny any” rule, allowed paths will be added as “allow” rules, such as PERMIT HTTP, with specifics determined by the following sections.

Although network addressing does not provide effective authentication of systems or users, restrictive endpoints can make it much more difficult for an attacker to exploit an otherwise straightforward vulnerability. It is also important to identify the endpoints carefully, particularly in cases where these endpoints might reside on internal rather than extranet or utility zones.

The direction of traffic, indicated by the source of the connection initiation, is useful for the rule definitions for several reasons. First, rules can be written so that only responses to internally originated allowed paths are allowed in from the untrusted zone, rather than explicitly permitting the protocol bidirectionally. In addition, the firewall may process rules at different times based on design and/or configuration.

26.5.2.2 Complexity of GSD Policies. Standard firewall rules operate on simple Boolean principles. For example, allow or deny network traffic that is going from host or network X to Y on port Z. The complexities required of GSDs evaluating network traffic are dramatically higher. For example, this evaluation could be a combination of a Boolean test to verify an inbound email address is from a trusted source, verify message contents are acceptable, and scan an attachment for viruses. Administrators must understand the higher-level protocols to ensure that the GSD policy matches the types of protections expected and required. As the number and complexity of the rules increases, so do the processing requirements for the GSD.

Beyond the basic firewall capabilities, GSD policies typically include per-rule enforcement of the additional security measures. For example, the GSD only uses network and/or transport layer filtering to restrict access to the organization’s VPN terminators. The policy may include WAF protections, but only for the utility zones. Inbound and outbound Web and file transfer traffic may have the additional requirement for NIPS inspection. Although this level of customization adds some administrative overhead, selectively (rather than broadly) applying additional protections in this manner can reduce the performance impact of the added protections.

26.5.2.3 Change Management. Whether managing one or one hundred policies, an essential element is to have a process to track policy changes. Change management can be cumbersome but has several advantages. First, this provides back-out information if a change were to cause issues. Second, it provides an audit trail of

26 · 22 GATEWAY SECURITY DEVICES

who requested the change (and why) in addition to who changed the policy. Lastly, it provides a method for streamlining change requests by providing a single method for accepting, reviewing, implementing, and validating policy changes.

26.5.2.4 Secondary Evaluation. Making policy changes tends to be a simple process, such as adding HTTPS access for a new extranet server. However, the more complicated the change, the more likely for mistakes to occur. Having another administrator evaluate the proposed change brings a fresh perspective that may catch a small discrepancy that could have negative consequences. Another step in the change management process is validation across multiple operational groups—providing an opportunity to detect potential conflicts with other parts of the infrastructure due to the change.

26.5.2.5 Auditing/Testing. Is your firewall or GSD working as expected? Is the GSD catching the most recent malware-infected attachment? Would you bet your organization's future on it? These questions are simple yet powerful reminders that you must verify that the network-security devices are working as expected. In addition to on-going and in-depth log reviews, a proper regiment of auditing and testing will help to answer these questions. In addition, management consoles should provide an audit log that tracks who makes changes to any part of the environment.

Vulnerability assessment and penetration testing are effective methods to determine the validity of policy rules. For example, the firewall should not allow an HTTP connection to a system with only SSL/TLS access configured. If the HTTP access succeeds, is the failure on the tested rule, is there another rule higher in the rule base erroneously allowing this access, or is something unexpected occurring? The tools and processes must be in place to answer these questions before someone else does.

26.6 MAINTENANCE. Patching workstations and updating malware definitions/signatures are common practices, but this process is even more crucial for systems protecting the network. It is essential to test each update's validity and stability to ensure faulty or rogue changes do not interrupt operations.

26.6.1 Patching. No system is inherently and infinitely secure, and it may be possible to subvert a security device due to system vulnerability. It is crucial to monitor GSD Websites for the most recent operating system and system component patches. By also monitoring vulnerability and exploitation information sources, it may be possible to ascertain more timely information. This additional research could result in being able to determine and implement a temporary solution until the vendor can provide a permanent fix.

Vendors can take weeks and months to develop and release a patch. In certain cases, third-party patches will become available for un-patched, actively exploited vulnerabilities. Although using these is an option, it is inadvisable due to the inability to verify the patch's integrity and safety.

26.6.2 Pattern Updates. Threats evolve at will. Automatic updates provide the smallest delta of exposure for pattern-based malware signatures. However, blindly trusting these updates in a production environment may have adverse effects. To avoid issues, establish a procedure that enables new signatures in monitor only mode to ensure there are no adverse effects before implementing full protection. If automatic updates

are not a viable option, then testing requires a lab environment or use of noncritical systems to vet the new patterns/signatures.

26.6.3 Logging and Alerting. Whether remaining local or transferring to a centralized management system, logs take up a large amount of disk space, and if left unviewed, are worthless to keep. There must be a log review process. Instead of trying to determine the anomalies from an entire log set, it is helpful remove known traffic to help expose the unknown and potentially malicious. For example, if you only expect outbound SMTP traffic from a single network, you would filter out those known items and more easily see if the other unauthorized hosts or networks are originating SMTP traffic.

Organizations with a large Web-based footprint will generate a large number of HTTP/HTTPS-related events because each new connection creates a log entry. By having a GSD do protocol inspection and logging, there is the potential of gaining a better understanding whether packets are expected or malicious. If there are other systems tracking and/or correlating these connections, it may be useful to turn off logging on selected GSD rules to reduce the overabundance of logs that are unnecessary to review.

A security incident and event management (SIEM) system provides an additional method for collection, aggregation, and consolidation of logs from many types of devices. The SIEM leverages baselining and configurable rules to correlate the logs and provide real-time incident-based alerting.

Alerting is complementary to and usually depends on the logging mechanism. Once the firewall or GSD generates a log entry, the administrator can configure alerting options when certain log conditions or threshold changes exist. For example, the administrator can configure an alert to send a notification if an internal system process changes state. By carefully determining alerting thresholds and notification methods, there is less opportunity to burden the administrator(s) with nuisance alerts.

26.6.4 Secure Baseline Configuration. Another crucial step to protecting network-security devices is to create a secure baseline configuration. In certain cases, the GSD vendor provides a hardened and/or proprietary version of an operating system. This should not be a “green light” that the device is secure and ready for production. Rather, this provides even more reason to take the time to evaluate the security posture of the device thoroughly.

Once a secure configuration is set, this then becomes the baseline configuration for the remainder of the systems. This provides a standard configuration helping to ensure each device functions and secures in the same manner. There should also be a process to ensure the integrity of the secure configuration as well as verifying and testing when valid updates occur.

26.6.5 Default Configurations. Default system and policy configurations vary widely; some implicitly deny, while others may implicitly allow. In no case should any network-security device deploy into production with a default configuration. Ensure that you determine whether the network-security device fails in an insecure or secure posture. Inline devices may fail insecure in an attempt to maintain traffic flow in the case of failure. Depending on the network, this may or may not be the optimal response. Although potentially disruptive, a fail insecure posture reduces the likelihood of anomalous or malicious traffic passing undetected.

26 · 24 GATEWAY SECURITY DEVICES

Implied Rules. Implied rules are separate from but are part of the default configuration. The network-security device will process the implied rules prior to packets getting to the policy rules. The implied rules may allow the GSD to process specific and known administrative traffic without using processing cycles to go through the entire rule base. It is essential to determine whether these rules exist as well as whether they match the desired security posture. If not, disable or modify the implied rules to fit specific protection needs.

26.6.6 Harden the Device. Protecting the network-security device is a critical part of the security of the overall infrastructure. The two most common ways to reduce these exposures are through the administrative console and validation using vulnerability assessment. The management or system console can provide information such as default listening ports, services running, and the like. If a service is not critical to the functioning of the firewall, disable it to remove any threat of it becoming a compromise vector. Even with the service disabled, ensure you continue to apply patches for those services. Only specific administrative hosts should have direct access to the system. As with the GSD policies, it is useful to validate that configuration changes are actually making the device more secure. By conducting a vulnerability assessment, you are able to determine whether unexpected services are still available or additional vulnerabilities exist.

26.7 DISASTER RECOVERY. The impact of a GSD outage can range from an annoyance to critical event depending on implementation, necessity, and disaster recovery planning. Since these systems represent part of the backbone of the security infrastructure, it is a necessity to provide continual, protected network access.

26.7.1 Fail-Over/High Availability. High availability (HA) architectures are essential in situations where reliable access is a necessity. The HA deployment will typically have an Active/Standby pair; where the active member is processing live packets and the standby member is ready to take over in the case of a failure of the active member. If the standby member is continually synchronizing connection information from the active member, there would be little to no loss of connectivity if the active member fails because the standby would then become active and already have the connection information to allow continued processing of the current sessions and service new sessions.

26.7.2 Load-Balancing. Distributing the load between multiple systems is another way to reduce an availability exposure. If the load equally distributes between two or more systems, the failure of one does not eliminate all access. One caveat is that the load balancer must continue to route each connection to the same system on the back-end to maintain connection information. Otherwise, it may be possible for the load balancer to route traffic to another system that does not know about the established connection (e.g., asymmetric routing).

26.7.3 Backup/Restore. Backup and restore functionality is the most rudimentary disaster recovery method. If the system crashes or suffers a compromise, there must be a way to recover the system in an efficient manner. By having a reliable backup process, it becomes easier to restore the device configuration in the event of a failure. Depending on the vendor, backups may consist of a text file or something more complex, like a GZIP file containing the crucial configuration information. The backup

process must include a method to move the backup to another system to eliminate a single point of failure. The restore process may involve restoring the operating system and/or the security device configuration. This may be as simple as uploading the backup file or may require an out-of-band connection to do prework before uploading a preserved configuration.

26.8 NETWORK-SECURITY DEVICE EVALUATION. As digital threats continue to evolve, so must network-security devices. Internet connectivity costs continue to decline and so does the ability to detect complex threats. It is a mistake to think the current security systems and infrastructure will be viable for an extended length of time. In essence, the infrastructure is continually under review. One crucial time to revisit these items is when it comes time to replace security devices.

Effective security lies at the intersection of protection/functionality, usability, and cost. Every situation has unique challenges and opportunities—the goal is to develop the best security solution to meet the organization’s ongoing risk requirements. The following sections provide a framework for evaluating network-security devices currently in-service or during a Request for Information (RFI). Please note that this section addresses the process over the lifecycle of the GSD architecture instead of providing detailed guidance on security-inspection capabilities. These guidelines provide a good basis for thoughtful analysis of site-specific requirements.

26.8.1 Current Infrastructure Limitations. It may be technically possible to do a one-for-one replacement of an existing firewall with a GSD, but it is important to review the current infrastructure to ensure maximum effectiveness of the new device(s).

- Are the current network-security devices past useful life?
 - This includes devices that are out of warranty, no longer vendor supported, and unable to meet current requirements.
- Is the Internet-facing architecture limiting GSD deployment options?
 - Having only a few publically routable IP addresses can limit the number of external service zones without extensive use of NAT.
 - Placing the GSD in an allowed path of all encrypted traffic may relegate the GSD to being more packet filter than extensible security solution.

26.8.2 New Infrastructure Requirements. The dynamics of network and security infrastructures shift constantly. Trends of rapidly escalating bandwidth usage or an increased reliance on encrypted communications are common. The prospect of adding the GSD capabilities have a dramatic influence on these decisions.

- Are there new demands for increased bandwidth, encryption, or application layer enforcement?
 - Determining new demands include observed or anticipated/projected growth.
- Is Internet-access redundancy becoming a necessity?
 - It is important to consider a GSD with built-in redundancy capabilities, such as Active/Passive failover or clustering.
 - Is your infrastructure able to support diverse carriers and/or routes to the Internet?

26 · 26 GATEWAY SECURITY DEVICES

26.8.3 Performance. Technological obsolescence continues to haunt organizations attempting to grow to meet internal and external demands.

- Does the existing device have excess capacity for future needs?
 - Security devices running at high processor and/or memory usage are good indicators that the system is at or reaching its maximum performance threshold.
 - Without extra processing capacity, a modest increase in network traffic or enabling a new feature could cripple an already resource starved device.

26.8.4 Throughput. The need for bandwidth is relentless. Bandwidth of 10 Gigabit is no longer sufficient in the core since the price and availability of 40 and 100 Gigabit is already increasingly obtainable. Standard 802.11ac is ready to eclipse the established 802.11n wireless standard and offer claimed speeds of a gigabit per second (or greater), leading organizations to question their use of wired connectivity. Organizations should take a realistic approach before paying for higher bandwidth solutions.

- Does the device meet bandwidth requirements?
 - The GSD must be able to sustain the necessary peak traffic loads without interruption or service degradation.
 - Are aggregated network interfaces supported to support modest increased bandwidth rather than paying for higher speed interfaces (e.g., multiple Gig interfaces versus 1×10 Gig)?
- Does the device have excess capacity for future needs?
 - Modular devices are able to increase memory, add network interfaces, or increase bandwidth by adding or replacing a hardware module.
 - Peaks in network traffic are inevitable. Having additional bandwidth capacity for existing GSD network segments will reduce the impact of these situations.

26.8.5 Implications of Added Features. Many vendors tout throughput at (or near) wire speeds. However, these statistics do not necessarily mirror reality as the standard throughput tests always consider the varying packet sizes and protocol mixtures. In actuality, packet types and sizes vary constantly; be sure to review vendor claims through independent testing organization and, if possible, internal testing.

- What performance impact does activating additional security features create?
 - The greater the number of additional functions—typically resulting in more detailed payload inspection—the increased negative impact on the device's processing power and bandwidth.
 - If requiring encryption, hardware acceleration, if available, will reduce much of this specific performance impact.
 - Be sure to evaluate the vendor's and independent documentation showing measured performance against varied traffic flows such as IMIX (Internet Mix) and EMIX (Enterprise Mix).

- What level of additional administrative overhead will the features create?
- Consolidating management of multiple security functions does not necessarily make them easier to manage. This also adds complexity depending how each subsystem integrates.

26.8.6 Management. GSDs typically require substantial planning, configuration, monitoring, and maintenance. Having a robust management platform in distributed GSD environments is essential to the success of the implementation.

- Does the current environment have the management features needed or required?
 - Self-evaluation of the current management environment is fairly easy, as there are already established likes, dislikes, nice-to-haves, must-haves, and must-nots.
- Is there the need/want for distributed or centralized management?
 - The size and type of GSD deployment is important to consider. It probably does not make sense to use an extensive management platform for a few devices. With larger geographically distributed environments, having centralized control of all devices is necessary for efficient and effective command and control.
- Are redundant management systems needed?
 - Redundant management systems ensure administrative control and logging of GSD devices in the case of a failure. Be sure to review management systems redundancy options to ensure the secondary system has functional parity.
- Is the ability to manage the system from both a centralized management console and/or directly from the device a necessity?
 - Certain types of GSDs allow system and policy changes to be made directly from the device. This feature can be useful during testing or troubleshooting but may cause confusion or misconfiguration if not properly understood and managed.
- Is encryption a requirement to protect management, policy, and logging functions?
 - The need to encrypt sensitive information is an important consideration for transmission of GSD management and logging functions. If sent clear-text, it is possible for someone to monitor these communications and gain significant intelligence about the network security architecture.
- Is detailed reporting mechanism a necessity?
 - Most logging systems provide the ability to filter data, but it may be useful to do more in-depth reporting. Some example reports include rule base hit percentages (e.g., which rules receive the highest percentage of hits) or traffic usage statistics (e.g., percent usage by protocol, network segment, host, and/or user).
- What level of granularity is necessary for management permissions?
 - With only a few administrators, this may not be as significant, but larger deployments may have distributed administrators. The GSD management system must provide role-based security with the ability to restrict access to certain tasks, areas, and/or logs. It may be useful to compartmentalize the systems and allow other support teams view-only access for troubleshooting and auditing purposes.

26 · 28 GATEWAY SECURITY DEVICES

- Are both GUI and/or command-line policy or device management options required?
- Certain GSD brands have the option of configuring devices using a more traditional command line interface and can be useful for quick troubleshooting and scripted changes. A drag-and-drop graphical environment uses the central management systems to easily create, change, and view policies and logs. If both options are available, ensure both options have feature parity.

26.8.7 Logging and Alerting. Although the GSD's primary responsibility is denying malicious traffic, logging and alerting play a critical role in the overall security posture. Logging is essential to investigating incidents, viewing trends, and may even be a regulatory requirement.

- How do you want to be able to filter logs?
 - Collecting, searching, and reviewing logs in a text-based format has advantages, including consolidation and scripting for log reviews. Text-based log require scripts to parse through logs but do have the advantage of being able to use complex queries and the ability to analyze logs on virtually any system.
 - Graphical user interfaces (GUIs) provide the ability to filter logs based on one or more criteria but are weak when attempting complex or recursive queries. A GUI increases the aesthetic appeal of the logs and can ease viewing by grouping or filtering different types of events, as well as adding color and/or graphics that help catch the eyes' attention more quickly. Although useful, the GUI may be slower to load and may restrict the ability to create complex queries.
- Do you want compressible logs?
 - Even with well-maintained logging standards and grooming processes, the sheer volume of GSD logs alone can be overwhelming. Text-based logs typically provide high compression ratios and easy archival. Some of the proprietary formats may automatically provide some compression but may not be able to match that of nonproprietary formats.
- How do you want to store logs?
 - GSD logging options include storage on the local device, on an integrated logging and management platform, or on a separate storage device. Local storage creates the risk of data loss if the GSD fails or potential for system impact if the logs fill the local storage. Sending the logs to other systems will increase network traffic, but this provides easier log management over the information's lifecycle.
- What types and granularity of alerts do you need?
 - Alerting helps to bring information to life without the need to watch logs every minute of the day. It may be possible to create email or SMS alerts an event occurs breaches a configured threshold (e.g., the GSD network throughput is more than 85 percent of the maximum possible or a host is attempting to attack the GSD).
 - It may be possible to develop detailed alerting conditions (e.g., criteria dependencies) to minimize erroneous alerts.

- Do you have a legal and/or regulator requirement to keep logs for a set period of time?
 - Internal and/or regulatory requirements may make it necessary to keep this data ranging from months to many years.

26.8.8 Auditability. Audit records provide an accounting of what changes occurred, when, by whom, and so forth. Having an integrated audit trail of GSD environment changes can be invaluable during an incident.

- Do you want to be able to audit device changes?
 - Changes to the device itself do not occur nearly as often as changes to policies. Having the ability to collect information about these changes can help uncover system instability, accidental misconfiguration, and/or malicious intent.
- Do you want to be able to audit policy changes?
 - GSD policies tend to change rapidly as new access requirements develop, new capabilities or requirements appear, and the ever-changing threat landscape progresses. Policy audit trails help to resolve mistakes and provide archival information of what changes occurred and when.
- What level of audit granularly is necessary?
 - Data such as date, time, type of change, to what system(s), and from what administrator are all valuable pieces of information. Increasing auditing granularity can increase the overall log volume and processing overhead.
- Should the audit logs be independent from the firewall event logs?
 - Having a logging system that automatically separates audit logs from other event logs helps ease viewing and searching. This also creates the ability to create more granular permission levels (e.g., who can see which type of logs).

26.8.9 Disaster Recovery. With GSDs providing consolidated security functions, incorporating disaster recovery (DR) options into the GSD environment helps ensure it does not become a single point of failure for the entire organization.

- What are your specific disaster recover requirements?
 - As mentioned earlier, different types of redundancy help during DR scenarios. High availability setups such as active/passive failover and clustering can help to increase overall availability.
- Does the device have easy-to-use backup and restore mechanisms?
 - The backup mechanism should provide a simple interface to complete backup and restores as well as transfer them off the local device for storage and archival.
- Do you want the ability to do automated restores?
 - Certain GSDs have the ability to do an automated or semi-automated restore using scripts or through pushable configurations from the management system.
- Should the system fail secure or insecure?
 - It is important to determine if the uptime advantage of a fail insecure system outweighs the risk of network traffic passing uninspected or the downtime associated with a fail secure system.

26 · 30 GATEWAY SECURITY DEVICES

- Do you need out-of-band access?
 - Having an out-of-band access solution such as a direct serial connection and/or dial-in solution may provide the ability to monitor and/or change the system during the network outage.

26.8.10 Usability. Having a management environment that has every feature imaginable is worthless if it is too complex and convoluted to operate and maintain.

- Is the management console intuitive?
 - The management console should have a consistent and simple interface to manage the devices and policies. The more intuitive the interface, the less time the administrators will need to spend figuring out how to complete otherwise easy tasks or troubleshooting issues.
- Are the primary functions easy to accomplish?
 - The interface should make it easy to follow and edit policies as well as view and filter logs.

26.8.11 Learning Curve. By choosing a GSD vendor with an intuitive interface and functionality, it should be much easier to learn the environment.

- Is training required to learn the new device(s) and management platform?
 - Even with the best interface and features, it may be necessary for the administrator(s) to get training to use the system effectively. Check with the vendor to see what training (basic through advanced) is available and at what cost. If possible, determine the effectiveness of the instructor(s) through referrals.
- If some of the security features are new to the organization, expect a steeper initial and increased ongoing learning curve due to the breadth and depth for each additional protection measure.
- How does the vendor approach security architecture?
 - Every GSD vendor has a little different view and implementation of security features. Some focus primarily on allowing or denying traffic, although others treat network traffic as flows between zones. Moving from one vendor type to another can be confusing and could slow or confuse the conversion.

26.8.12 Features. Although the GSD platform may be able to provide a single source for network-security protections, it is important to remember that it may not be cost or resource effective to meet the organization's security needs and posture.

- Are you looking for a device to be an all-in-one solution?
 - The ability to provide a single solution security platform has merits, but each additional feature has an impact on performance and availability, and when implemented improperly, increases the potential to cause issues.
- What features do you want the GSD to have?
 - Common UTM features may include firewall, IPS, VPN, anti-malware, anti-spam, DLP, and Quality of Service (QoS).
 - Common NGFW features include port-independent application identification and enforcement for sub-features of a particular protocol.
 - Does the platform support full IPv6 enforcement across all security functions?

26.8.13 Price. Be sure to understand the cost implications of the entire GSD infrastructure over its lifetime.

- What will be the *total* cost of ownership (TCO) of the upgrade or replacement?
 - Areas for considerations include: hardware purchase price; price for requested security features (additional features, if added later, will increase the overall costs and may require new hardware); management infrastructure (hardware and software); hardware and software maintenance fees; training costs; direct or third-party support contract; potential conversion downtime; and learning curve.

Initial Cost

- How much will the new GSD equipment cost?
 - This includes the price of the GSD, expansion cards, and management devices.
 - An appliance may be a more cost-effective alternative long term if there are multiple deployment options as the vendor is solely responsible for issues.
- How much extra will shipping cost?
 - If this is a distributed deployment, there may be extra shipping costs and tariffs associated with getting the equipment to international locations.
- How much will it cost to purchase the features I need?
 - This is highly dependent on the GSD. Certain GSDs come with everything out of the box, while others provide some basic functionality including the firewall, VPN, and basic protocol inspection but charge extra to use the full functionality of the existing items and/or to add new functionality.
- How much is it necessary to invest in training to learn the new solution?
 - Training often includes attending offsite courses (which may require additional travel expenses). In some cases, it may be more cost effective to bring a trainer in-house to provide a more tailored training program. A train-the-trainer methodology can be a money-saving option, depending on team size and funding.

Ongoing Costs

- How much is the yearly hardware and/or software maintenance?
 - The maintenance contract may be negotiable based on length of term and costs (potentially based on a percentage of the purchase).
- What level of service do you require?
 - GSD vendors provide different service levels to correspond with response times, escalation ability, and access to additional information. In accordance, the higher level of service, the more this will cost.
- Can the provider support you at each of your locations?
 - If necessary, major issues may require a vendor or vendor partner to come onsite to complete a repair. If available, determine the cost (time and travel) before using this type of service.
 - If you have international deployments, be sure to understand the vendor's ability to provide general warranty repair and/or onsite service for those locations.

26 · 32 GATEWAY SECURITY DEVICES

- Is there a requirement for an onsite spare?
 - If the DR plan requires quick recovery, having an onsite spare may help. The disadvantage to having a spare (not a redundant pair) is that it most likely will become an idle asset. Be sure to weigh this versus the cost of a higher-level service contract or local availability of replacement parts.
- Do you need additional consulting/support time?
 - Vendors and vendor partners may provide blocks of time where a dedicated resource can come onsite for additional support, planning, and platform reviews.

26.8.14 Vendor Considerations. Being able to trust that a vendor's product will protect the organization is crucial. Be sure to feel comfortable with every aspect of the product and service before turning over the network security reins. In addition to getting the features required, the vendor providing the solution should have a solid security foundation, financial stability, and adequate support resources.

- Will this vendor meet the organization's current and future needs?
 - This key question focuses on the vendor's ability to provide a quality product, support that product, and grow with your needs. Be sure to evaluate the vendor's product roadmap to see how the product (hardware, functionality, cost, etc.) will evolve and when currently unavailable features will be available in the product.
- Does the vendor already support or have experience with deployments similar to yours?
 - If the vendor already has customers with an infrastructure and needs similar to yours, this may provide additional ideas and/or information to make the deployment more successful.

26.8.14.1 Reputation. Although infighting and opinions about the best security platforms abound, the selected vendor should be an active member of the security community.

- Does this vendor have a good reputation in the security community?
 - There are no shortage of product reviews and comparisons to help determine whether a product or vendor has a solid reputation for quality and service. These are not the ultimate arbiter of a good product but are a foundation for additional research.
- Will they provide references?
 - Check with the vendor to see if another company (or two) will provide a reference as to their experience with the product and service.
- What is the vulnerability history of the current and previous systems?
 - Check vulnerability and exploit monitoring sites to determine vulnerability history.
- What is the mean time to correct vulnerabilities?
 - Although the optimal time to resolve the vulnerability is immediately (or prevent it before it happens), check to see how long it takes vendors to respond to and resolve vulnerabilities. This includes verifying the fix corrected the problem the first time.

- What is the mean time to correct application identity issues and/or gaps?
- The complexity and changing nature of application layer protocols requires active vendor participation. Determine the process, timelines, and potential costs associated with the vendor correcting (or supporting) application identity needs.

26.8.14.2 Support Options. Due to the complexity and breadth of functionality these devices possess, the selected vendors must have a robust support infrastructure to resolve issues.

- How experienced are the front-line and higher-tier technicians?
 - Ask the vendor to provide information regarding training and experience of the different support technician levels.
- Are there different tiers of initial call support?
 - Determine whether all support calls originate through the main support/service desk or if it is possible to have a dedicated (typically shared among other organizations supported) resource.
- Do you have the ability to escalate-on-demand?
 - Determine whether it is possible to escalate an issue immediately (and at what cost) if the local administrators complete standard troubleshooting steps.
- Are you willing to work with systems during beta testing?
 - Depending on risk tolerance, being a beta partner with the vendor may provide early access to fixes and enhancements.
- What are current and previous clients' experiences with support quality and availability?
 - Again, ask for references to get real-world perspective.

26.8.15 Managed Security Service Providers. Organizations have the ability to transfer varying levels of internal network security responsibilities to a Managed Security Service Provider (MSSP). Use of the MSSP may be an opportunity to supplement off-shift log reviews, consolidation, and/or alerting. In addition, there may be an opportunity to transfer maintenance and change control to alleviate internal resource constraints and/or knowledge gaps. Choosing this type of service requires detailed investigation.

- What is the MSSP's reputation/experience/workload?
 - The MSSP should have trained and experienced personnel to support your GSD infrastructure.
 - Determine the number of clients per support resource and if other MSSP locations can continue support and operations if a failure occurs at one MSSP location.
- Is it possible to do this securely?
 - Ensure the MSSP complies with secure storage of collected information and access to the GSD management infrastructure.

26 · 34 GATEWAY SECURITY DEVICES

- If necessary, how will the MSSP follow change control?
 - Determine the change control process before turning over operational responsibility. This includes determining change reviews, change windows, change approvals, service-level agreements (SLAs) regarding time to complete, etc.
- Can the MSSP meet your SLA requirements?
 - Set clear expectations during contract negotiations when establishing SLAs. The more stringent the SLA, the more likely the cost is to increase. Develop metrics to assess the MSSP's effectiveness in achieving the SLA requirements.
- At what cost?
 - The cost of doing business with the MSSP increases based on the number of services and/or devices. Be sure to investigate the contract to understand all potential fees or additional requirements that may drive up the cost after the signing of the initial contract.

26.9 CONCLUDING REMARKS. The requirements for network security are changing constantly. The organizations are under continued pressure to meet customer and business partner demands for information and access. Technologies such as mobile devices and extranets continue to blur the previous accepted reality of true network borders. Perimeter security is no longer as easy as installing a firewall or requiring proxy services for outbound connections. Reliance on a specific technology or security ideology is insufficient to protect the information and systems integral to the success of an organization. The frequency and veracity of both external and internal attacks requires a more robust and flexible mechanism to combat these increasing threats, and the GSD leapt forward to provide the current generation of perimeter protection technologies.

The GSD retains all of the previous firewall-based functionality such as allowed-path control, VPN services, and network address translation while providing the flexibility to integrate additional services designed to provide visibility into and protection from a multitude of threats. The addition of anti-malware capabilities provides a new layer of protection by relieving hosts from being the only location providing full detection, prevention, and remediation services. The integration of proxy services, application and content control, and intrusion prevention allows GSD deployments to simplify the network-security architecture and opens up new inspection and protection opportunities.

Today's threats provide little insight into how protection measures will need to evolve to meet the next-generation attacks and attackers. To remain a viable security option, the GSD security vendors must remain agile. The integration and implementation of new protection measures will need to be simple and seamless. As processing power continues to increase, so will the capabilities of the GSD to take on greater workloads and complexity. Basic content inspection will give way to a greater understanding of and protection for data context, value, and flows. The support and protection of worldwide networks will require providing the full existing set of GSD functionality for IPv6 traffic.

No matter the threat, no matter the network, no single device is a silver bullet to complete security. Each organization must evaluate all avenues of protection to ensure that the technologies deployed meet the security functionality required.

27.1 SECURITY BEHIND THE FIREWALL. Even today, when asked how they would go about securing a computer or computer network, most people mention firewalls, the first widely accepted network security devices. As network security has become a nonoptional facet of system management, firewall mechanisms of various sorts have become a standard fixture in many networks.

As in any complex protection function, firewalls are necessary but not sufficient to completely protect enterprises from security breaches. Expecting firewalls to provide complete protection is tantamount to expecting guards at the gates of corporate campuses to prevent destructive behavior on the part of those operating vehicles within the facility. A lot can happen as traffic flows between hosts on internal networks; even items that appear benign to gatekeepers can be subverted to carry destructive payloads. Thus, most modern network security architectures include intrusion detection and intrusion prevention systems.

Intrusion detection systems (IDSs) are software or hardware systems that automate the monitoring of events occurring within a computer system or network. IDSs not only collect and synchronize records of these events; they also analyze them for signs of security violations. In strictest terms, vulnerability assessment systems (VASSs) are a special class of IDSs in which the system relies on static inspection and attack reenactment to gauge a target system’s exposure to specific security vulnerabilities. Intrusion prevention systems (IPSs) are another special class of IDSs in which the system is designed to react to certain detected attacks in a prespecified way.

In recent years, the realm of intrusion detection has broadened and deepened, driven by a number of factors. Security personnel, architectural and operational alike, have gained more experience with IDS technologies, working with commercial product providers to expand product capabilities and management schemes to fit current needs. As operational personnel have become more comfortable in using these systems, they have moved certain IDS capabilities to core network management venues. Finally, threats have evolved, driving needs that IDSs are uniquely qualified to address.

The evolution of IDS has resulted in some changes in nomenclature and tradecraft associated with it. One of these changes is that vulnerability assessment is considered a stand-alone discipline, driven by market needs that are often different from those influencing IDS. Another is that intrusion prevention has evolved as a stand-alone product category, offering the ability to respond automatically to certain classes of attacks. Thus, vulnerability assessment is treated as a separate topic in this *Handbook* (covered in Chapter 46), while both IDS and IPS are discussed in this chapter.

27.1.1 What Is Intrusion Detection? Intrusion detection is the process of collecting information about events occurring in a computer system or network and analyzing them for signs of *intrusions*. *Intrusions* are defined as violations of security policy, usually characterized as attempts to affect the confidentiality, integrity, or availability of a computer or network. These violations can come from attackers accessing systems from the Internet or from authorized users of the systems who attempt to overstep their legitimate authorization levels or who use their legitimate access to the system to conduct unauthorized activity.

Intrusion detection systems are software or hardware products that automate this monitoring and analysis process.

27.1.2 What Is Intrusion Prevention? Intrusion prevention is the process of coupling intrusion detection (as defined) with specified responses to certain detected intrusion scenarios. The triggering events can be viewed as a special subset of intrusions, and are often characterized in richer quantitative and qualitative terms than more generic IDS triggers. For example, a specific IPS might focus on monitoring certain types of network traffic. When the rate of a particular traffic type exceeds the anticipated threshold, the IPS would react in a prespecified way (e.g., limiting the rate of subsequent traffic of that type).

27.1.3 Where Do Intrusion Detection and Intrusion Prevention Fit in Security Management? Intrusion detection is a necessary function in most system security strategies. It (and its offshoot, vulnerability assessment) is the primary security technology that supports the goal of *auditability*. “Auditability” is defined as the ability to independently review and examine system records and activities to:

- Determine the adequacy of system controls
- Ensure compliance with established security policy and operational procedures
- Detect breaches in security
- Recommend any indicated changes¹

The presence of a strong audit function, in turn, enables and supports several vital security management functions, such as incident handling and system recovery. Intrusion detection also allows security managers a flexible means to accommodate user needs while retaining the ability to protect systems from certain types of threats.

There is some debate over whether IPS will displace IDS in the security management lineup. This displacement is unlikely for the time being because of the binding between IDS and audit. As security operations become more tightly integrated with traditional system administration and operations, audit functions are necessary to support root cause analysis in diagnosing and addressing system failure. Badly tuned security devices can create problems in operations; it is important to be able to identify and correct such issues quickly and appropriately. Audit functions are also necessary to measure the effectiveness of security measures in mitigating security threats. Although it may appear that transparently detecting and blocking attacks is the optimal security process, such transparency—that is, lack of an audit trail—interferes with demonstrating effectiveness of security measures against real threats. In other words, in order for security management to justify a budget for security measures, it must be able to document and quantify the suitability and effectiveness of such measures. Therefore, regardless of the effectiveness of IPS in blocking attacks, IDS will likely always be necessary to support these audit functions. IDS provides the baseline information on the attack profiles and frequencies that allow managers to demonstrate the effectiveness and return on investment of preventive mechanisms. Without hard evidence of attack frequencies, security managers are left in the position of the man waving a dead chicken around his head while standing on a street corner. Asked why he is doing that, he answers, “To keep the flying elephants away.” “But there are no flying elephants,” protest the observers. “See? It works!” replies the lunatic. For more information on auditing, see Chapter 54 in this *Handbook*.

27 · 4 INTRUSION DETECTION AND INTRUSION PREVENTION DEVICES

Although intrusion detection and intrusion prevention systems are necessary as system security functions, they are not sufficient to protect systems from all security threats. IDS and IPS must be a part of a more comprehensive security strategy that includes vulnerability assessment, security policy and procedural controls, network firewalls, strong identification and authentication mechanisms, access control mechanisms, file and link encryption, file integrity checking, physical security measures, and security training.

27.1.4 Brief History of Intrusion Detection. Intrusion detection is the automation of manual processes that originated in the earliest days of data processing. Joseph Wassermann of the Bell Telephone Company documented the origin of system and security audit as early as the mid-1950s, when the first computerized business system was being designed and implemented.²

Auditability was a key security feature from the earliest days of computer security, as proposed in J. P. Anderson's 1973 research study chartered by the U.S. Air Force.³ Anderson proposed a scheme for automating the review of security audit trails in 1980, in a research report considered by many to be the seminal work in intrusion detection.⁴ Dorothy Denning and Peter Neumann led a study of intrusion detection, conducted from 1984 to 1986, producing another seminal work in intrusion detection in 1986, in which Denning proposed a model for intrusion detection.⁵

An instantiation of Denning's intrusion detection model was prototyped as the Intrusion Detection Expert System (IDES) by a team at SRI International. IDES was a hybrid system that constructed statistical profiles of user behaviors as derived from operating system kernel audit logs and other system data sources. IDES also provided a rules-based expert system that allowed users to specify patterns of events to be flagged as intrusions.⁶ IDES and the Next Generation IDES (NIDES) system that followed it marked an era in which numerous intrusion detection research projects and prototype systems were developed, including Haystack (Haystack Labs and U.S. Air Force), NADIR (Los Alamos National Laboratory), Wisdom and Sense (Los Alamos National Laboratory and Oak Ridge National Laboratory), ISOA (PRC, Inc.), TIM (Digital Equipment Corporation), ComputerWatch (AT&T), and Discovery (TRW, Inc.).⁷

In the late 1980s, researchers at the University of California, Davis, designed the first network-based intrusion detection system (initially called the Network Security Monitor, but later renamed NID), which functioned much the same as many current commercial network-based intrusion detection products.⁸ A subsequent U.S. Air Force-funded research product called the Distributed Intrusion Detection System (DIDS), explored coordinating network-based and host-based intrusion detection systems. DIDS was prototyped by teams at the University of California, Davis, Haystack Laboratories, and Lawrence Livermore National Laboratory.⁹

Intrusion prevention was proposed as a logical next step to intrusion detection almost from the start of intrusion detection research. Support for certain models of intrusion prevention grew when concerns regarding attacks on the TCP/IP network infrastructure (e.g., packet flooding and malformed packet attacks) grew in the mid- to late-1990s. Other types of IPS were proposed to deal with kernel-level hacks and information leakage issues.

27.2 MAIN CONCEPTS. Several strategies used in performing intrusion detection serve to describe and distinguish specific intrusion detection systems. These affect the threats addressed by each system and often prescribe the environments in which

specific systems should be used. As noted, intrusion prevention relies first on intrusion detection strategies; thus, the differentiators will be highlighted as appropriate.

27.2.1 Process Structure. Intrusion detection is defined as a monitoring and alarm generation process, and, as such, it can be described using a simple process model. This model is outlined here and will be used to illustrate the fundamental concepts of intrusion detection.

27.2.1.1 Information Sources. The first stage of the intrusion detection process comprises one or more information sources, also known as event generators. Information sources for intrusion detection may be categorized by location: network, host, or application.

27.2.1.2 Analysis Engine. Once event information is collected, it is passed to the next stage of the intrusion detection process, in which it is analyzed for symptoms of attack or other security problems.

27.2.1.3 Response. When the analysis engine diagnoses attacks or security problems, information about these results is revealed via the response stage of the intrusion detection process. Responses span a wide spectrum of possibilities, ranging from simple reports or logs to automated responses that disrupt attacks in progress. The presence of these automated responses defines an intrusion prevention system.

27.2.2 Monitoring Approach. The first major classifier used to distinguish intrusion detection systems is the monitoring approach of the system. Monitoring is the action of collecting event data from an information source and then conveying that data to the analysis engine.

The monitoring approach describes the perspective from which intrusion detection monitoring is performed. The primary monitoring approaches found in intrusion detection systems today are *network based*, *host based*, and *application based*.

27.2.3 Intrusion Detection Architecture. Even in the early days of manual security audit, researchers noted that in order for audit information to be trusted, it should be stored and processed in an environment separate from the one monitored. This requirement has evolved to include most intrusion detection approaches, for three reasons:

1. To keep an intruder from blocking or nullifying the intrusion detection system by deleting information sources
2. To keep an intruder from corrupting the operation of the intrusion detector in order to mask the presence of the intruder
3. To manage the performance and storage load that might result from running intrusion detection tasks on an operational system

In this architecture, the system running the intrusion detection system is called the *host*. The system or network being monitored is called the *target*.

27.2.4 Monitoring Frequency. Another common descriptor for intrusion detection approaches is the timing of the collection and analysis of event data. This is

27 · 6 INTRUSION DETECTION AND INTRUSION PREVENTION DEVICES

usually divided between *batch-mode* (also known as *interval-based*) and *continuous* (also known as *real-time*) approaches.

In batch-mode analysis, the event data from the information source are conveyed to the analysis engine in a file or other block form. As the name suggests, the events corresponding to a particular interval of time are processed (and results provided to the user) after the intrusion has taken place. This model was the most common for early intrusion detection because system resources did not allow real-time monitoring or analysis.

In real-time analysis, event data from the information source are conveyed to the analysis engine as the information is gathered. The information is analyzed immediately, providing the user with the opportunity to respond to detected problems quickly enough to affect the outcome of the intrusion.

27.2.5 Analysis Strategy. In intrusion detection, there are two prevalent analysis strategies, *misuse detection* and *anomaly detection*.

In misuse detection, the analysis engine filters event streams, matching patterns of activity that characterize a known attack or security violation. In anomaly detection, the analysis engine uses statistical or other analytical techniques to spot patterns corresponding to abnormal system use. Anomaly detection is based on the premise that intrusions significantly differ from normal system activity. In general, intrusion detection systems rely more heavily on anomaly detection and quantitative measures to detect and block attacks.

27.3 INTRUSION PREVENTION. As discussed, IPSs are often considered a special case of IDS in which automated responses are specified. However, with the adoption of the first generation of network IPS products, additional specifications for IPSs have evolved in addition to those assigned to IDS.

27.3.1 Intrusion Prevention System Architecture. As in intrusion detection, most IPSs separate the monitoring and analysis platform from the target platform being monitored. Additional differentiations are drawn between those IPSs that separate the monitoring and analysis platform from the response platform (these are labeled “stand-alone” IPSs) and those that integrate all the functions in a single unit, usually a firewall, network switch, or router (these are labeled “integrated” IPSs.)

27.3.2 Intrusion Prevention Analysis Strategy. IPSs generally use the same structural approach to data analysis as IDS, but the nomenclature for the analysis strategies differs. IPS analysis schemes fall into two general categories, rate based and content based.

Rate-based IPS analysis makes the decision to block network traffic based on indicators of network load, as measured by statistics such as connect rates and connection counts. This category of analysis is especially useful for detecting packet flood distributed denial-of-service (DDoS) attacks.

Content-based IPS analysis makes the decision to block network traffic based on indicators of anomalous packets and specific content (often represented as IDS signatures). This approach is useful for detecting malformed packet DDoSs and other types of attacks not readily spotted by quantitative measures.¹⁰

27.4 INFORMATION SOURCES. Information sources represent the first stage of the intrusion detection process. They provide event information from monitored

systems on which the intrusion detection process bases its decisions. Information sources encompass both *raw* event data (e.g., data collected directly from system audit and logging mechanisms) as well as data output by system management utilities (e.g., file integrity checkers, vulnerability assessment tools, network management systems, and even other intrusion detection systems). In this section, information sources for intrusion detection are classified by location: network, host, or application.

27.4.1 Network Monitoring. The most common monitoring approach utilized in intrusion detection systems is *network based*. In this approach, information is gathered in the form of network packets, often using network interface devices set to promiscuous mode. (Such a device operating in promiscuous mode captures all network traffic accessible to it—usually on the same network segment—not just traffic addressed to it.) Other approaches for performing network-based monitoring include the use of *spanning ports* (specialized monitoring ports that allow capture of network traffic from all ports on a switch) on network switches or specialized Ethernet network taps (e.g., sniffers) to capture network traffic.

27.4.2 Operating System Monitoring. Some monitors collect data from sources internal to a computer. These differ from network-based monitoring in the level of abstraction at which the data is collected. *Host-based* monitoring collects information from the operating system (OS) level of a computer. The most common sources of operating system–level data are operating system audit trails, which are usually generated within the OS kernel, and system logs, which are generated by OS utilities.

27.4.3 Application Monitoring. *Application-based* monitoring collects information from running software applications. Information sources utilized in application-based approaches include application event logs and application configuration information.

Application-based information sources are steadily increasing in importance as systems complexity increases. The advent of object-oriented programming techniques introduces data object naming conventions that nullify much of an analyst's ability to make sense of file access logs. In this situation, the application level is the only place in the system in which one can “see” the data accesses at an appropriate level of abstraction likely to reveal security violations.

One special case of application-based monitoring comprises an entire product category in security. This type of system (sometimes called extrusion detection) monitors data transfers, looking for anomalies associated with data movement across policy boundaries. Such data monitoring is very popular as a compliance mechanism for enterprises dealing with consumer, financial, or other regulated data.

27.4.4 Other Types of Monitoring. As noted, intrusion detection information sources are not limited to raw event data. In fact, allowing intrusion detection systems to operate on results from other systems often optimizes the quality of the intrusion detection system's results. When the data are provided by other parts of the system security infrastructure (e.g., network firewalls, file integrity checkers, virus scanners, or other intrusion detection systems), the sensitivity and reliability of the intrusion detection system's results can increase significantly.

27 · 8 INTRUSION DETECTION AND INTRUSION PREVENTION DEVICES

27.4.5 Issues in Information Sources. There are several issues involving information sources for intrusion detection. The major ones that have persisted over the history of intrusion detection include:

- In host-based systems, there must be a balance between collecting enough information to accurately portray security violations and collecting so much information that the collection process cripples the monitored system.
- The fidelity of the intrusion detection process is dependent not only on collecting the appropriate information but on collecting it from appropriate vantage points within the monitored system or network.
- If the IDS is expected to produce event records that will be used to support legal processes, the system must collect and handle event information in a way that complies with legal rules of evidence.
- The information collected by IDSs often includes information of a sensitive nature. This information must be secured and handled in a way that complies with legal and ethical standards.

27.5 ANALYSIS SCHEMES. Once information sources and sensors are defined and placed, the information so gathered must be analyzed for signs of attack. The *analysis engine* serves this purpose in intrusion detection, accepting event data from the information source and examining it for symptoms of security problems. As mentioned earlier, intrusion detection systems typically provide analysis features that fall into two categories, *misuse detection* and *anomaly detection*.

27.5.1 Misuse Detection. *Misuse detection* is the filtering of event streams for patterns of activity that reflect known attacks or other violations of security policy. Misuse detectors use various pattern-matching algorithms, operating on large databases of attack patterns or *signatures*. Most current commercial intrusion detection systems support misuse detection.

Misuse detection presumes that there is a clear understanding of the security policy for the system, which can be expressed in patterns corresponding to desirable activity and undesirable activity. Therefore, signatures can be described in terms of “this should never happen” as well as “only this should ever happen.” Signatures also can range from simplistic *atomic* (one-part) checks to rather complex *composite* (multipart) checks. An example of an atomic check is a buffer overflow signature, in which one looks for a particular command, followed by a string exceeding a particular length. An example of a composite check is a race condition signature, in which a series of carefully timed commands occur. Signatures are gathered and structured in some way to optimize the filtering of event data against them.

The next requirement for misuse detection is that the event data collected from information sources be encoded in a way that allows it to be matched against the signature data. There are various ways of doing this, ranging from regular expression matching (sometimes called “dirty word” matching) to complex coding schemes involving state diagrams and Colored Petri Nets. State diagrams are a graphical scheme for modeling intrusions. They express intrusions in terms of *states*, represented by nodes or circles, and *transitions*, represented by lines or arcs. Colored Petri Nets are an extension of the state diagram technique that add colored *tokens*, which occupy state nodes, and whose color expresses information about the context of the state.

In some IDSs and content-based IPSs, significant resources are devoted to identifying malformed network packets, especially those in which the format of the content of the packet does not match the format of the service (e.g., SMTP) or of the associated port number of the packet. This malformed packet scheme represents one of the major categories of DDoS attacks, which seek to deny network access to legitimate users.

27.5.2 Anomaly Detection. *Anomaly detection* is the analysis of system event streams, characterizing them using statistical and other classification techniques in order to find patterns of activity that appear to deviate from normal system operation. This approach is based on the premise that attacks, and other security policy violations, are a subset of abnormal system events.

Several common techniques are used in anomaly detection:

- **Quantitative analysis.** Most modern systems that use anomaly detection provide quantitative analysis, in which rules and attributes are expressed in numeric form. The most common forms of quantitative analysis are triggers and thresholds, in which system attributes are expressed as counts occurring during some time interval, with some level defined as permissible. Triggers and thresholds can be simple, in which the permissible level is constant, or heuristic, in which the permissible level is adapted to observed levels. Network intrusion prevention systems targeting DDoS attacks often use heuristic triggers and thresholds to characterize the normal bandwidth loads, connect rates, and connection counts in network traffic.
- **Statistical analysis.** Most early anomaly detection systems used statistical techniques to identify abnormal data. In statistical analysis, profiles are built for each user and system resource, and statistics are calculated for a variety of user and resource attributes for a particular interval of time (usually a “session,” defined as the time elapsed between login and logout).
- **Learning techniques.** There has been a great deal of research interest in using various learning techniques, such as neural networks and fuzzy logic, in performing anomaly detection. Despite encouraging results, there remain many practical impediments to using these techniques in production environments. The practical impediments arise due to the mismatch between those attributes that are suitable for characterization by neural networks and fuzzy logics and those attributes that are actionable by operational personnel and systems. The value of using neural networks (most of them utilizing fuzzy logic) is that they can characterize and recognize very subtle signs of trouble in systems. This is of value in situations where the problems being detected are not subtle. However, in security breaches, the difference between normal behavior and security attack is often influenced by the system context; in these scenarios, few, if any, neural networks can provide insights regarding how they reached their decisions regarding the suspicious events on which they trigger. A security person in an operational context usually requires this sort of insight in order to devise an appropriate reaction to the detected intrusion.
- **Advanced techniques.** Anomaly detection as applied to intrusion detection remains an active research area. Recent research efforts include the application of such advanced analytic techniques as genetic algorithms, data mining, autonomous agents, and immune system approaches to the problem of recognizing new attacks

27 · 10 INTRUSION DETECTION AND INTRUSION PREVENTION DEVICES

and security violations. Again, these techniques have not yet been widely fielded in commercial IDSs, although they have appeared in special purpose products.

27.5.3 Hybrid Approaches. There are significant issues associated with both misuse detection and anomaly detection approaches to event analysis for intrusion detection; however, combining both approaches provides considerable benefit. The anomaly detection engine can allow the IDS to detect new or unknown attacks or policy violations. This is especially valuable when the target system protected by the IDS is highly visible on the Internet or other high-risk network. In IPS, anomaly detection applied to network traffic attributes allows one of the only means to deal with packet-flood DDoS attacks, a growing concern in today's networks.

The misuse detection engine, in turn, protects the integrity of some anomaly detection engines by assuring that a patient adversary cannot gradually change behavior patterns over time in order to retrain the anomaly detector to accept attack behavior as normal. Thus, the misuse detector mitigates a significant deficiency of anomaly detection for security purposes.

27.5.4 Issues in Analysis. Here are a few of the many issues in intrusion detection analysis:

- Misuse detection systems, although very effective at detecting those scenarios for which detection signatures have been defined, cannot detect new attacks.
- Anomaly detection systems are capable of detecting new attacks but usually have false positive rates so high that users often ignore the alarms they generate.
- Anomaly detection systems that rely on artificial intelligence (AI) techniques often suffer from a lack of adequate training data. (Data are used to define the detector's logic for distinguishing "normal" from "abnormal" events.)
- Malefactors with access privileges to the system, while anomaly-detection systems are being trained, can covertly teach the system to accept specific patterns of unauthorized activities as normal. Later, the anomaly-detection systems will ignore the actual misuse.

27.6 RESPONSE. The final stage of intrusion detection, response, consists of the actions taken in response to the security violations detected by the IDS. Responses are divided into *passive* and *active* options. The difference between passive and active responses is whether the user of the IDS, or the system itself, is responsible for reacting to the detected violations. As discussed, the former option is associated with classic IDS; the latter is associated with IPS.

27.6.1 Passive Responses. When passive responses are selected, the IDS simply provides the results of the detection process to the user, who must then act on these results, independent of the IDS. In this option, the user has total control over the response to the detected problem. In some IDSs, the information provided to the user regarding detection results can be divided into *alarms* and *reports*.

27.6.1.1 Alarms. Alarms are messages that are communicated immediately to users. Commercial IDSs use a variety of channels for conveying these alarms to security personnel. The most common is a message screen or icon written to the IDS control

console. Other alarm channels include pagers, email, wireless messaging, and network management system traps.

27.6.1.2 Reports. Reports are messages or groups of messages that are generated on a periodic basis. They typically document events that have happened in the past and often include aggregate figures and trends information. Many commercial IDS products support extensive reporting features, allowing a user to set up automatic report generation with several versions, each targeting a different level of management.

27.6.2 Active Responses: Man-in-the-Loop and Autonomous. When an IDS provides active response options, these usually fall into two categories. The first requires the IDS to take action, but with the active involvement of an interactive user. This option is sometimes called a man-in-the-loop mechanism. This option is preferred for critical systems, as it allows an operator to track an attacker or intervene in a sensitive situation in a flexible, exacting way.

The other active response option, which usually defines an IPS, provides for preprogrammed actions taken automatically by the system with no human involvement. The automated response option is required when dealing with certain sorts of automated attack tools (viruses or worms) or DDoS attacks. These attacks proceed at machine speed and therefore are outside the reach of a human-controlled manual intervention. As automated and DDoS attacks are the tool of choice for online extortionists, the number of IPSs fielded in commercial networks has grown rapidly over the past few years.

27.6.3 Automated Response Goals. Automated responses support three categories of response goals:

1. Collecting more information about the intrusion or intruder
2. Amending the environment (e.g., changing a switch or router setting to deny access to an intruder)
3. Taking action against the intruder

Although the last of these groups, sometimes labeled *strike back* or *hack back*, occasionally is discussed in security circles, the other options are far more productive in most situations. At this time, taking action against the intruder is considered inappropriate in almost all situations, and should be undertaken only with the advice and counsel of a legal authority.

Amending the environment and collecting more information can occur in either stand-alone or integrated fashions.

27.6.3.1 Stand-Alone Responses. Some automated responses are designed to use features that fall entirely within the intrusion detection system. For instance, an intrusion detection system may have special detection rules, more sensitive or detailed than those provided in normal modes of operation. In a stand-alone adaptive response, the IDS would use the more sensitive rules when evidence of the preamble of an attack is detected. This allows the IDS to turn sensitivity levels up only when the additional detection capabilities are needed, so that false alarm rates are reduced.

27.6.3.2 Integrated Responses. The response option often considered the most productive is that of using integrated measures that change the system settings to block the attacker's actions. Such responses can affect the configuration of the target system, the IDS/IPS host, or the network on which both reside. In the first case, the IDS/IPS might change the settings of the logging mechanisms on the target host to increase the amount or type of information collected. The IDS also might change its analysis engine so that more subtle signs of attack are recognized. In another response option reflected in commercial products, the IDS responds to an observed attack signature by querying the target system to determine whether it is vulnerable to that specific attack. Should the vulnerability be present, the IDS directs the target system to correct that vulnerability. In effect, this process provides the target system with an immune function and permits it to "heal" itself, either blocking an attack outright or else interactively repairing any damage done in the course of the attack. Finally, some systems may use special-purpose decoy systems, called *honey pots* or *padded cells*, as diversions for attackers. When these systems are provided, the IDS may be configured to divert attackers into the decoy environments.

In a special case of integrated response seen in many commercial IPS offerings, the IPS is integrated with a switch or router. When an attack is detected, the switch or router is reconfigured on the fly to block the source of the attack. Other IPS offerings that are designed to deal with DDoS attacks use multiple IDS/IPSs to detect the attacks, then manipulate the switching fabric¹¹ to divert the attacks from the targeted systems. Over time, such IPS features will likely be integrated with network infrastructure devices, as many firewall features already have done.

27.6.4 Investigative Support. Although the primary design objective of intrusion detection systems is detecting attacks and other possibly problematic system events, information collected and archived by IDSs also can support those charged with investigating security incidents. This functional requirement may levy additional technical requirements on IDSs. For instance, if investigators plan to use IDS monitoring features to perform a targeted surveillance of an attack in progress, it is critical that the information sources be "silent" so that adversaries are not aware that they are being monitored. Furthermore, the IDS monitors must be able to convey information to the investigators through a trustworthy, secure channel. Finally, the IDS itself must be under the control of the investigators or other trusted parties; otherwise, the adversaries may mask their activities by selectively spoofing information sources. Perhaps the most important thing for investigators to remember about IDSs is that the information provided should be corroborated by other information sources (e.g., network infrastructure device logs), not necessarily accepted at face value.

27.6.5 Issues in Responses. As in information sources and analysis strategies, certain issues associated with IDS response features have endured over the history of intrusion detection. The principal issues are:

- Users' needs for IDS response capabilities are as varied as the users themselves. In some systems environments, the IDS response messages are monitored around the clock, with real-time action taken by system administrators based on IDS alarms. In other environments, users may use IDS responses, in the form of reports, as a metric to indicate the threat environment in which a particular system resides. It is important to consider the specific needs of the user when selecting an IDS.

- Given false-positive error rates for IDSs, response options must be tunable by users. Otherwise, users will simply tune out the IDS responses. This nullifies the value of the IDS.
- When the IDS provides automated responses to detected problems, there is a risk of the IDS itself launching an effective denial-of-service attack against the system it is protecting. For instance, suppose an IDS is configured with rules that tell it “upon detecting an attack from a given IP address, direct the firewall to block subsequent access from that IP address.” An attacker, knowing this IDS is so configured, can launch an attack with a forged IP source address that appears to come from a major customer or partner of the organization. The IDS will recognize the attack and then block access from that organization for some period of time, effecting a denial of service.

27.7 NEEDS ASSESSMENT AND PRODUCT SELECTION. The value of intrusion detection products within an organization’s security strategy is optimized by a thorough needs assessment. These needs and security goals can be used to guide the selection of products that will enhance the security stance of the organization.

27.7.1 Matching Needs to Features. The needs most often addressed by intrusion detection and intrusion prevention systems include:

- Prevention of problem behaviors by increasing the risk of discovery and punishment for system attackers.
- Detection of security violations not prevented (or even, in some cases, not preventable) by other security measures.
- Documentation of the existing level of threat to an organization’s computer systems and networks.
- Detection and, where possible, mitigation of attack preambles. (These include activities such as network probes, port scans, and other such “doorknob rattling.”)
- Diagnosis of problems in other elements of the security infrastructure (i.e., malfunctions or faulty configurations).
- Granting system security personnel the ability to test the security effects of maintenance and upgrade activities on the organizational networks.
- Providing information about those violations that do take place, enabling investigators to determine and correct the root causes.
- Providing evidence of compliance with a given regulatory requirement for information protection. This represents a significant need for members of various regulated industries, such as banking and health care.

Regardless of which of these specific needs are relevant to the user, it is important to consider the ability of the intrusion detection system to satisfy the needs of the specific environment in which it is installed. A critical part of this determination is considering whether the intrusion detection system has the ability to monitor the specific information sources available in the target environment. What is even more important is whether the organizational security policy translates into a monitoring and detection policy that can be used to configure the IDS (or in the case of an IPS, a monitoring, detection, and response policy.) The structure of the security policy is especially critical to the success of an IPS.

27.7.2 Specific Scenarios. There is no universally applicable description for computer networks or the IDSs that protect them. There are, however, some common scenarios, given current trends in networking and system usage.

A popular justification for using IDSs early in an organization's security life cycle is to establish the threat level for a given network enclave. Network-based IDSs often are used for this purpose, with monitors placed outside the organizational firewall. Those who are responsible for winning management support for security efforts often find this use of IDSs to be quite helpful.

Many organizations use IDSs to protect Web servers. In this case, the nature of the interactions that the Web server has with users will affect the selection and configuration of the IDS. Most Web servers serve two types of functions: (1) informational (e.g., Web servers that support simple HTTP and FTP queries from users) and (2) transactional (e.g., Web servers that allow user interaction beyond simple HTTP or FTP traffic). Transactional Web servers are usually more difficult to monitor than informational servers, as the range of interactions between users and servers is wider. For critical transactional Web servers, security managers may wish to consider multiple IDSs, monitoring the servers at multiple levels of abstraction (i.e., application, host, and network).

The third scenario involves organizations that wish to use IDSs as additional protection for specific portions of their networked systems. An example of this is the medical organization that wishes to protect the patient record database systems from privacy breaches. In this situation, as in the Web server example just given, it may be advisable to use multiple IDSs, monitoring interactions at multiple levels of abstraction. The output of these multiple systems can be synchronized and inconsistencies noted for a reliable indication of threat levels. Another example that is increasingly common is the organization that is concerned about wireless connectivity. In this case, WiFi monitoring products are commercially available, with information collection and monitoring features that are similar to those of classic IDSs.

In recent years, the expanding use of wireless local area networks (WLANs) in buildings and campuses has stimulated the development of wireless intrusion detection and prevention systems (WIDPSs). The basic principles are the same as for other IDSs and IPSs, with the addition of an interesting wrinkle: The WIDPSs are often used to discover unauthorized access points installed on an organization's WLANs by rogue employees or by intruders. Karen Scarfone and Peter Mell, in their July 2012 edition of NIST SP 800-94, point out that WIDPS sensors should be placed in areas where there should be no wireless network activity. Some security managers walk through and drive around their facilities with WIDPS tools on their laptop computers to identify unauthorized access points. However, completely passive eavesdropping on WLAN traffic cannot be detected.¹²

In extensive networks, should the security architect decide to layer multiple IDSs and IPSs, a security event monitor/security information manager (SIM/SEM) may be required. Such a system would be necessary to consolidate and integrate the results of each IDS/IPS into a coherent set of conclusions.

27.7.3 Integrating IDS Products with Your Security Infrastructure.

As mentioned, an IDS is not a substitute for a firewall, virtual private network, identification and authentication package, or any other security point product. However, an IDS can improve the quality of protection afforded by the other point products by monitoring their operation, noting signs of malfunction or circumvention. Furthermore,

an IPS can interact in concert with the rest of the point products to help block an attack in progress.

27.7.4 Deployment of IDS Products. The first generations of IDS installations have yielded some insights associated with deployment of IDSs. The key points include the location of sensors, scheduling the integration of IDSs, adjusting alarm settings, and outsourcing IDS/IPS services.

27.7.4.1 Location of Sensors. There are four general locations for IDS sensors:

1. Outside the main organizational firewall
2. In the network DMZ (inside the main firewall, but outside the internal firewalls)
3. Behind internal firewalls
4. In critical subnets, where critical systems and data reside

As mentioned, IDS sensors placed outside the main organizational firewall are useful for establishing the level of threat for a given network. Sensors placed within the DMZ¹³ can monitor for penetration attempts targeting Web servers. IDSs monitors for internal attacks are placed on internal network segments, behind internal firewalls. And for critical subnets, IDS sensors usually are placed at the choke points at which the subnets are connected to the rest of the corporate network. In the case of wireless networking, specialized IPS devices serve to discover and report unauthorized access to networks via WLAN access points or open software access points, through misconfigured WLAN interfaces on laptops and other WLAN devices. These IPS devices are usually placed behind firewalls and distributed across the physical space occupied by the organization and its users.

27.7.4.2 IDS Integration Scheduling. Early generations of intrusion detection products proved that integration processes must not be rushed. IDSs still rely on operator interactions to screen out false alarms and to act on legitimate alarms. Hence, it is critical that the processes provide adequate time for operational personnel to learn the behavior of the IDS on target systems, developing a sense of how the IDS interoperates with particular system components in different situations. This wisdom applies even more to IPS installation, where a miscue in specifying a response can have disastrous effects on the function of critical networks.

27.7.4.3 Alarm Settings. IDSs have significant false alarm rates, with false positive rates as high as 80 percent in some situations. Many knowledgeable IDS integrators advise that alarms be suspended for a period of weeks, even months, as operators gain familiarity with the IDS and target systems. It is especially wise to delay activation of automated responses to attacks until operators and system administrators are familiar with the IDS and have tuned it to the target environment.

27.7.4.4 Outsourcing of IDS/IPS. Any discussion of IDS and IPS strategies would be incomplete without mention of outsourcing these security services. There are significant advantages associated with this approach, especially in enterprises too small to afford an extensive security staff. As in other areas of IT outsourcing, one must have an extremely clear idea of the specific security and operational goals desired

in order for this approach to be effective. A clearly worded security policy that reflects current concerns is essential. The advantages of outsourcing are many: Managed security service providers usually have considerable experience in dealing with IDS and IPS equipment, their staffs are often well trained and experienced in the use of the equipment, monitoring personnel are usually in attendance around the clock, and contract terms often include specific levels of service agreements.

In the words of a wise CISO, “outsourcing isn’t offloading.” That means that outsourcing security functions does not relieve you of the responsibility for system security. It also means that you must exercise due diligence in selecting the service provider, tasking and managing it, and monitoring it to ensure that your policy goals are being well served by the provider.

27.8 CONCLUSION. Intrusion detection and intrusion prevention are valuable additions to system security suites, allowing security managers to spot, and sometimes block, those security violations that inevitably occur despite the placement of preventive security measures. Although current commercial products are imperfect, they serve to recognize many common intrusion types, in many cases quickly enough to allow security personnel and IPSs to block damage to systems and data. Furthermore, as research and development in intrusion detection and prevention continues, the quality and capabilities of available IDSs and IPSs will steadily improve.

28 · 2 IDENTIFICATION AND AUTHENTICATION

28.1 INTRODUCTION. *Authorization* is the allocation of permissions for specific types of access to restricted information. In the real world, authorization is conferred on real human beings; in contrast, information technology normally confers authorization on *user identifiers* (IDs). Computer systems need to link specific IDs to particular authorized users of those IDs. Even inanimate components, such as network interface cards, firewalls, and printers, need IDs. *Identification* is the process of ascribing an ID to a human being or to another computer or network component. *Authentication* is the process of *binding* an ID to a specific entity. For example, authentication of a user's identity generally involves narrowing the range of possible entities claiming to have authorized use of a specific ID down to a single person.

The focus of this chapter is on person-to-computer authentication. In practice, we also need computer-to-person authentication to prevent spoofing of services on a network. This type of authentication is increasingly important, especially on open networks such as the Internet, where users may be misled about the identity of the Websites they visit. For example, some criminals send unsolicited email messages in Hypertext Markup Language (HTML) to victims; the messages include links that are labeled to suggest an inoffensive or well-respected Website, but the underlying HTML actually links to a fraudulent site designed to trick people into revealing personal information, such as credit card numbers or details to support theft of identity. More generally, computer-to-computer mutual authentication, typically in both directions, is essential to safeguard critical transactions such as those of interbank transfers and business-to-business electronic commerce.

In the early decades of computer usage, most computers authenticated users who accessed mainframes from within a single enterprise. User IDs therefore could be assigned in a centralized and controlled manner. Even so, identifiers have never necessarily been unique, for there is no obligatory one-to-one relationship between a user ID and a human being's real-world identity. For example, several people could share an account such as *inventory clerk* without interference from the computer; at most, the operating system might be configured to prevent simultaneous sharing of an ID by limiting the number of sessions initiated with a specific ID to one.

Conversely, a single user often has many user IDs. For example, there may be unique identifiers for each of dozens of Websites for music clubs, book clubs, enterprise email, and so on. Even on the same computer, a given user might have several accounts defined for different purposes; *jane.doe* and *jdoe* might be identifiers for two different application packages on a system. These multiple identifiers cause problems for administrators if they do not know that the same user is associated with the different IDs; they also cause practical problems for users who have to use different authentication methods for a range of IDs. One of the critical goals of today's identification and authentication (I&A) research and development is to develop reliable and economical methods for *single signon*, whereby users would not have to reidentify and reauthenticate themselves when accessing different computer systems linked into an Internet. For details of I&A in facilities security, see Chapter 23 in this *Handbook*.

28.2 FOUR PRINCIPLES OF AUTHENTICATION. Authentication of a claimed identity can be established in four ways:

1. What only you know (passwords and passphrases)
2. What only you have (tokens: physical keys, smart cards)

3. What only you are (static biometrics: fingerprint, face, retina, and iris recognition)
4. What only you do (dynamic biometrics: voice, handwriting, and typing recognition)

In each approach, the assumption is that no one else but the authorized user of an identifier has access to the password or token and that the probability of simulating static or biometric data is acceptably low.

These methods can be combined; for example, passwords often are combined with tokens or biometrics to provide stronger authentication than is possible with either one alone. A familiar example of this *two-factor authentication* occurs with automatic teller machine (ATM) cards. Possession of the card (the token) and knowledge of the personal identification number (the PIN, corresponding to a password) are required to access a user's bank account.

This chapter introduces each of these four authentication methods and provides additional details for each. For discussions of methods of bypassing and subverting identification and authentication techniques, see Chapter 15 in this *Handbook*.

28.2.1 What Only You Know. Password- or passphrase-based authentication is so widely used that any person who has had any contact with computers and networks probably has had several passwords. Although password technology often is poorly administered and insecure (and frustrating) for users and administrators, passwords can be deployed much more securely and conveniently than they usually are. Many security professionals have felt and hoped for years that passwords would eventually be phased out, to be replaced by tokens or biometrics, but the consensus today is that passwords are not likely to disappear soon and that they will continue to be the dominant authentication technique for years to come.

Demonstrating knowledge of a password does not directly authenticate a human being. It simply authenticates knowledge of the password. Unauthorized knowledge of, or guessing at, a password can lead to impersonation of one user by another; this is called *spoofing*. The theft of a password can be difficult to detect since it is not a tangible asset. Passwords are also very easy to share. It is common for senior executives to give their passwords to their assistants to facilitate their work, even though assigning proxy privileges would be as effective and more secure. Students of security—including criminal hackers—quickly learn that poor password management can be widespread unless organizations provide consistent awareness, education, and training; for example, naïve users sometimes place their passwords on sticky notes under their keyboards or even in plain view on the side of their monitors.

28.2.2 What Only You Have. Authentication based on possession of a token is used where higher assurance of identity is desired than is possible by passwords alone. As with passwords, possession of a token does not directly authenticate a human being; rather it authenticates possession of the token and ability to use it. Sometimes a password or PIN is required to use the token, thus establishing two-factor authentication; the theory is that the requirement to have both elements decreases the likelihood of successful spoofing.

Tokens can take on a variety of forms. The oldest token is the physical key for a physical lock, but these are not often used for securing computer systems. *Soft tokens* are carried on transportable media or even accessed over a network from a server. Soft tokens contain only data; they typically require a password to access the contents.

28 · 4 IDENTIFICATION AND AUTHENTICATION

Modern tokens are usually implemented in self-contained hardware with computing capability. Examples include:

- Credit card–size devices with a liquid crystal display (LCD) that display pseudo-random numbers or other codes.
- LCD devices in the shape of a key fob using the same algorithms as the credit card–shape devices.
- Hardware devices called *dongles* that plug into input-output ports on computers. Examples include dongles for serial ports, parallel ports, Universal Serial Bus (USB) ports, and PC-card interfaces.

All tokens used for computer authentication require software to process information residing in or produced by them. The most significant distinction is whether the tokens require electronic contact with the authentication system. *Contactless* tokens are easier to deploy because they do not require specialized readers. For example, the credit card and key fob pseudorandom number generators simply require the user to enter the visible code in response to a prompt from the authentication software. Contactless tokens are more limited in function than *contact tokens*. For instance, a contact token can be used to create digital signatures whereas a contactless token cannot do so practically.

In cyberspace, a token does not authenticate by means of physical characteristics. Rather the token has some secret, either exclusive to itself or possibly shared with a server on the network. Authentication of the token is really authentication of knowledge of the secret stored on the token. As such, authentication based on possession of a token is tantamount to authentication based on what the token knows. However, this secret can be longer and more random than a secret that a user has to retain in human memory, such as a password. Unfortunately, building cost-effective and secure tokens from which the secret cannot be extracted by tampering or by brute-force guesswork has proven much more difficult than initially anticipated. In the early 1990s, many security professionals believed that tokens would replace passwords; in fact, however, although tokens continue to be an attractive authentication technology, they probably will not become pervasive soon because of the consistent (but highly debatable) belief that passwords are less expensive to implement and manage than other methods of authentication (see Section 28.7).

28.2.3 What Only You Are. Biometrics takes authentication directly to the human being. This topic is covered more extensively in Chapter 29 in this *Handbook*, but the basics can be mentioned here.

As humans, we recognize each other by a number of characteristics. Biometric authentication seeks to achieve a similar result in cyberspace. A *static biometric* is a characteristic of a person such as fingerprint, hand geometry, or iris pattern; more dramatically, it could be the DNA of an individual. The likelihood of two individuals having identical fingerprints, iris patterns, or DNA is minuscule (with exceptions for genetically identical siblings). Biometrics requires specialized and expensive readers to capture the biometric data, making widespread deployment difficult.

Biometrics also suffers from the problems of replay and tampering. Thus, the biometric reader must itself be trusted and tamper-proof; this reduces the likelihood of an attacker capturing the data input and replaying it at a later time, or creating false biometric profiles to trick the system into accepting an imposter. Moreover, the biometric

data themselves must be captured in proximity to the user to reduce the likelihood of substitution, such as in the case of stolen blood used to fool a DNA-based biometric system. If the data are transmitted to a distant server for authentication, the transmission requires a secure protocol, with extensive provisions for time-stamping and rapid expiration of the data.

28.2.4 What Only You Do. *Dynamic biometrics* captures a dynamic process rather than a static characteristic of a person. A well-known example is that of signature dynamics. Signature dynamics involves recording the speed and acceleration of a person's hand as a signature is written on a special tablet. Rather than merely the shape of the signature, it is the dynamic characteristics of motion while writing the signature that authenticates the person—motions that are extremely hard to simulate. Another possibility is to recognize characteristics of a person's voice as he or she is asked to read aloud some specified text. Keystroke dynamics of a person's typing behavior is another alternative.

As in all other forms of authentication, dynamic biometrics depends on exclusion of capture and playback attacks, in which, for example, a recording of someone's voice might be used to fool a voice-recognition system. Similarly, a signature-dynamics system might be fooled by playback of the data recorded from an authentic signature. Encryption techniques help to make such attacks more difficult.

Security experts agree that biometrics offer a stronger guarantee of authentication, but deployment on a large scale remains to be demonstrated. Whether this technology becomes pervasive ultimately may be determined by its social and political acceptability as much as by improved technology.

28.3 PASSWORD-BASED AUTHENTICATION. Passwords are the pervasive technology for authentication in cyberspace today. At a conservative estimate, there are close to a billion password-based authentications per day. Examples include the vast number of Internet users and the number of passwords each one uses every day. However, the current deployment of password technology needs to be improved in many ways. Today users must remember too many identities and corresponding passwords. Also, the deployed technology is more fragile than it needs to be; for example, many users choose passwords that can be guessed easily. Passwords are never going to be as secure as the strongest biometric systems, so one would not use them as the sole basis for, say, launching nuclear missiles. However, their use can be made strong enough for many less critical transactions.

The next sections review the major risks of password use and their mitigation by technical, social, and procedural means.

28.3.1 Access to User Passwords by System Administrators. One of the most dangerous practices in use today is the storage of unencrypted user passwords accessible to system administrators. In some sites, new users receive passwords that are assigned and written down by system administrators. If these passwords are used only once, for the initial logon, the user can be forced to choose or create a truly secret password that no one else knows. However, in many such sites, administrators keep control of a paper or electronic record, usually for quick access when users forget their own passwords. Such access completely destroys an important element of I&A: *nonrepudiation*. If someone else has access to a password, then authorized users can reasonably *repudiate* transactions by claiming that their identities were spoofed. It is difficult to counter such repudiation, especially in a court of law considering

28 · 6 IDENTIFICATION AND AUTHENTICATION

an accusation of malfeasance by the authorized user of that password. In general, passwords that will be used repeatedly should not be written down, and they should not be accessible to system administrators. Critical passwords can be written down, stored in tamper-proof containers, and locked away where at least two signatures will be required for retrieval in case of emergency.

28.3.2 Risk of Undetected Theft. Perhaps the biggest intrinsic risk with passwords is that they can be stolen without knowledge of the user. Observation of someone typing in a password is sufficient to leak it. This can happen surreptitiously without the victim's explicit knowledge. A related risk is disclosure of a password to an attacker who persuades the legitimate user to reveal it by posing as a systems administrator who needs the password to do something beneficial for the user. Loss of a physical token eventually may be discovered, since it is missing, although the possibility of cloning these devices remains. Loss of a password, however, can be discovered only by detecting its misuse or by finding it in the possession of an unauthorized user (e.g., in a list of passwords cracked by using a dictionary-based *password-cracking* program, as described in Section 28.3.6).

There are several mitigations of this risk. First, user education and awareness are critically important. People need to treat important secrets with the care they deserve. In an unsafe environment, a password should be typed in discreetly. Efforts to be discreet should be positively reinforced while negligence in exposing passwords during entry should be considered akin to bad social behavior.

User education and awareness, although extremely important, can never be the whole solution. People will inevitably slip up and make mistakes. Some of us are more negligent than others. Others will be observed surreptitiously. In some cases passwords will be revealed to computers with Trojan horses (see Chapter 16 in this *Handbook*) that capture them. Technologists must pursue technical and human solutions to mitigate these risks.

Since some losses of control over passwords are inevitable, it logically follows that password-based authentication should be used only in situations where misuse detection is not only feasible but actually convenient to do in real time. To make this possible, the system architecture should centralize the information needed for misuse detection in one place. If the required information is dispersed across many servers, it will be difficult to coordinate the different audit trails. Traditionally, users of password systems have not considered the need for misuse detection. However, modern security is firmly based on a mix of prevention and detection techniques. Security professionals should apply similar thinking to authentication systems. Ease of misuse detection should be an important criterion in the design of any authentication system. For password-based systems, misuse detection capability should be considered an essential requirement. (For information on intrusion-detection systems, see Chapter 27 of this *Handbook*.)

What else can system designers do to mitigate this risk? It should be made easy for users to change their passwords themselves. Having a system administrator change a password that will be used more than once is illogical.

If a user feels that a password may have been compromised, changing it should be a simple matter. In particular, the system should never prevent a user's attempt to change a password. Some deployed systems will deny change of a password if the password was changed recently, say in the past 24 hours. Although there are reasons for this kind of restriction, it may create a bigger risk than the one it purports to prevent.

Users should be encouraged to change their passwords fairly often; a typical allowable lifetime for a password is between 30 and 90 days. Without occasional changes,

a compromised password could be held until the malicious attacker finds opportunity to use it. Frequent changes to passwords reduce the window of opportunity for such attackers.

28.3.3 Risk of Undetected Sharing. Another major risk of passwords is the ease with which they can be shared. There are many examples of sharing between executives and their secretaries, between physicians and office staff or nurses, between professors and their secretaries or students, and among coworkers in any activity. User education and strict policies against password and account sharing are obvious first steps to deter this possibility. Strict policies can be effective within an organization, but their deterrent effect may not carry over to large consumer populations. Misuse detection also can be employed to enforce a strict policy.

The root cause of password sharing within an organization is the lack of effective delegation mechanisms whereby selected privileges of one user can be delegated to another. Better authorization mechanisms could eliminate much of the perceived need for password sharing. It should be possible for secretaries to read their bosses' email under their own identities and passwords. In fact, the bosses should be able to segregate the email that the secretaries can read while denying access to more sensitive email. Moreover, reading the boss's email should be possible without allowing the secretary to send email under the boss's identity; a proxy privilege could allow secretaries to answer their boss's email while signing the replies with their own names. In the nonelectronic world, secretaries routinely answer mail for other people without impersonating them, and this should be the practice with computers as well.

Sharing of passwords among consumers is likely to occur when the cost to consumers is minimal. Although consumers are unlikely to share passwords for an online bank or brokerage account with others, they may be willing to share passwords for an online subscription service, possibly with many friends. A dishonest consumer may even make a business of reselling the service. One way to deter such piracy would be to tie exposure of the password to exposure of a sensitive secret of the consumer, such as a credit card number. Few people, criminal or not, would hand over a password that includes their own credit card number.

Another approach that reduces account sharing is one-time passwords that are generated by inexpensive tokens that have recently been distributed to consumers by Web merchants and banks (e.g., Citibank starting in May 2006) as a method for authenticating identity.¹ These tokens generate random passwords that change every minute or so and that can be traced to the specific unit that creates them—and that unit can be tied precisely to the original recipient. Not only does such a system make password sharing virtually impossible, but a shared password can be traced directly to the violator of the terms of use and result in legal action and fines. For more on one-time passwords, see Section 28.4.1.

28.3.4 Risk of Weakest Link. One of the frustrations of passwords is that users have to remember too many. Thus, users tend to repeat selection of the same password at multiple sites. This is a serious risk. Exposure of a user password at a poorly maintained site can lead to penetration of the user's account at numerous other sites. It is not easy to deploy technical measures to protect directly against this risk. A particular site can force a user to pick a complex password or can even choose the password for the user. However, it cannot prevent use of the same password elsewhere. This is one area where user education, awareness, and self-interest are paramount.

28 · 8 IDENTIFICATION AND AUTHENTICATION

Malicious attackers can set up rogue Websites easily, to entice users to register for attractive services, whereupon the user's password for other sites may be revealed.

Password safes are available in which difficult-to-guess passwords can be stored and accessed once a master password is supplied. These tools can be helpful, but they increase the importance of creating a suitable master password and of safeguarding it against discovery.

A technical solution to mitigate this problem is to avoid the requirement that a user has to register at multiple sites with user IDs and passwords. Instead, the user should register at a few trusted sites, but the user ID should be usable at multiple sites by secured sharing of assurances that the user has in fact been identified and authenticated sufficiently for business to continue. This is essentially what public key infrastructure (PKI) seeks to do. Once a user has identified him- or herself to a provider of such electronic credentials (client certificates), the certificate becomes a method for authentication. For example, some banks provide a service that allows a user to create a unique number that can substitute for their credit card number in a particular transaction. The user authenticates to the bank site, obtains a unique certificate that substitutes for the credit card number, and gives it to the merchant. The merchant can verify that it generates a valid transaction authorization, but never knows the original credit card number. With authentication based on client certificates, it is not necessary to expose a user's password to multiple sites. An effective marriage of passwords and PKI would reduce the exposure to the weakest link. For more details of PKI, see Chapter 37 in this *Handbook*.

A similar approach stores sensitive information in one place and then directs businesses to that place for payment information. For example, today a number of systems (e.g., PayPal) allow a user to register credit card information once, with a trusted service, and then pay online retailers (e-tailers) via that service.

28.3.5 Risk of Online Guessing. Authentication systems are susceptible to guessing attacks. In *online guessing*, an attacker tries to authenticate using a valid user ID and a guessed password. If the password has been poorly selected, the attacker may get lucky. The attacker also may be able to exploit personal knowledge of the victim to select likely passwords. This approach exploits the documented tendency of naive users to select passwords from lists of obvious words, family, friends, pets, sports, commercial brands, and other easily obtained information. For example, studies of password files consistently show that the most frequently selected password in the world is "password"; the second most frequent is the user ID itself or the user ID backward. An account with the same password as the user ID is often called a *Joe account*, as in User ID: joe; Password: joe.

Another kind of password vulnerable to guessing is a password assigned by default; for example, many software installations create accounts with the same password on all systems. Documentation usually warns users to change those *canonical passwords*, but many people ignore the warning. Canonical passwords are particularly dangerous when they grant access to powerful accounts, such as root accounts or to support functions.

The first line of defense against online attacks is to enforce password complexity rules, in addition to user education and awareness. Many systems today require a minimum of eight-character passwords with a mix of upper- and lower-case letters, numerals, and possibly special characters. Nonetheless, online guessing attacks are still possible, and system logging (see Chapter 53) or application logging (see Chapter 52) can be helpful in identifying successful impersonation. For example, log files may

show that a particular user has never logged on to a particular account outside working hours, yet someone has logged on as that user in the middle of the night.

Some systems react to online attacks by a simple rule that locks the account after a certain number of failed attempts. This rule may have been borrowed from a similar rule with ATM cards. The rule actually makes sense in the context of ATMs, with two-factor authentication based on possession of the card and knowledge of the PIN. However, in a password-only scheme, the “three strikes and out” rule can lead to denial of service to legitimate users. An attacker can easily lock up many accounts by entering three wrong passwords repeatedly, as discussed in Chapter 18 about denial of service in this *Handbook*. A more graceful rule slows down the rate at which password guessing can be attempted, so that a legitimate user may be perceptibly slowed down in authentication but not denied. For example, locking an account for a couple of minutes after three bad passwords suffices to make brute-force guesswork impractical.

In addition, intrusion-detection systems can be configured to alert system administrators immediately upon repeated entry of bad passwords. Human beings then can intervene to determine the cause of the bad passwords—user error or malfeasance.

28.3.6 Risk of Off-Line Dictionary Attacks. The paramount technical attack on password-based authentication systems is the *dictionary attack*. Such attacks start with copying the password file for a target system and placing it on a computer under the attacker’s control. The password file normally uses *one-way encryption* that allows the system to encrypt an entered password and compare it to the encrypted form of the legitimate password. If the two encrypted strings match, the entered password is presumably correct, and so the system authenticates the user ID.

The dictionary attack is described as off-line because the attacker obtains the necessary information to carry out the attack and then performs computations off-line to discover the password from this information. It is a guessing attack because the attacker tries different likely passwords from an extensive list of possible passwords (the *dictionary*). The list of likely passwords is called a dictionary because it includes words from one or more natural languages, such as English and Spanish; specialized versions used with *password-cracking* programs may sort words by frequency of use rather than alphabetically to speed up successful guesses.

The initial response to dictionary attacks was to stop users from selecting passwords that could be cracked via a dictionary attack. In essence, the system would try a dictionary attack; if it succeeded, it would prohibit the user from selecting this password. This is not a productive approach because attackers’ dictionaries are often ahead of the system’s dictionaries. The productive approach is to prevent the attacker from collecting the information necessary to carry out the dictionary attack.

Designers of password-based authentication systems were slow to recognize the risk of dictionary attacks. It has long been understood that passwords should not be stored on a server in cleartext because this becomes a single point of catastrophic failure. Time-sharing systems of the early 1970s stored passwords in a “hashed” form. Knowledge of the hashed form of a password did not reveal the actual password. Authentication of passwords was achieved by computing the hash from the presented password and comparing with the stored hash. The UNIX system actually made the hashed form of user passwords easily readable, since reversing the hash was correctly considered computationally infeasible. However, knowledge of the hashed form of a password is sufficient for dictionary attacks. The attacker guesses a password from a list, or dictionary, of likely passwords, computes its hash, and compares it with the stored hash. If they match, the attacker’s guess is verified; otherwise the attacker tries

28 · 10 IDENTIFICATION AND AUTHENTICATION

another guess. Since the late 1980s, UNIX systems have stopped making the file of hashed passwords easy to read, so this vulnerability has been reduced.

UNIX also introduced the concept of a *salt* to make dictionary attacks more difficult. The user password and a random number called the salt are hashed together and stored on the server. The salt itself is also stored on the server. To authenticate a user, the presented password and the stored salt are hashed and compared with the stored hash value. Use of a salt means that a separate dictionary attack is required for every user, since each password guess must be hashed along with the salt. Otherwise, the same attack could be run simultaneously against multiple presented passwords.

28.3.7 Risk of Password Replay. If a password is transmitted in cleartext from client to server, it is susceptible to being picked up on the network by an intruder. This is called *password sniffing*. Many systems require the password to be sent to the server in cleartext. Others require transmission of a hash of the password (usually without a salt). Transmitting the hash of a password is risky for two reasons:

1. The hash is sufficient for a dictionary attack unless a salt is used and kept secret.
2. The attacker does not even need to recover the password. Instead, the attacker can replay the hash of the password when needed.

Many existing systems are susceptible to sniffing of passwords on the network in cleartext or hashed form. Fortunately, technical solutions to this problem do exist.

One approach to the replay threat is to use the server's public key to encrypt any transmission of password-related information to the server: Thus, only the server can decrypt the information by using its private key. This is essentially what server-side Secure Shell (SSH) and Secure Sockets Layer (SSL) do. The server-side mode of both SSL and SSH require the server to have a public key certificate. The client-side mode of these protocols requires that the client also have a public key certificate. This approach can be effective but has its own risks.

An alternate approach is to avoid transmitting the password but instead to employ a protocol that requires knowledge of the password to run successfully. One of the earliest and best-known systems to take this approach is Kerberos. In this system, a user's password is converted to a secret key on the client machine and also stored on the Kerberos server. When the user requests authentication, the Kerberos server sends the user's machine a secret session key encrypted using the shared secret key derived from the user's password. The ability to decrypt this message correctly demonstrates knowledge of the password without actually transmitting it, in cleartext, hashed, or encrypted form. Unfortunately, the Kerberos protocol is susceptible to dictionary attacks; any client machine can pretend to be any user and can obtain the necessary information required for a dictionary attack.

Kerberos also does not use a salt, so the same dictionary attack can be applied to multiple users at one time. Kerberos Version 5 provides for a preauthentication option, which makes it somewhat harder to gather the information for a dictionary attack. The data are no longer available by simply asking the Kerberos server for them; instead they must be sniffed on a network. Recent experiments have shown that dictionary attacks on Kerberos are very practical, so this is a serious vulnerability of a widely deployed password-based authentication system.

Since the early 1990s, many password-based authentication protocols have been published that do not suffer from the dictionary attacks to which Kerberos is so

vulnerable. In particular, *zero-knowledge password proofs* are based on the idea that two parties (computers and people) can demonstrate that they know a secret password without revealing the password. These methods depend on the ability to establish that the two parties both independently selected the same number—but without knowing what the specific number is.² One popular conceptual model of this process is the zero-knowledge password proof, which runs as follows:

1. Two people want to test whether they share a secret number (in this thought experiment, a single digit between 1 and 10). In this example, the shared number is 3.
2. The two people have a deck of 10 blank cards.
3. The first person counts down to the third card and makes a mark on the right edge of that card.
4. The deck of cards is arranged so that the second person can mark the left edge of the cards but cannot see the right edge.
5. The second person also counts down to the third card (in this example) and marks the left edge.
6. The card deck is shuffled so that the sequence order is lost and then displayed to both parties.
7. If a single card has a mark on both the right edge and the left edge, then the two parties share the secret number, but neither had to reveal exactly which number it was.³

It will be interesting to see if this approach to authentication can be implemented on actual computers and if it is commercially used on a significant scale in the coming years.

28.3.8 Risk of Server Spoofing. As mentioned earlier, one widely used approach to preventing password exposure in transit on a network is to send passwords from client to server encrypted using the server's public key. The server, which has the corresponding private key, can decrypt the password to recover it. Knowledge of the public key is not sufficient for a spoofer to determine the private key. Naïve protocols for protecting the private key can be susceptible to replay attacks. However, there are two well-designed protocols in widespread use today.

Server-side SSL is the protocol that has been used by most Web surfers. In this protocol, the server's public key is used to secure transmission of the user's password from client to server. Like all public key-based schemes, the Achilles' heel of this protocol lies in authentic knowledge of the server's public key. The technology of public key certificates seeks to provide public keys with good assurance of the identity of the server to which they belong. A full discussion of issues with Public Key Infrastructure technology appears in Chapter 37, but it suffices to observe that there are pitfalls with the use of certificates for authentication of servers. A rogue server can collect a user's password by pretending to be something other than what it is. Relying on the look and feel of a Web page for server authentication is hardly sufficient, since it is easy to copy an entire Web page for use as a decoy and to establish confidence before capturing confidential information. An improvement on Website authentication is to associate a specific image and identifying strings (e.g., a picture of a hippopotamus labeled "Archie's Favorite Critter") with a user ID; the Website authenticates itself to

a specific user (e.g., Archie) by displaying that user's chosen image.⁴ Authenticity of the server's certificate can be spoofed in many ways that are hard for the user to detect, and manipulation of the trusted root certificates that are configured in the user's Web browser is possible. Moreover, while trust ultimately chains up to a root certificate, the owner of a single certificate below a trusted root is capable of considerable mischief. Server-side SSH is a similar protocol, typically used to provide secure remote access to UNIX servers. Server-side SSL and server-side SSH share the same fundamental vulnerabilities: Both can be spoofed by certificate manipulation. The use of server-side SSL to protect transmission of passwords from client to server is prevalent on the Internet today, but it is important for customers of authentication products to understand the risks inherent in this approach.

In the client-side mode of these protocols, there is no need for a password to be transmitted from client to server, since client-to-server authentication is based on the client's use of its own private key to generate a digital signature. Hence, client-side protocols are not vulnerable to password capture by server spoofing.

28.3.9 Risk of Password Reuse. The need to change passwords with some reasonable frequency is well recognized, but what is reasonable frequency? And how draconian should the enforcement be? It seems that security administrators have pushed too far on these questions. Forcing users to change passwords every month, and enforcing such rules ruthlessly, actually could lead to less security rather than more because so many frustrated users write down and store their ever-changing passwords in nonsecure places. There is a real risk here, created by well-meaning security administrators who have made the problem worse than it inherently is.

Systems that choose a password for the user have their own set of problems and are generally too user unfriendly to be viable in the Internet age. This discussion focuses on systems that allow users to select their own passwords.

How does exposure of a password increase with time? Even the strongest password-based system, with immunity to off-line dictionary attacks and password capture by server spoofing, faces increased exposure as time passes. Over a long period of time, a slow, ongoing, online guessing attack could be successful. Also, the likelihood of inadvertent disclosure by surreptitious observation, or exposure on a Trojan horse-infected computer, increases with time. Nevertheless, a good password, carefully chosen by the user to be safe from dictionary attacks and well memorized by the user, should not be changed casually. A change every six months may be appropriate for well-chosen, brute-force-resistant passwords.

Enforcing password changes is a complicated business, and one where the security community has not really done a good job. It is not difficult to keep track of the age of a password and to force a change when an appropriate time has passed. The difficulty is in forcing the new password to be independent of the old one. In fact, the likelihood is that the new password will be a slight variation of the old one. For example, appending the numeral designating a month to a fixed string enables users to have almost the same password, even if they are forced to change it every month. Some systems will keep a history of recently used passwords to prevent their reuse. A system that keeps a history of, say, five passwords can be fooled by rapidly changing the password six times. To prevent this, there are systems that will not allow a user to change password more than once a day. This has the unfortunate effect of actually increasing risk of password exposure, since a user who realizes that the current password may have been inadvertently exposed cannot change it, exactly when the need to do so is greatest.

28.3.10 Authentication Using Recognition of Symbols. An interesting new approach to user authentication is recognition of particular faces from among a large selection of random photographs. Passfaces software works in this way:

[A] user sets up an array of photographs and puts some familiar ones into the pool to use as keys—the faces of people the user recognizes; then the software can produce a 3×3 grid of random selections including one of the key pictures. The user picks out the familiar picture and then repeats the exercise twice more with new sets of eight strangers and one friend to authenticate the user.⁵

A white paper explains how human beings are particularly good at recognizing faces; indeed, it seems that we have special circuits that have evolved for rapid and accurate perception of faces. According to the paper, advantages of “using Passfaces over passwords” are that Passfaces:

- Can’t be written down or copied
- Can’t be given to another person
- Can’t be guessed
- Involve cognitive not memory skills
- Can be used as a single or part of a dual form of authentication

The power of the system is enhanced by setting parameters to interfere with misuse of the faces. For example:

In some high-security applications the grids of faces may be displayed only for a very short time. A half second is long enough for practiced users to recognize their Passfaces. Combined with masking (faces in a grid are overwritten with a common mask face) it is extremely difficult for “shoulder surfers” to learn the Passfaces as the user clicks on them.

28.4 TOKEN-BASED AUTHENTICATION. Token-based authentication relies on something that the user possesses that no other user of the identifier is supposed to possess or be able to access. This authentication can be achieved in many ways, including:

- Access cards
- Proximity and Touch Cards
- Smart cards and dongles
- One-time password generators
- Soft tokens

For details of authentication in physical-security systems, see Chapter 23 in this *Handbook*.

28.4.1 Card Entry Systems.⁶ The means of encoding identification data on the cards include optical bar code, magnetic stripe, smart cards with embedded chips that store biometric data, and cards with embedded bits of metal. Most bar codes are not secure; the cards are easily duplicated. Although the newer, two-dimensional bar codes are nearly tamperproof, they cannot store much information. Magnetic-striped cards also have many drawbacks: They cannot store much data, and they are easily

28 · 14 IDENTIFICATION AND AUTHENTICATION

altered, copied, or erased (often by accident). In time, the magnetic data decays and must be reprogrammed. Magnetic card readers are not practical outdoors, because of weather and vandalism. Heavily used magnetic card readers and the cards themselves wear out quickly.

Cards with embedded metal bits are effective. The encoding cannot be seen except by X-ray, and it is durable and permanent. The cards must be held against, or inserted into, a reader that scans the card for the position of each bit. They hold very limited data, the coding is factory installed and cannot be changed, and spare cards must be inventoried. In addition, with the right equipment, these cards can be copied.

Methods of using entry cards include proximity, touch, insertion into a slot that returns the card when it is authenticated, or swiping the card through a narrow channel or in and out of a slot. Swiping is fast, but the card must be hand held. Inserting a card has the same shortcoming as swiping and is slower. Wear, weather, or vandalism can damage the card and card reader.

28.4.2 Proximity and Touch Cards.⁷ The best of the new card access control systems use proximity or touch cards. These cards communicate with readers using infrared or microwave transmissions. The reading device powers some types of cards, while others contain miniature batteries. Physically, the cards and card readers are weatherproof, vandal resistant, and do not wear out. Proximity card readers can be surface mounted, recessed flush into a wall, or entirely concealed within a partition so that they do not call attention to a security door.

Touch cards are functionally similar to proximity cards, but they must be held briefly against a reader that is usually visible. Touch cards cost a little less than proximity cards and are good only for entrances with little traffic. The touch-card system is slower, and the cards more easily lost, stolen, or forcefully taken.

Proximity cards (which include RFID cards as well) may be used while concealed inside a pocket, handbag, or wallet. Some are worn concealed or hung on neck lanyards. A proximity card that is also an ID badge that everyone in the workplace wears at all times can access both doors and workstations without being touched. Temporary badges customarily are issued to all visitors, even when escorted, and can be used for access control and to monitor areas entered. Temporary badges are quickly activated with specific privileges and can be revoked automatically and immediately when necessary. Increasingly, the visitor cards are created quickly on site with the visitor's picture and perhaps biometric data as well printed on the card. Longer-term temporary badges can be issued to vendors, contractors, and external employees, although it is best that security personnel store visitor badges safely while the person is off the premises.

The new systems provide many useful functions. They are usually laminated and sealed to prevent wear, damage, or alteration. Individual cards are quickly prepared, activated, and canceled—all on site. The system can restrict entry to specific places, days, and times, and holiday restrictions also can be programmed. Any card can be locked out immediately if lost or stolen, or when the owner leaves.

The newer 13.56-MHz proximity cards function up to three feet away from the card reader; older cards were limited to a range of about four inches. The newer cards are also faster, hold more data, and offer more functionality. Many of the card readers also can write data to the card. There is a trade-off, however, between useful operating range and the amount of data stored. The farther the range, the less the data stored. Most proximity systems are adjustable to optimize distance and speed. For example, on outer perimeter doors, where quick, convenient access is more important than tight security, the systems are set for maximum range. Inner doors that need higher security

are adjusted to utilize more information and to function at a shorter distance, which is still far greater than the older systems allowed. It is not easy without very high-tech equipment, but proximity and touch cards can be compromised.

There are also self-expiring visitor badges that noticeably change color or prominently display the word “expired” after an elapsed period. Self-expiring badges are reusable and come with a fixed expiration period that is usually from two to 24 hours following each activation. These badges cannot be reactivated, except with very sophisticated equipment.

Cards are not the only proximity or touch devices. Keys or patches also are used. The keys can be small, rugged, and easily attached to a key ring or to a small handheld wand that a security guard might use. The patches work in place of touch cards, or with separate access control systems, to upgrade existing legacy systems. The patches are about the size and thickness of a quarter and are easily attached to anything a person normally carries, such as an ID card or badge, a pager or cell phone, or the inside of a wallet. The newer RFID devices will be even smaller.

Card access often is used for all equipment rooms containing servers, network components, or telephone gear; for off-hour access to information systems by users, technicians, and administrators; and for any areas where high-value items are stored. Card systems usually are integrated with premises security to control access to and egress from the building, elevators, service areas, parking, and restrooms, and other parts of the information infrastructure that can also take advantage of the access controls. Plan ahead and consider where additional access control points may someday be needed. Piecemeal additions at a later date can be costly.

Each entry into a controlled area should be logged in a way that cannot be compromised. Logs should provide an accurate audit trail of everyone who sought entry, when, and whether access was denied. Where stronger security is needed, each egress should be logged in the same way. The logging system is best monitored by software that can review all system data in real time, flag trouble quickly, issue periodic summary reports, and quickly search and summarize unusual events. Reviewing logs manually is a cumbersome, time-consuming task. If only manual auditing is possible, there must be a firm policy to do this every few days.

Token-based entry systems by themselves do not provide strong protection. Therefore, some degree of authentication is required.

28.4.3 Smart Cards and Dongles. Another form of token is a smart card. These cards can go into a PC card reader or can be read by a specialized reader. *Dongles* are smart cards that fit into input-output ports such as Universal Serial Bus (USB). A smart card has its own processing capability and typically stores a private key associated with the user. Often, a password or PIN is required to access the card, thereby providing two-factor authentication capability. The smart card enables user authentication by signing some challenge presented to it with the user’s private key. The signature is verified by means of the user’s public key. A complete discussion of such smart cards involves consideration of public key cryptography, public key certificates or so-called digital certificates, and supporting infrastructure or PKI (see Chapter 37 in this *Handbook*). Suffice it to say that smart cards have long been considered essential for widespread use of public key technology but so far have not been widely deployed.

Hardware tokens offer the potential for stronger authentication than passwords but have seen only limited use due to their perceived costs and their infrastructure requirements. Whether they can be deployed in a scale of millions of users remains to be seen. Authentication by tokens is really authentication by something that the

token knows. Since tokens can be programmed to remember and use secrets much more effectively than humans can, they offer the potential of strong cryptographic authentication, but tamper-proof tokens are not easy to produce. In recent years, attacks based on differential power analysis have proven effective in determining the secret keys and PINs stored on smart cards. These attacks require physical access to a card whose loss probably would be known, so although they may not always be feasible, they certainly call into question the presumed tamper-proof nature of smart cards. As smart cards are more widely deployed, other ingenious attacks are likely to be pursued. Smart cards are more susceptible to secret extraction than tokens because their computations leak such information in the form of electromagnetic radiation.

In comparing tokens with passwords, one can argue that undetected theft is easier with passwords. The token is a physical object whose absence is noticeable. However, tokens create their own problems. Like password generators, they are vulnerable to physical damage and compromise. Smart cards typically are built from thin plastic with a chip embedded in them, making the entire unit susceptible to failure from damage. In addition, users typically may store cards with other credit cards in a wallet or pocket, either of which presents additional environmental hazards. However, for certain industries, the cost of replacing lost or damaged tokens may be worth the reduction in undetected sharing, since a token can be used by only one person at a time.

28.4.4 Soft Tokens. The idea of *soft tokens*, or *software tokens*, has been proposed as a low-cost alternative to hardware tokens. Early soft tokens consisted of a user's private key encrypted with a password and stored on some transportable medium, such as a floppy disk. Such a scheme is extremely vulnerable to dictionary attacks because a guessed password can be verified easily (by testing a putative private key to see if it decrypts a message encrypted using the user's known public key). Moreover, the physical transport of floppy disks and the possible lack of floppy disk drives have led people to store these soft tokens on network servers so they are accessible as needed. Unfortunately, this location also makes them easily accessible to attackers. Protecting access to soft tokens on a network server by means of a password simply returns to the problems of password-based authentication.

It has been suggested that a user's public key could be kept secret and known only to trusted servers to avoid dictionary attacks on the encrypted private key. This approach comes at the severe cost of a closed PKI rather than an open PKI. Schemes for retrieving the private key by means of a secure password-based protocol have been published and are being implemented by some vendors. These schemes ultimately revert to password-based authentication as their foundation. Schemes based on splitting the private key into two parts have been developed. One part of the private key is computed from the password; the other part is stored on an online server, which functions as a network-based virtual smart card. Both parts of the private key are needed for user authentication but are never brought together in one place.

An alternative scheme would be to store the user's entire private key on an online server and make its use contingent on a secure password-based protocol. This approach allows the server to impersonate any user at will and may not be suitable in all environments. However, in all cases, the security of the token relies on the integrity of the computer that uses it. Newer implementations of soft tokens rely on asymmetric cryptography to eliminate the security concerns with storing private keys in a file or other transportable location. The soft token can generate its own key pair and exchange public keys with the authentication server. Although this increases the security of the soft tokens, the concept is inherently weak and prone to attack.

The U.S. Federal Government established a standard for the identity cards it has mandated for all federal employees and contractors. The original Homeland Security Presidential Directive 12 (HSPD 12), dated August 27, 2004, was entitled “Policy for a Common Identification Standard for Federal Employees and Contractors.” It defined these requirements for secure and reliable identification that—

- Is issued based on sound criteria for verifying an individual employee’s identity
- Is strongly resistant to identity fraud, tampering, counterfeiting, and terrorist exploitation
- Can be rapidly authenticated electronically
- Is issued only by providers whose reliability has been established by an official accreditation process⁸

28.4.5 One-Time Password Generators. A popular form of token, from vendors such as RSA Data Security Inc. and CryptoCard, displays a one-time password, typically a six- or eight-digit numeral, which changes each time an access button is pushed or when a given time has elapsed since the password was last used. The user authenticates by entering the user ID and current value displayed by the token.

The password is called one-time because it expires at the end of its allowable period for use. The token is typically contactless, in that it does not need electrical contact with the computer where the user is presenting authentication data. The user transfers the necessary information from the token via a keyboard or other input device. To make this a two-factor authentication, a fixed user password is also required in addition to the changing one-time password displayed by the token. These tokens are based on shared secret keys, so both the token and the server have a shared secret. The server and the token need to be initialized and then kept synchronized for this scheme to work. In the case of RSA’s SecurID, if the time discrepancy between a specific token and the authenticating system exceeds a specified limit, the authenticating software adjusts a value in an internal table to compensate for the time slippage. Vendors such as CryptoCard have developed event-based authentication algorithms to solve the “slippage” problem. These tokens use a seed with the algorithm to generate a unique value for each button push or other activating action. After the next login, that value is now “known” to the authenticating system, and a new value must be provided. The token’s value increments based on the seed, without requiring synchronization with the authenticating system.

Password generators must be protected against physical tampering. These devices typically include several measures to cause destruction of the electronic circuits if the outer case is opened; for example, in addition to epoxy-resin glue, tokens may include light-sensitive components that are destroyed immediately by exposure to light, rendering the unit unusable. Some password generators and smart cards cannot even be opened to replace batteries, so the entire card must be replaced on a predictable schedule. Tokens of this kind are available that are guaranteed to last one year, two years, or three years without having the batteries wear out.

28.4.6 Authentication Using Mobile Devices. Another form of token-based authentication increasingly available for access to restricted Websites such as bank account pages registers a mobile device such as a cell phone or a tablet that is capable of receiving Short Message Service (SMS) text messages. During login, the authorized user receives a one-time code to enter in the Web page. This approach puts

28 · 18 IDENTIFICATION AND AUTHENTICATION

additional value on security measures to protect the mobile device; for example, short timeouts requiring entry of a PIN, encryption of data in the device's memory, and methods for remotely inactivating or wiping the device if it is lost or stolen.

28.5 BIOMETRIC AUTHENTICATION. Biometric authentication looks like an excellent solution to the problem of authentication in cyberspace. However, there are several challenges in implementing biometrics, including drawbacks in accuracy (false-positive and false-negative results), loss of biometric identifiers, security of templates, and privacy concerns. For a full treatment of biometric authentication, refer to Chapter 29 in this *Handbook*.

28.6 CROSS-DOMAIN AUTHENTICATION. As more systems and processes become Internet enabled, people come to expect a seamless experience between organizations and applications across the Internet. Furthermore, the ever-increasing risk of identity theft has made individuals and organizations more careful about sending too much identity information across an untrusted network. Over the past several years, efforts have increased to enable easy but secure sharing of authentication and authorization information between organizations. Using the Security Assertion Markup Language (SAML), researchers are developing methods enabling one organization to share just enough information between systems to enable a transaction, without compromising privacy. Shibboleth, a project started in 2000 as an Internet2 middleware initiative, is an open-source project using SAML.⁹ Organizations using Shibboleth as a basis for designing new federated authentication and authorization implementations include InCommon¹⁰ and the UK Access Management Federation for Education and Research.¹¹ To facilitate this kind of information sharing, the participating organizations need to share details about their security policies and procedures, so each may decide in advance whether it will trust the authentication assertions of the other. This kind of information sharing is accomplished most effectively via the policies and practice statements used in a PKI. For details on PKI and certificate requirements for cross-domain authentication, refer to Chapter 37 in this *Handbook*.

28.7 RELATIVE COSTS OF AUTHENTICATION TECHNOLOGIES. One of the frequent responses from security professionals in discussions of identification and authentication using anything other than passwords is that the expense of buying new equipment is prohibitive. However, passwords are not free. In an analysis of the costs of managing passwords, RSA Data Security, makers of the SecurID token, estimated deployment costs (initializing user accounts) at about \$12 per user over three years and management costs (replacing forgotten passwords and resetting locked accounts) at about \$660 per user over three years. Worse yet, the well-established failure of most users to select strong passwords (i.e., those resistant to guessing, dictionary attacks, and brute-force attacks) makes passwords a weak authentication mode in practice. In comparison, token-based and biometric authentication are more readily affordable and more effective than passwords.¹²

28.8 CONCLUSIONS. Identification and authentication are the foundations for almost all other security objectives in cyberspace. In the past, these problems often were viewed as simple ones whose solution was assumed, before the real security issues came into play. Important standards for computer security were published and practiced without much attention to identification and authentication. In cyberspace,

the problems associated with I&A are severe, and they have barely begun to be solved effectively. A robust, scalable identification and authentication infrastructure is vital to achieving security. Technologies such as tokens and biometrics hold out considerable promise, but their deployment requires infrastructure costs dominated by the cost of hardware for readers and the like. Meanwhile, passwords continue to be strengthened, as we better understand the real risks in using them and as we develop technical means to mitigate those risks. The fact that modern operating systems continue to provide simple password-based authentication, vulnerable to dictionary attacks, reflects poorly on the pace at which security technology is adopted in the marketplace. Looking to the future, one can predict that we will see a mix of passwords, biometrics, and tokens in use, perhaps in two- or three-factor configurations. Biometrics and tokens are likely to dominate the high-assurance end, while passwords will dominate the lower end.

One of the misconceptions that security specialists should seek to dispel is that identification and authentication are *sufficient* for improving public safety. However, assigning a reliable and nonrepudiable identity to someone is in no way equivalent to asserting the trustworthiness of that individual. In closed populations such as employee pools, employers can check the background of potential employees and monitor the performance of existing employees; under those circumstances, knowing someone's identity at the entrance gate may indeed improve security. However, when dealing with a large number of unscreened people, such as potential air passengers, confidently being able to name them tells us nothing about their trustworthiness. Having a clerk at a government office glance at fuel-oil invoices and a birth certificate before granting someone a photo ID is no basis for assuming that the carrier of the valid ID is an inoffensive traveler. As several writers have noted, unambiguously knowing the name of the suicide bomber sitting next to you in a plane is not a reasonable basis for complacency. Timothy McVeigh, the Oklahoma City bomber, was a perfectly identifiable citizen of the United States, but he committed his atrocity nonetheless.¹³

Since September 11, 2001, the air transport industry has been a very public example of both the difficulty of strong identification and authentication and the use of identification and authentication as a public relations substitute for substantive security involving thorough passenger screening. The inherent difficulties of authentication are becoming evident to the lay public and to political and corporate leaders. It is very difficult, perhaps even impossible, to guarantee foolproof identification and authentication in free societies. As technologists, we realize that absolute guarantees cannot be achieved in cyberspace. Too many security professionals seek absolute goals, and too many security technologies are marketed as being stronger than they really are. Our profession will benefit greatly if we address practical problems with practical cost-effective techniques and develop a sound security discipline that contains, bounds, and mitigates the inevitable residual risk that we must face in any large-scale human situation.

28.9 SUMMARY. Passwords are widely used in practice and will continue to be a dominant form of user authentication. There are many risks in deploying passwords, and a number of widely used password systems have serious vulnerabilities. Nonetheless, technical measures can mitigate the inherent vulnerabilities of passwords. Although it takes great skill and care, with our current understanding it is technically possible to build and deploy strong password-based authentication systems using commercial products. The truly inherent risks of undetected theft and undetected sharing can be largely mitigated by new technologies, such as intrusion detection systems. Undetected

28 · 20 IDENTIFICATION AND AUTHENTICATION

sharing may be deterred further by a system that couples high-value secret data, such as credit card account numbers, with passwords. Tokens are available to generate one-time passwords or to communicate directly with authentication systems. Although costs have been dropping, tokens are still not as widely deployed as early predictions suggested they would be. Biometric authentication has been implemented only infrequently and on a small scale but offers great potential, especially for high-security applications. Interesting new research and applications are extending the use of authentication (and authorization) over untrusted networks between federated organizations.

29 · 2 BIOMETRIC AUTHENTICATION

29.1 INTRODUCTION. Once exclusively the purview of law enforcement, intelligence, and national security agencies, biometrics—the automated recognition of people based on their physiological or behavioral characteristics—has finally entered the business mainstream as a method of identification and authentication for access to physical and logical infrastructure. Once a pipe dream, biometric authentication technologies have substantially improved security, convenience, and portability over other commonly used methods of authentication. Adoption rates are still slower than some security professionals have desired; but falling costs, improvements in technologies, increased security needs, and changing government regulations are encouraging the adoption of biometrics.

29.2 IMPORTANCE OF IDENTIFICATION AND VERIFICATION. Ensuring the identity and authenticity of persons is a prerequisite to security and efficiency in present-day organizational operations. Intruders can damage physical and logical infrastructure, steal proprietary information, compromise competitive assets, and threaten organizational sustainability. Traditional methods of recognition and identification, wherein one individual identifies another based on his or her voice, physical appearance, or gait, are impractical, inefficient, and inaccurate in the scope of contemporary organizational operations. To address the need for rapid, efficient, and cost-effective authentication, organizations today primarily rely on the two methods of “something you know” and “something you have” (either applied individually or in combination) to verify the identity of persons accessing their physical and/or logical infrastructure. The most robust authentication systems use multiple factors of authentication. These forms of authentication are described in Chapter 28 in this *Handbook*.

29.3 FUNDAMENTALS AND APPLICATIONS. Biometrics are based on the measurement and matching of distinctive physiological and/or behavioral characteristics. The former are based on direct measurement of a physiological characteristic of some part of the human body. Examples of physiological biometrics include finger, hand, retina, face, and iris scans. The latter indirectly measure characteristics of the human body based on measurements and data derived from an action. Commonly used behavioral biometrics include voice and signature scan and keystroke pattern.

29.3.1 Overview and History. The use of nonautomated biometrics dates back to the beginning of human civilization, when individuals first began identifying other individuals based on certain physical or behavioral characteristics. The concept of biometrics as a means of authentication dates back more than 2,000 years. As early as 300 BC, Assyrian potters used their thumbprint as an early form of brand identity for their merchandise. The use of handwritten signatures (chops) in classical China is another example of an early biometric. In the first instance of a formal, legal biometric authentication system, fingerprints were used to sign contracts during the Tang dynasty (AD 618–906).

The development of contemporary biometric systems can be viewed as an outgrowth of the efforts of forensic scientists and law enforcement agencies to identify and classify criminals in the late nineteenth and early twentieth centuries. In 1882, Alphonse Bertillon introduced a system of body measurements called *anthropometry* to identify criminals. This system was proven unreliable because the measurements taken were not globally unique. A student of Bertillon, Edmund Locard, later proposed a fingerprint system based on the work of Sir Edmond Galton to identify people by analyzing unique points in fingerprint ridges and pores. Locard’s system, which used 12 Galton points,

is considered reliable to this day. This methodology underlies fully automated modern biometrics, including the Integrated Automated Fingerprint Identification Systems (IAFIS) used by law enforcement agencies. Commercial biometric systems (typically relying on hand geometry) designed for use in physical access to buildings, emerged in the 1960s and 1970s.

Biometric methods of identification and identity verification, including automatic fingerprint analysis and facial recognition technologies, have been available and used by some government/public agencies (e.g., law enforcement, intelligence, and national security) and a few private industries (e.g., facial recognition scans in casinos) since the 1960s and 1970s. Notwithstanding the potential benefits and advantages over other authentication methods, biometrics have not been widely applied, particularly in the corporate world. Analysts cite high costs of equipment and implementation, technological problems, vulnerabilities of specific biometrics, lack of standards, and user resistance (notably, concerns over privacy) as reasons for the lack of implementation.

However, beginning in the 1990s, significant improvements in biometric technologies, a movement toward standardization, regulatory changes requiring organizations to adopt stringent security and privacy controls, and significantly reduced costs have encouraged wider adoption. A number of U.S. Government agencies (e.g., Department of Homeland Security, Department of Transportation, Department of Defense, Customs and Border Protection, Department of Justice, National Library of Medicine) and businesses in certain industries (e.g., health care and finance) have significantly increased their use of biometrics during the past few years—a factor that is likely to encourage other organizations to adopt biometrics as well. HP and Lenovo offer fingerprint scanners on their notebook computers, enabling users to increase security by requiring a finger swipe and a password (or just a finger swipe) to access files. Other computer manufacturers and peripheral vendors have added fingerprint scanning to computer keyboards and/or developed standalone fingerprint scanners that connect to computers via a Universal Serial Bus (USB) port.

Some analysts see the 2001 attacks on the World Trade Center and the Pentagon also as a key impetus behind the increased usage of biometrics for authentication and identification. The terrorist attacks have been critical in encouraging adoption not only because they have heightened the security concerns of companies and agencies but also because the impact and implications of the terrorists' attacks seem to have lowered users' resistance to the use of biometrics by employers and government. In other words, in the same way that the threat of global terrorism reduced public objections to possible infringements on civil liberties as a result of implementation of the USA PATRIOT Act and other security-focused measures, these attacks also appear to have rendered many people less sensitive to the potential privacy-invading implications of biometrics. Boroshok reported in 2007 that a survey sponsored by AuthenTec found that 71 percent of U.S. consumers would pay more for biometric security options in their cell phones and 63 percent of consumers would pay an additional cost for these options to be added to their personal computers.¹

The changing security environment has prompted forecasts of rapid growth in biometrics. In 2004, the International Biometric Group (IBG) had predicted rapid growth for the biometrics industry over the next several years from revenues totaling under \$50 million in 2004 to revenues of almost \$200 million in 2008.² In late 2003, analysts at the San Jose, California-based market research firm Frost and Sullivan predicted that biometric applications from commercial applications (not including the Federal Bureau of Investigation's IAFIS) would jump from \$93.4 million in 2001 to \$2.05 billion by 2006—up from the \$700 million (in 2006) that these analysts predicted prior

29 · 4 BIOMETRIC AUTHENTICATION

to the September 11, 2001, attacks. In January 2009, IBG released their most recent projections of market growth for the biometrics industry. They estimated that biometric industry revenues will grow from \$3.01 million in 2007 to over \$7.4 million by 2012.³ This is a far cry from their initial projected growth rate published in 2004, and may be attributed to a lack of standards, regulatory issues, and privacy groups that decried the invasion of their privacy by these devices (IBG hasn't publicly released a more recent report so we can't tell if these projections were met).

Despite rosy projections from industry analysts, adoption of biometric authentication systems continues to lag. Some firms continue to cite cost issues (though this is dwindling) and privacy concerns, while others point to problems surrounding biometric implementation in airports and among government agencies. Overall, surveys of companies indicate that forecasts of dramatic and rapid growth in biometrics implementation may be overstated.

This has been proven to be true by the recent 2013 Spending Priorities Survey put out by *InformationWeek*. Of the 513 businesses that responded to the survey, 13 percent had budget decreases from their 2012 budgets, with 43 percent having no change in their budgets—for many, it's a “do what you can with what you have” mentality. However, in spite of this, 58 percent of those surveyed wanted to improve their security overall.⁴ In another 2013 survey, however, the *InformationWeek* survey “Strategic Security Survey” revealed 52 percent of the more than 1,000 respondents wanted to increase their identity and password management practices.⁵ The seeming disconnect may be attributed to management wanting to keep costs down, and the ever-changing world of regulations—many are waiting to see what the landscape will look like when the dust settles.

A 2003 Forrester Research survey found that only 1 percent of companies had implemented biometric systems, just 3 percent had a biometric system rollout in progress, only 15 percent were testing biometrics, and 58 percent of those surveyed had *no plans* to try biometrics. Ten years later, we still have yet to see any substantial adoption of biometric authentication.

29.3.2 Properties of Biometrics. The contemporary meaning of biometrics emphasizes its automated aspects, which allow for deployment on a large scale. The most widely cited definition of biometrics is some variation of “the automatic identification of a person based on his or her physiological or behavioral characteristics.”⁶ The term “biometrics” generally is used as a noun to refer to the automatic recognition of persons based on their physical or behavioral characteristics. The term “biometric” can be used as a noun in reference to a single technology or measure (e.g., finger scan is a commonly used biometric) or as an adjective, as in “a biometric system uses integrated hardware and software to conduct identification or verification.”⁷

Biometrics have long been touted as a possible solution to the problems and vulnerabilities of other commonly used methods of authentication and identification. They represent sophisticated versions of the traditional means of identification, such as a guard allowing access to a user whom the guard recognizes by sight. Biometrics commonly are defined as automated methods of recognition/verification/identification of individuals based on some measurable physiological or behavioral characteristics, such as fingerprints, hand geometry, facial shape, iris pattern, voice, signature, and the like.

Whereas identification (ID) badges and keys authenticate the user based on something the user possesses, and passwords/personal identification numbers (PINs) authenticate the user based on what the user knows, biometrics allows authentication and identity verification based on who the user *is*. Because biometric methodologies of authentication actually base identification on physiological or behavioral “pieces” of the

user, biometrics represents the only form of authentication that *directly authenticates the user*.

Biometrics have a number of other obvious advantages over other commonly used authentication methods. Unlike an ID badge or a USB key, one cannot easily lose or misplace a fingerprint or other biometric measures. Likewise, unlike the case with passwords and PINs, one does not need to remember and one is not subject to forgetting a physiological or behavioral characteristic. Although biometric measures *can* be compromised, in general, a biometric is much more difficult to manipulate by stealing, forging, sharing, or destroying than other commonly used authentication tools. Biometrics also provide considerable convenience, as opposed to the hassle of memorizing dozens of passwords.

Although the initial costs are quite high, the implementation of biometric systems typically results in much lower administrative costs than other access methodologies due to fewer calls to the helpdesk for technical support to reset passwords, no need to issue replacement ID badges, and so on. For these and other reasons, biometrics are viewed as providing better security, increased efficiency, and more reliable identity assurance than other commonly used methods of authentication/identification based on what a user possesses or what a user knows.

In theory, almost any human physiological and/or behavioral characteristic can be used as a biometric measure. However, to fit within a viable, potentially accurate, and practical biometric system, the biometric used should also satisfy four other requirements offered by Jain⁸ and Bolle, Connell, Pankanti, Ratha, and Senior⁹:

1. **Universality.** Every person should have the biometric characteristic.
2. **Uniqueness.** No two persons should be the same in terms of the biometric characteristic. Jain proposed the somewhat lower standard of distinctiveness, defined as “any two persons would be sufficiently different in terms of the characteristic.”¹⁰
3. **Permanence.** The biometric should be relatively invariant over a significant period of time.
4. **Collectability.** The biometric characteristic should lend itself to quantitative measurement in a practical manner.

Bolle, Connell, Pankanti, Ratha, and Senior argued that the biometric should also have a fifth attribute: acceptability, defined as “the particular user population and the public in general should have no strong objections to the measuring/collection of the biometric.”¹¹ Jain argued that a practical biometric system should consider two other attributes: (1) performance, which is “the achievable recognition accuracy and speed, the resources required to achieve the desired performance, as well as the operational and environmental factors that affect the performance,” and (2) circumvention, which “reflects how easily the system can be fooled using fraudulent methods.”¹² Along with this line of thinking, we find that the BYOD explosion among the workplace is opening an avenue for identity and access management. With the acquisition of AuthenTec by Apple in 2012, suppositions were running amok with the proposition of a new mobile-enabled biometric device for use inside and outside the enterprise. While the BYOD era has brought about the “acceptability” attribute, Jain’s idea of the proper operational and environmental factors are still there—how largely this will be accepted will be determined by how well these can be managed and centralized using IAM systems.¹³

29.3.3 Identification, Verification, and Authentication. Biometrics can be used to fill several roles related to identification and authentication (for more

background on those concepts, see Chapter 28 in this *Handbook*). These roles are often conflated in the use of the term *biometric authentication*, when in fact the system using the biometric data may be performing identification, verification, or authentication... or some combination of these. To avoid confusion in the use of terms, it is important to distinguish the various ways in which biometrics are used.

Identification systems answer the question, *Who do you claim to be?* They allow for selecting a single subject from a possible group of subjects based on the presentation of the identifying information. Identification systems often are referred to as *1: N* (one-to-*N* or one-to-many) systems because the subject's biometric information is compared against multiple (*N*) records in the attempt to determine which one is a match. This kind of system has application in searching for a positive match (such as the facial recognition one might want to do in airports or stadiums for finding terrorists), as well as a negative match (designed to ensure that a person's biometric information is *not* present in the database, such as preventing people from enrolling more than once in large-scale benefits programs). But biometric identification also can serve as a convenient substitute to entering a username or swiping a card to proffer a claim of identity to an automated entry or logical access control system.

Verification systems answer the question, *Are you who you claim to be?* They attempt to match proffered information (passwords, token identifiers, or biometric data) with previously registered ("enrolled") credentials stored in the system; the match to be attempted is selected by a specific user identifier (ID) presented by the subject. Biometric verification systems are referred to as *1:1* (one-to-one) systems because, while they may contain thousands or even millions of biometric records, they are "always predicated on a user's biometric data being matched against only his or her own enrolled biometric data."¹⁴ Thus, the presentation of biometric information is intended to confirm (or authenticate) the veracity of the subject's claim to the presented identity.

Whether one of these biometric systems qualifies as an *authentication* system depends on the implementation. A biometric verification system, which pairs a user ID with biometric information, always performs both identification and authentication. In that case, the biometric data is being used in place of a known password or the output of an authentication token, and may increase security by avoiding some of the vulnerabilities that plague other authentication credentials. A biometric identification system, on the other hand, does not always perform authentication. It *may* also fill the role of an authentication system if additional authentication factors (such as a PIN) are presented to confirm that the biometric information is in fact being presented by the subject the system identifies as being linked to the information. Without a second piece of information to confirm the linking, the use of a biometric identifier substitutes for the presentation of other user identifiers (such as typing in a user ID), and in this sense is not performing authentication.

It may be argued that because biometric data refers directly to some part of a subject's body or to an observable characteristic of the subject's behavior, presentation of biometric credentials should be considered a form of direct authentication. On this line of argument, in the same way that a security guard recognizes authorized employees at the gate in a combination identification/authentication action, a biometric identification system is in a sense authenticating the subject. This argument, however, glosses over the vulnerabilities that can plague both approaches: the guard can be fooled through disguises, can misidentify siblings (especially twins), or can simply miss a sufficiently similar face. Similarly, the automated biometric identification system can be fooled by spoofed credentials, as well as failing to distinguish between very similar biometric data. Relying on the single biometric presentation for both identification and

implicit authentication is certainly quicker and more convenient, but may introduce risk that should be mitigated by a second authentication factor.

Biometric identification systems are more difficult to design and implement than verification systems because of the extensive biometric database search capabilities needed. Additionally, identification systems are more subject to error than verification systems, because many more matches must be conducted, matches that increase the opportunity for error. Verification systems are overall much faster (often rendering a match/no match decision within less than a second) and more accurate than identification systems. Verification systems, as opposed to identification systems, predominate in private sector applications, particularly for computer and network security applications. Verification systems also predominate in applications designed to authenticate rights-to-access to buildings and rooms, although sometimes identification systems are also deployed in high-security environments. Identification systems are often found in public sector applications, such as law enforcement (e.g., parole and prison administration, forensics, etc.), large-scale public benefits programs, intelligence, and national security applications.

29.3.4 Application Areas. Although there are many potential applications for biometrics, the primary ones can be divided into four categories: systems security (logical access systems), facilities access (physical access systems), ensuring the uniqueness of individuals, and public identification systems. The common thread among these four applications is that they all rely on individuals enrolled in the systems. The significance of whether individuals are enrolled or not enrolled will be explained in Section 29.3.5.

29.3.4.1 Security (Logical Access Systems). Logical access systems “monitor, restrict, or grant access to data or information.”¹⁵ Examples include accessing a computer or network or accessing an account. In these systems, biometrics replace or complement PINs, passwords, and tokens. The volume and value of electronic commerce plus the value of sensitive and personal information transported and/or stored on networks and computers make the use of biometrics to secure logical access a much more robust industry segment than physical security.

The use of biometric technologies for logical access control is still very much in its infancy. The most common biometric approach is to use fingerprint readers, either with a stand-alone USB reader or with a reader embedded in a laptop. Manufacturers are beginning to incorporate the Trusted Platform Module (TPM) chip in new laptops to support a variety of cryptographic applications. In combination with biometric devices like fingerprint readers, the TPM chip can allow applications like Microsoft’s BitLocker to apply biometric access control to encrypted volumes on a hard drive. Such technologies are still new enough to suffer problems with backward compatibility and inter-vendor support, but they offer the promise of much more secure logical access.

29.3.4.2 Facilities Access (Physical Access Systems). Facilities access systems “monitor, restrict, or grant movement of a person or object into or out of a specific area.”¹⁶ In these systems, biometrics replace or complement keys, access cards, or security cards, allowing authorized users access to rooms, vaults, and other secure areas. Physical access systems often are deployed in major public infrastructure settings, such as airports, security checkpoints, and border facilities, in order to monitor and restrict movements of unauthorized or suspicious persons. In addition to entry to secure rooms, physical access systems, when applied in business settings, include

29 · 8 BIOMETRIC AUTHENTICATION

time-and-attendance systems by combining access to a location with an audit of when the authentication occurred.

Biometric technologies have been in use for physical access control for some time but still represent a range of possible implementations, from stand-alone fingerprint-reading door locks to complete systems with central storage of biometric templates, logging, and power failure protection. Selecting a system from within such a wide product range must fit into the overall security stance of the facility, particularly in regard to the storage of templates. In a simple stand-alone door system, for example, fingerprint templates would be stored in or near the locking device, and the system might not have any logging features. Unless coupled with surveillance and intrusion alarms anticipating physical compromise, these devices are more appropriate for lower security applications, such as storage facilities where physical key access might not be preventing theft. More centrally connected systems, however, offer greater integration into overall monitoring and control of access but suffer from communication and power issues as they push templates across a network. Selecting a product that interacts well with other parts of the overall access control system is crucial.

29.3.4.3 Ensuring the Uniqueness of Individuals. Uniqueness biometric identification systems typically focus on preventing double enrollment in programs or applications, such as a social benefits program. The main use of this application occurs in the public sector, although similar systems could be implemented to prevent double enrollment in employee benefits programs.

29.3.4.4 Public Identification Systems. A final biometric application of note is its use to identify criminals and/or terrorists. Criminals and terrorists can wear disguises, acquire fake documents, and change their names, but biometric data are fairly difficult to forge. In 2004, the United States Department of Defense started the Automated Biometric Identification System (ABIS), which collects biometric data on Iraqi insurgents in a manner compatible with IAFIS. This allows for identification of known repeat offenders and wanted persons. Soldiers also use the Biometric Automated Toolset (BAT) developed by the Army's Language Technology Office to identify persons on the scene of bombing attacks. Anyone present in the area can be cross-referenced with an existing database of insurgents. The BAT is also used to enroll and identify members of the Iraqi army. Although biometric systems hold much promise, it is also important to understand there are still limitations of current technology, but with the advent of nanotechnology, many of these are quickly being overcome.

29.3.5 Data Acquisition and Presentation. As Jain explains, "A biometric system is essentially a pattern recognition system that operates by acquiring biometric data from an individual, extracting a feature set from the acquired data, and comparing this feature set against the template set in the database."¹⁷ The starting point for the biometric system is *enrollment*: A user's biometric data are initially collected and processed into a template, the form in which they are then stored for ongoing use. As Woodward, Orleans, and Higgins explain, "Templates are not raw data or the scanned images of a biometric sample, but rather they are an accumulation of the distinctive features extracted by the biometric system."¹⁸ Liu and Silverman describe the template as "a mathematical representation of biometric data. A template can vary in size from 9 bytes for hand geometry to several thousand bytes for facial recognition."¹⁹ Templates are proprietary to each vendor and technology with little or no interoperability between systems. This lack of interoperability is attractive from a privacy perspective

but unattractive from the perspective of cost effectiveness and the prospective implementer who is concerned about committing significant investment to a single nonstandardized technology.

The term “presentation” refers to the process by which a user provides biometric data to an acquisition device by looking in the direction of a camera, placing a finger on a pad or sensor, or some other specified physiological exam. For purposes of verification or identification, the user presents biometric data, which are then processed and converted to a template. This template is an extraction of distinctive features and is not adequate for the reconstruction of the original biometric data. The scanned template is then matched against the stored enrollment template(s). Each time a user makes a presentation, a new template is created and matched. It is important to note, especially from the perspective of privacy concerns, that biometric systems do not store raw biometric data; instead they use the data for template creation and, in most cases, discard the biometric data. The biometric system’s match/no-match decisions are based on a score, which is “a number indicating the degree of similarity or correlation resulting from the comparison of enrollment and verification templates.”²⁰ Like the templates, the scoring system is based on proprietary algorithms; there is no standard system.

29.4 TYPES OF BIOMETRIC TECHNOLOGIES. As previously noted, biometrics generally can be grouped into two categories: physiological and behavioral. The International Biometric Group provides data on comparative market share of various biometric technologies. The IBG data focus on market share from commercial and government applications. The top eight biometric technologies are all from the physiological category (see Exhibit 29.1).

Five of these biometrics are discussed in detail in the next sections.

29.4.1 Finger Scan. Finger scan or fingerprint technology is by far the most widely deployed biometric technology. Finger scan’s number-one status as a biometric is maintained even if the extensive use of fingerprinting by law enforcement agencies is excluded. The type of fingerprinting employed in commercial biometric systems differs from the one used in law enforcement. In most commercially available biometric applications, the station provides only for the scan of a single finger on one hand, whereas

EXHIBIT 29.1 Comparative Market Share of Biometric Technologies by 2015

Market Share	
Biometric Technology	2015 (projected)
Finger scan	15%
Facial scan	15%
Hand scan	1%
Iris scan	16%
Vein	10%
Voice	13%
Signature	10%
AFIS/Livescan	16%

29 · 10 BIOMETRIC AUTHENTICATION

law enforcement agencies often rely on full sets of fingerprints. In addition to being the most widely used biometric, fingerprinting is also one of the oldest and most well-researched biometric technologies. Because it is a widely used, well-documented, and mature technology, costs for the deployment of finger-scan-based technologies are relatively low. Single-quantity pricing for a workstation version with associated software can be as low as \$150; server versions are currently priced as low as \$50 per unit.

The strengths of finger scan are one of the principal reasons for its popularity and include:

- Wide use.
- Mature technology.
- Low cost.
- High ease of use. (Very little training is required to place a finger on a finger pad.)
- Ergonomic design. (Comfortable to use for most users.)
- Low error incidence. (False match rates are extremely low; crossover error rate is lower than voice scan and facial recognition, higher than hand geometry and iris scan.)
- Fast transaction times. (In most systems, authentication takes less than a second.)
- Capacity to be deployed in a wide range of environments (e.g., on workstations, doorways, indoors/outdoors).
- Ability to increase accuracy levels by enrolling multiple fingers.
- Can provide identification with a high level of accuracy (if properly configured to include multiple enrolled fingers) in addition to verification.

Despite its multiple strengths, finger scan is not without significant weaknesses. As Chirillo and Blaul note, some of this technology's weaknesses stem from the same factors that lend it its strengths. "Because fingerprint technology is one of the oldest and most well-known technologies, a good amount of information is publicly available on how to defeat it."²¹ A number of ways exist to foil finger scans and produce a false match (false accept), including the use of a dummy finger constructed of latex or other material, manipulation of the scanner so as to raise the latent print of the person who used the scanner previously, and even use of an actual finger that is no longer attached to a body. (Most finger scanners cannot discriminate between live and dead tissue.) Because of these factors, the security levels of finger scans are not actually as impressive as the low error rates seem to indicate. It should be noted that countermeasures could be taken to overcome the vulnerability of finger scans to fraud. For example, enrolling additional fingers makes fraud more difficult. To reduce the chance that the system will be foiled by synthetic or dismembered fingers, thermal and/or moisture scanners can be added to the sensors to detect finger temperature and moisture levels that would indicate the vitality of the finger.

Other weaknesses include:

- A scanner requires frequent maintenance because screens/sensors tend to retain an obstructing buildup of user skin oil and residue.
- Performance can deteriorate over time, both because of aging of the users (and wearing away of fingertips) and because of the need for system maintenance.
- Finger-scan biometrics are obviously not appropriate for users with missing hands or hand disabilities.

- Performance levels deteriorate among users who have hand tremors because the presentation of biometric data will be distorted.
- Performance levels also deteriorate when users' fingers are either overly dry (a certain amount of normal skin moisture is needed for an accurate reading) or overly moist or oily (as from too much hand lotion).
- There is a small but significant failure to enroll (FTE) rate even among a population with hands and without disabilities. The FTE rate for finger scans is estimated at 2 to 10 percent and is attributed to persons with genetically indistinct prints, scarred fingers, dry skin, and fingerprints worn down by age and/or manual labor.

Perhaps the biggest weakness of finger scan, however, has nothing to do with the accuracy and reliability of the technology. Instead, it relates to user acceptance. Because of the association of finger scans with law enforcement and criminality, often such scans are not readily accepted by users who dislike the technology's "taint" with forensic applications and who may worry that finger-scan biometric data will be used for other purposes.

According to Chirillo and Blaul, "Another reason fingerprint technology is not highly accepted is that it may require individuals to share or touch the same device that others touch."²²

29.4.2 Facial Scan/Recognition. Bolle, Connell, Pankanti, Ratha, and Senior note that "face appearance is a particularly compelling biometric because it is one used every day by nearly everyone as the primary means for recognizing other humans. Because of its naturalness, face recognition is more acceptable than other biometrics."²³ However, user acceptance of facial scans drops significantly when users discover that it has been used covertly. As Imparato observes, "Of all the biometric technologies currently in use, face recognition is arguably the most controversial."^{23, 24} Like finger scans, face recognition relies on the identification of unknown face images by comparison to a database of (known) face templates. Face recognition is used overtly in access control where it is used for one-to-one identification. This application yields relatively high performance because the environment is highly controlled and input data are predictable. Face recognition may also be used covertly in surveillance where it is used to locate people in crowds (one to many), albeit with mixed results. For example, the city of Virginia Beach, Virginia, has employed a face recognition system to identify known (pre-enrolled) felons for over five years, but has yet to identify a single criminal. A variety of facial recognition technologies, ranging from single image, video sequence, three-dimensional image, near infrared, to facial thermograms, are available.

Facial recognition offers these benefits:

- It has the capacity to leverage existing image acquisition equipment, such as digital cameras, Web, video, and the like.
- Because facial recognition is a software-based technology, it is often unnecessary to purchase new hardware, especially given the number of Closed Circuit Television (CCTV) and surveillance cameras in broad use.
- The lack of need for specialized hardware can help keep the cost of this technology down, assuming that high software costs do not counterbalance the savings from the hardware.
- It is the only biometric capable of identification at a distance without the subject's cooperation or even awareness.

29 · 12 BIOMETRIC AUTHENTICATION

- It is easy to use. All that is required is that the user (or target) look at the camera.
- It does *not* require the user to touch any device (a major objection for some users with finger scans and hand scans).
- When deployed in verification situations, facial scans have extremely low failure-to-enroll rates. (Unlike fingerprints, human faces are almost always distinctive.)
- They are capable of enrolling static images (e.g., photographs on driver's licenses), a factor that makes it possible to implement very large scale enrollments at a relatively low cost and in a brief amount of time.

Facial recognition systems have a number of serious weaknesses too. The predominant weakness (which derives from a combination of the technology's other weaknesses) is the low accuracy and high error rate of this biometric. Whether deployed covertly or overtly, facial recognition has the lowest accuracy rate among all five top biometrics. Tilted heads and low camera resolution still confounds the programs, as evidenced in the Boston bombings of 2013.²⁵

Evidence of the technology's low accuracy rate comes from a study at Palm Beach (Florida) International Airport that showed that the system failed more than 50 percent of the time to match the 15 employees who had enrolled in the database for a trial run. Out of 958 pass-throughs, the system matched the employees' faces just 455 times. Some studies suggest that accuracy improvements can be made in facial recognition systems, but these improvements will come at a very high cost. For example, a facial recognition software package from Visionics FaceIt resulted in impressively low error rates, as long as lighting conditions were perfect. The software costs \$30,000 for a three-camera system.

Other weaknesses include:

- False matches (false accepts) routinely occur in the case of twins, and most systems are insensitive enough for someone skillful at disguise and impersonation to trick the system into a false match.
- More likely than false matches, however, are false nonmatches (false rejects), which can occur as a result of facial expressions; changes in hairstyle, makeup, facial hair, significant changes in body weight, eyeglasses, and age-related facial changes.
- The acquisition environment can have a dramatic impact on facial recognition system accuracy. In particular, lighting, either too bright or too dim, can dramatically increase the error rate.
- The perceived threat to privacy. Overtly deployed facial recognition technologies (e.g., used for identification and access) are generally judged relatively unobtrusive and meet with a high level of user acceptance. However, covertly deployed systems, such as those used for surveillance, pose significant threats to privacy. This threat is generally viewed as much more serious than that posed by the other top biometrics.

29.4.3 Hand Geometry Scan. Hand geometry scans refer not to handprints or to any analogy of fingerprints but rather to the geometric structure (or geometric invariants) of the human hand. Nanavati, Thieme, and Nanavati explain that "hand-scan technology utilizes the distinctive aspects of the hand—in particular, the height and width of the back of the hand and fingers—to verify the identity of individuals."²⁶ The

leading hardware maker for this technology, Recognition Systems, Inc. (RSI), has a basic hand scanner that takes upward of 90 measurements from three to four enrollments to create a user template that includes length, width, and thickness, plus surface area of the hand and fingers. Newer systems include temperature-sensing mechanisms to ensure “live” subjects. All the components of a hand scan system (acquisition hardware, matching software, storage components) reside within a stand-alone device. Hand scans are a well-established biometric technology (they have been in widespread use since the 1970s), but compared to other leading biometrics, hand scans tend to be much more limited in their range of applications. Hand scans are used exclusively for verification rather than for identification because the hand measurements are not distinctive or specific enough to allow for identification applications. For this reason, hand scans are used mostly for physical access and time-and-attendance applications. In the latter case, they are used as a way to eliminate the problem of “buddy-punching” whereby one employee punches in or out for a coworker who is not present.

Hand scan technology has changed very little since it was first introduced over 30 years ago, so its strengths and weaknesses are well established. The principal strengths of the hand scan include:

- Operates in very challenging environments. (The equipment is typically unaffected by light, dust, moisture, or temperature.)
- Established and reliable technology.
- Ease of use. (Users simply stick their hand in the unit; placement matters little.)
- Resistance to fraud compared to other biometrics. (It would be difficult and time consuming to substitute a fake sample.)
- Small template size (as low as 9 bytes; much smaller than other biometrics, allowing for storage of thousands of templates in a single unit).
- Based on a relatively stable physiological characteristic.
- High level of user acceptance and lack of attached stigma.

Problems reported in using hand scans include:

- Limited accuracy (which in turn limits its use to verification not identification). The relatively low accuracy of hand scan (higher than facial recognition and behavioral biometrics but lower than finger and iris scans) is a result of the general lack of physical variety expressed in the hand as well as the relatively small number of features measured by hand scan.
- Comparatively large form factor (This limits the technology’s deployment in computer-oriented applications that require hardware with a smaller footprint.)
- Some people resent forced contact with possibly unclean surfaces.
- Ergonomic design limits its use by some populations (e.g., the disabled).
- Comparatively high cost. While the cost of palm scanners has come down to around \$500 for a USB model, enterprise level scanners are still a rather pricey unit, even with the increase in companies producing them.

29.4.4 Iris Scan. Iris scan technology uses the unique pattern formed by the iris—the colored part of the eye bounded by the pupil and the sclera—to identify or verify the identity of individuals. The iris pattern is unique, for even in the same

29 · 14 BIOMETRIC AUTHENTICATION

individual, no two irises are alike. The uniqueness of iris patterns has been likened to that of multilayered snowflakes. To put this into perspective, the chance of mistaking one iris pattern for another is 1 in 10^{78} ! Iris scans accomplish this by allowing for more than 200 points of reference for comparison, as opposed to the 60 to 70 used in fingerprints. The unique aspects of the iris make it an ideal biometric for high-security applications; enrolling both irises from the same individual can enhance the level of security. In addition to high-security physical access applications, iris-scan technology has been used in automated teller machines (ATMs) and banking kiosks. It is also now being used among police departments in handheld units to identify suspects, and is being introduced for such jobs as border crossings, and is being regularly used in India, Iraq, and Dubai.²⁷

The most important strength of iris biometrics is its accuracy, the most critical weakness of facial scanning. Of all the leading biometrics, iris technology has the lowest error rate and the highest level of overall accuracy. Other strengths of this biometric include:

- Ability to be used both for verification and for identification.
- Stability of its biometric characteristics over a lifetime.
- Relative difficulty to fake or spoof because it is an internal biometric.
- The fact that the iris is minimally subject to outside influences when compared to biometrics like fingerprints and faces.

The major weaknesses of the iris biometric concern user perceptions and problems in the user-technology interface. Other weaknesses include:

- Acquisition of the image requires moderate training and attentiveness: Users must stand still and look straight into the scanner with eyes open and unblinking.
- Users often report some physical discomfort with the use of eye-based technology, although less so than with retina scanning technology.
- Anecdotal reports also suggest a fairly high level of user psychological resistance to iris-scanning technology, with some users believing that the scanner will lead to eye damage.
- Can be adversely affected by lighting and other environmental conditions (although not to the extent of facial scanning).
- In some cases eyewear adversely affects performance (although many iris devices can scan people wearing glasses or contact lenses).
- Although the iris is a relatively stable biometric, it is affected by aging and disease.
- Relies on proprietary hardware and software technologies.
- Costs tend to be high compared to finger scanning, hand scanning, and many facial recognition systems.

On the other hand, the per unit cost of the leading hardware/software combination technology has dropped to as low as \$300 per seat, still higher than finger scans but significantly lower than the over \$5,000-per-seat price seen a few years ago.

29.4.5 Voice Recognition. Voice recognition biometrics “utilizes the distinctive aspects of the voice to verify the identity of individuals.”²⁸ Voice recognition

generally is classified as a behavioral biometric, although it actually combines elements of behavioral and physiological biometrics: “The shape of the vocal tract determines to a large degree how a voice sounds, a user’s behavior determines what is spoken and in what fashion.”²⁹ Stated somewhat differently, “voice is a behavioral biometric but is dependent on underlying physical traits, which govern the type of speech signals we are able and likely to utter.”³⁰ Because of comparatively low levels of accuracy and considerable user variability in voice dynamics, this biometric generally is used only for verification, not identification. Commonly deployed voice recognition systems can be divided into two types: text-dependent systems (the speaker is prompted to say a specific thing) and text-independent systems (the authentication system processes any utterances of the speaker), which provide a higher level of security because they are more difficult to spoof and provide better accuracy than text-dependent systems.

Strengths of voice recognition include:

- Capacity to leverage existing telephony infrastructure (as well as built-in computer microphones).
- Low cost when existing infrastructure is used.
- Ease of use.
- Interface with speech recognition and verbal passwords.
- High level of user acceptance. (This biometric does not suffer from the negative perceptions associated with all of the other leading biometrics.)

Weaknesses of voice recognition include:

- More susceptible to replay attacks than other biometrics.
- Accuracy levels are low compared to iris scanning, finger scans, and hand scans.
- Accuracy levels are negatively affected by ambient noise and low-quality capture devices.
- Accuracy, security, and reliability are challenged by individual variations in voice, such as speaking softly or loudly, hoarseness or nasality because of a cold, and so on.
- The stability of the biometric is affected by illness, aging, and other user behaviors including smoking.

29.4.6 Other Biometric Technologies. The five major biometric technologies just discussed collectively comprise the vast majority of biometric technology under deployment. Other biometric technologies that register on market share breakdowns are two of the behavioral type: signature scan and keystroke scan. Although both of these behavioral biometrics are well accepted (signature scanning more so than keystroke scanning), their usefulness is limited by their lack of accuracy.

Other behavioral biometrics under investigation include gait and lip motion. One physiological biometric that has received considerable attention because of its high accuracy and security rates is retinal scanning. However, most analysts believe that the problems associated with retinal scanning (lack of user acceptance, high cost, difficult and painful acquisition process) outweigh any advantages to this biometric. The consensus seems to be that iris scanning has replaced retinal scanning as the eye scanning biometric of choice.

29 · 16 BIOMETRIC AUTHENTICATION

The use of DNA as a biometric identifier has also been investigated, although it has significant weaknesses including the fact that DNA in body tissues (e.g., epithelial cells) can be obtained surreptitiously and transferred easily for nefarious purposes whereas the official methods of collection (e.g., taking blood samples) are relatively intrusive.

Other physiological biometrics that may prove useful in the future include body odor, skin reflectance, and ear shape.

29.5 TYPES OF ERRORS AND SYSTEM METRICS. All types of identification and authentication systems suffer from two types of errors: false accepts and false rejects.

29.5.1 False Accept. Also known as false match, false positive, or type 1 error, false accept is the likelihood, expressed as a percentage, that an imposter will be matched to a valid user’s biometric. In some systems, such as those that attempt to secure entry to a weapons facility, a bank vault, or a high-level system administrator account, the false match/false accept rate is the most important metric to watch. In other systems, such as a facial recognition system deployed by a casino in an effort to spot card counters, a high level of false matches may be tolerated.

29.5.2 False Reject. Also known as false nonmatch, false negative, or type 2 error, false reject is the probability that “a user’s template will be incorrectly judged to *not* match his or her enrollment template.”³¹ False nonmatches typically result in the user being locked out of the system. These false nonmatches can occur because of changes in a user’s biometric data, changes in how the biometric data is presented, and/or changes in the environment. Biometric systems are generally more susceptible to false rejects than they are to false accepts.

29.5.3 Crossover Error Rate. An important metric in biometric systems is the *crossover error rate* (CER), also known as the equal error rate (EER). This useful metric is the intersection of the false accept and false reject rates. In general, a lower CER indicates the biometric device is more accurate and reliable than another biometric device with a higher CER. Exhibit 29.2 provides a summary of benchmark test–based accuracy/error rates for the five most prevalent biometric technologies. Each biometric technology is rank-ordered from most accurate to least accurate based on CER.

EXHIBIT 29.2 Accuracy/Error Rates of Leading Biometric Technologies

Biometric	False Match Rate	False No-Match Rate
Iris scan	0.0001%	1.1–1.4%
Finger scan	0.02%	.6%
Hand scan	0.3%	3.0%
Voice (text independent)	2–5%	5–10%
Voice (text dependent)	2.0%	0.03%
Face scan	.1%	1–2.5%

Source: Based on data contained in Anil K. Jain (2008), “Biometric Authentication,” *Scholarpedia*, 3(6); 3716.

29.5.4 Failure to Enroll. Another critical metric in biometric systems is FTE. As Ashbourn explains, FTE refers to “a situation whereupon an individual is unable to enroll their biometric in order to create a template of suitable quality for subsequent automated operation.”³² Common reasons for failure to enroll include physical disability and a user whose physiological/behavioral characteristics are less distinctive than average. Nanavati, Thieme, and Nanavati observe that failure to enroll can be a major problem in “internal, employee-facing deployments” in which “high FTE rates are directly linked to increased security risks and increased system costs.”³³ A final important metric is the “transaction time.” Transaction time refers to “a theoretical time taken to match the live template against a reference sample.”³⁴

29.6 DISADVANTAGES AND PROBLEMS

29.6.1 General Considerations. Despite the many advantages over other commonly used authentication systems, the implementation of biometric authentication controls carries a number of risks and disadvantages. Even the most accurate biometric system is not perfect, and errors will occur. The error rates and the types of errors will vary with specific biometrics deployed and the circumstances of deployment. Certain types of errors, such as false matches, may pose fundamental, critical risks to organizational security. Other types of errors—failure to enroll, false nonmatch—may reduce organizational productivity and efficiency and increase costs. Organizations planning biometrics implementation will need to consider the acceptable error threshold. In any event, organizations deploying biometric authentication systems must not be lulled into a belief that they are invulnerable to errors and/or fraud. Certain biometric systems (e.g., iris scanning) are fairly impervious to fraud, while others (especially behavior-based systems) are much more susceptible to it. Facial scanning systems can be foiled with clothing, makeup, eyeglasses, and/or changes in hairstyle. Even relatively stable physiology-based biometrics like fingerprint scans can be defrauded with the use of rubber or gelatin fingers. Matsumoto outlines a gummy finger approach designed to fool even those countermeasures mentioned in Section 29.4.1.³⁵ The protein used has a similar galvanic response to flesh and, since it is very thin and attached to a live finger, has the correct temperature. In some cases, blowing warm air over the scanner may even raise the latent print of the intruder’s predecessor.

The deployment of commonly used authentication systems (i.e., ID badges, passwords, etc.) requires relatively little training, although one could argue that better training on the development and use of passwords would improve security. This limited need for training is not the case with most of the most commonly used biometric systems. Both systems administrators and users need instruction and training to ensure smooth operation of the system. Some biometric systems are exquisitely sensitive to intra- and inter-user variation in presentation and performance. Their effectiveness becomes substantially compromised and error rates substantially increase in cases of significant variation and/or irregular presentation. A related problem concerns user acceptance of the biometric system. Some users may object to the deployment of biometrics due to concerns over privacy and intrusiveness. In other instances, users may object to the deployment of biometrics and avoid optimal interface with the system because of safety and/or health concerns, general fears, and/or cultural and religious beliefs. For example, some individuals may be concerned that biometric systems that require them to touch a finger pad or hand pad will unnecessarily expose them to germs and place them at risk for illness. Some users may fear that eye scans will damage their

eyes. Other users may object to eye scans on the basis that the eyes are the window to the soul. Anderson notes that some persons may object to the use of biometrics due to a personal interpretation of religious doctrine.³⁶ Notwithstanding users' beliefs and perceptions about the biometric system, in many cases features or elements related to the users and/or the operating environment will influence the successful implementation and effectiveness of the system.

29.6.2 Health and Disability Considerations. Individuals with arthritis and/or certain other disabilities and physical limitations may be unable to enroll in systems and subsequently, to align themselves physically in an optimal position with respect to biometric sensors. For example, users with severe hand arthritis may be unable to place their hand firmly as required on the hand geometry sensor, and users with migraines and associated photophobia may find it physically too uncomfortable to look straight into the light sensor for the iris scan. Some disabled people may have to be excluded from biometric systems altogether. Some relatively minor disabilities, such as a slight tremor, may compromise a legitimate user's ability to gain access through certain biometric systems. Variations in physical size can also influence system accuracy. An iris scanner positioned for a standard height range may fail to capture images of either very short or very tall individuals, or in some cases an individual's hands or fingers may be either too large or too small to be read accurately in a hand or finger scanner. Likewise, individuals with neck and back problems may find it difficult to use some biometric devices, depending on the kind of positioning required. Systems that rely on behavioral biometrics such as voice or signature are particularly vulnerable to variations and irregularities in user characteristics. For example, users who speak too softly, too loudly, or too rapidly may cause system errors. Minor changes in users' health can affect some biometric readings. Excessive skin moisture or lack of skin moisture can impact finger scans.

Although one of the ideal properties of a biometric is its universality, in reality not everyone has the characteristic or has it to the same degree. For example, some people are born without distinct fingerprints. In other cases, users may have lost the distinctiveness of their fingerprints because of years of manual labor, use of certain chemicals, scarring, or the aging process. Anderson notes that "people with dark-colored eyes and large pupils give poorer iris codes."³⁷ Certain eye diseases and metabolic conditions may also reduce or negate the efficacy of eye scan authentication. Age has a significant impact on the user-biometric-system interface. Definite physiological changes are associated with the aging process and can result in poor template matching with the live biometric. In this case, reenrollment may be needed. Fingerprints are affected by the aging process as the skin becomes drier and more brittle; voice patterns change in tonal quality over time; and facial shape or appearance may shift with age. Overall, the acceptability of a biometric system will be lessened if there is the impression that implementation of the system discriminates against, or has an otherwise adverse impact on, the disabled, the ill, ethnic minorities, the elderly, and other protected or traditionally disadvantaged groups of users. Organizations must ensure compliance with the Americans with Disabilities Act when implementing biometric authentication systems. Compliance may involve providing alternative methods of authentication to those affected.

29.6.3 Environmental and Cultural Considerations. A broad range of factors in the operating environment can also impact the effectiveness and acceptability of biometric systems. User-related cultural, social, and behavioral factors can influence

system performance. For instance, the accuracy of facial scans can be compromised by users' changes in hairstyle, facial hair, and headwear as well as by changes in an individual's physical appearance because of significant weight gain or loss. The accuracy of voice/speech recognition systems is affected by the distance between the scanner and the user as well as by the volume of speech. Fingerprint recognition is impeded in cases when users' skin is too dry, whether the condition arises as a result of aging, skin disease, environmental factors, or occupation-related factors, such as frequent hand washing among healthcare professionals. Factors in the surrounding ambient environment may also affect the accuracy of the biometric system. Ambient lighting will influence accuracy and error rate in facial scans and, to a lesser extent, in iris scans. Noise levels can impede the effectiveness of voice recognition systems. Humidity and air temperature can affect the accuracy of fingerprint and hand scans.

29.6.4 Cost Considerations. Although the cost of biometric system implementation has fallen dramatically in the past few years, it is still a major barrier for many organizations. Costs vary significantly depending on the type of system. Recent reports suggest that newer fingerprint scanners can be purchased for as little as \$50 per unit; voice recognition systems can cost in excess of \$50,000. However, even the least expensive biometrics systems are likely to cost more than simpler versions of traditional authentication systems. Experts estimate minimum costs, including hardware and software, at \$200 or so per user and upward of \$150,000 for corporate-wide protection in a medium-sized business. Compounding the cost issues are problems related to the lack of clear standards and the lack of clear interoperability between various biometric authentication systems.

Many of the problems and difficulties with biometrics systems are likely to be corrected or significantly mitigated with technological improvements, better user and administrator training, and good control of environmental conditions. In other cases, problems can be overcome or ameliorated with the use of countermeasures, such as combining different types of biometrics, combining biometrics with traditional authentication systems, and so on. Two major concerns that will continue to loom large and deserve closer examination are biometric identity theft and user privacy.

29.6.5 Attacks on Biometric Systems. Although biometrics are much less vulnerable to attack than other authentication controls, they are not immune to fraud. Moreover, when a biometric identity is stolen or spoofed, it creates a much bigger problem than that created by the theft of an ID badge, USB key, or password because a biometric cannot be simply canceled and replaced. One of the principal advantages to using biometrics for authentication is their invariability over time. Consequently, when an imposter or intruder defrauds a biometric authentication system and creates a false match error, the entire biometric security system is defrauded and the individual authorized user's biometric integrity is compromised. Likewise, Prabhakar, Pankanti, and Jain note, "One disadvantage of biometrics is that they cannot be easily revoked. If a biometric is ever compromised, it is compromised forever."³⁸

A number of analysts believe that the ultimate solution to the problem of biometric identity theft lies in the development of "cancelable biometrics." Researchers at IBM have developed a prototype for the cancelable biometric that incorporates a repeatable distortion of the biometric. Similar in theory to the use of public and private keys for encryption, a unique distortion of the biometric is introduced at each enrollment. Therefore, if a user's biometric is compromised, only the one system is defrauded, not every system in which the user is enrolled.

29.6.6 Privacy Concerns. The use of biometric authentication controls raises significant privacy concerns, particularly in comparison to conventional authentication methods like passwords and ID badges. User objections to biometrics are often based on privacy concerns, sometimes articulated in terms of the user's sense of the intrusiveness of the biometric system. Anecdotal reports suggest that public perceptions of intrusiveness vary among different biometrics and in how biometrics are implemented. With regard to the latter, Nanavati, Thieme, and Nanavati³⁹ report that there is a greater risk of privacy invasiveness when:

- Deployment is covert (users are not aware of the system's operation) versus overt.
- The system is mandatory versus opt-in.
- The system is used for identification rather than verification.
- It is deployed for an indefinite duration versus fixed duration.
- It is deployed in the public versus the private sector.
- The user is interfacing with the system as an employee/citizen versus an individual/customer.
- An institution, not the user, owns the biometric information.
- The biometric data are stored in a template database versus the user's personal storage.
- The system stores identifiable biometric data versus templates.

A vivid example of the public's lack of acceptance of the covert use of biometric systems comes from the 2001 Super Bowl and the uproar that ensued after the Tampa Police Department deployed facial scanning technology for the purpose of picking out criminal suspects from the audience. In contrast, in the aftermath of the 2001 attacks on the World Trade Center and the Pentagon, there has been fairly widespread public acceptance of the use of facial scanning at airports in the United States.

Users generally view behavior-based biometrics, such as voice recognition and signature verification, as less intrusive and less privacy-threatening than physiology-based biometrics. Facial scanning is viewed as having a high potential for privacy invasion because of the capacity to deploy it without the user's knowledge and participation. Finger scans may be viewed as intrusive and privacy-invasive because of their association with law enforcement functions. The level of intrusiveness of the scanning technique appears to affect users' perception of privacy invasion, with iris scanning provoking more privacy objections than hand scanning. Civil libertarians and users also raise privacy objections over biometric systems that have the potential to uncover additional information about the user beyond the biometric identity. For example, finger scans, because of their capacity to be linked to large law enforcement databases of fingerprints, could be used to reveal information about the user's criminal background. Iris scans have the capacity to reveal confidential medical/health information about the user. Probably one of the most troubling privacy-related aspects of biometrics is the potential for large-scale linkage between biometric systems and the use of biometric data to facilitate large-scale national ID programs. Even though employers may design a biometric system for purely in-house use in order to facilitate verification of employee identities on corporate networks, federal regulations and laws such as the USA PATRIOT Act may eventually compel employers to surrender employees' private biometric data to government authorities.

In summary, the major privacy concerns associated with biometric deployments include:

- Users' loss of anonymity and autonomy
- Risk of unauthorized use of biometric information and/or unauthorized collection of biometric information
- Unnecessary collection of biometric information
- Unauthorized disclosure of biometric information to others
- Systematic reduction of users' reasonable expectation of privacy
- Potential for misuse on the part of overzealous or corrupt government agents

Many of these concerns can be generally lumped under the heading of "function creep" or "mission creep," wherein biometric systems designed for user authentication may, over time, be used for purposes not originally intended. An example of "mission creep" is the use of Social Security numbers (SSNs) for identification. The original Social Security cards were stamped "Not for Identification." However, many organizations (including the Internal Revenue Service) use SSNs for identification purposes.

Notwithstanding the privacy risks, supporters of biometric authentication systems argue that, properly deployed and with adequate best practice controls, biometric systems actually can function to enhance and protect privacy. Woodward, Orleans, and Higgins point out that "several newly developed biometric technologies use an individual's physical characteristics to construct a digital code for the individual without storing the actual physical characteristics," thus creating a sort of *biometric encryption* that can be used to protect the privacy of an individual's financial, medical, or other data.⁴⁰ Nanavati, Thieme, and Nanavati argue that "privacy-sympathetic" biometric systems can be designed.⁴¹ Such systems would:

- Have limited system scope.
- Eschew use of biometrics as a unique identifier.
- Limit retention of biometric information.
- Limit storage of identifiable biometric data.
- Limit collection and storage of extraneous information, while including "opt-out" provisions for users.
- Enable anonymous enrollment and verification.
- Provide means of correcting and accessing biometric-related information.
- Limit system access.
- Use security tools and access policies to protect biometric information.
- Make provisions for third-party audits.
- Disclose the system purpose and objective.
- Disclose enrollment, verification, and identification processes.
- Disclose policies and protections in place to ensure privacy of biometric information.
- Disclose provisions for system termination.⁴²

29 · 22 BIOMETRIC AUTHENTICATION

In contrast to this view, Alterman argues that the deployment of biometric systems and the use of biometric data for identification and verification are ethically questionable because they always entail a violation of privacy and autonomy. Alterman finds “something disturbing about the generalized use of biometric identification apart from the standard data privacy issue.”⁴³ He maintains that biometric data “has inherent moral value”⁴⁴ but does not go so far as to argue against *any* deployment of biometric identification or verification systems. Rather, he maintains that they must be judiciously implemented and deployed only with due consideration to users’ privacy concerns.

29.6.7 Legal Issues. Within the legal system, as mentioned, the question arises as to the validity of using biometrics. As many consider this to be an invasion of privacy on many levels, the actual definition of this should be briefly touched on.

According to current law, there are four separate categories of “invasion of privacy”:

1. An intrusion into your private life—this is usually done by someone attempting to secretly learn something about you.
2. A public disclosure of private facts about yourself by someone other than yourself.
3. The use of your name, likeness, or both for monetary gain without your consent.
4. Any publication placing you in a false light.

With biometrics, the primary concern seems to stem from the first, and sometimes the second categories. Possibly these fears (and valid concerns, in light of recent government mandates and actions) may be alleviated by only storing a digital template, or a marker similar to those used in algorithms, rather than the actual image. TSA has been forced to use scans that show only a resemblance of the person in the scanner, and not an actual naked picture. The company they were using up to this time could not comply with their software, and thus lost the contract. With this, the possibility of the government being kept on a leash and not infringing on our Constitutional rights becomes a bit brighter.

29.7 RECENT TRENDS IN BIOMETRIC AUTHENTICATION

29.7.1 Government Advances in Biometric Authentication. Although private-sector organizations are increasingly adopting biometric technologies for their authentication needs, the government (public) sector has led investment in biometrics. The 2001 terrorist attacks on the World Trade Center and the Pentagon, and the ensuing USA PATRIOT Act, have encouraged increasing government commitment to biometric technologies. The Department of Defense (DoD), the Department of Homeland Security (DHS), the Immigration and Naturalization Service, and the Department of Transportation are the government agencies most involved in the deployment of biometrics technologies. The DoD’s Common Access Card program involves putting biometric technology on a smart ID card.⁴⁵ The US-VISIT program under the DHS is another government program that incorporates biometrics (including face and fingerprint) into a smart ID card. Another DHS program, the Transportation Worker Identity Credential, incorporates biometric information in an ID card.

29.7.2 Face Scanning at Airports and Casinos. After the 2001 terrorist attacks on the World Trade Center and the Pentagon, most of the nation’s airports

moved to incorporate face-scanning technologies into their security systems. Most studies of the effectiveness of these systems, however, have revealed their high error rates and low accuracy rates.

Casinos utilize facial scanning systems to identify professional “advantage players” and cheats. Although this is largely unregulated in the United States, Canadian casinos must notify players regarding the use of such systems. Casinos share data on professionals and cheats. One firm has networked 125 casino surveillance operators in the United States, Canada, Puerto Rico, Aruba, and the Bahamas and provides real-time alerts and other information useful in identifying suspicious players. However, it is unclear as to how such systems may be affected by international law. Article 12 of the United Nations Universal Declaration of Human Rights guarantees that “[n]o one shall be subjected to arbitrary interference with his privacy, family, home or correspondence, nor to attacks upon his honor and reputation. Everyone has the right to the protection of the law against such interference or attacks.”⁴⁶ Whether this system amounts to arbitrary interference or an attack on one’s honor has not been addressed by the courts, but a case clearly could be made that covert use of such systems does so. A best practice for any surveillance system is informed consent. Organizations should clearly post notifications about the use of surveillance systems in order to protect themselves from legal challenges.

29.7.3 Increased Deployment in the Financial Industry. Usually slow to embrace new technologies, the financial industry is one of the leaders in the adoption of biometric authentication controls. Current deployments range from fingerprint scanners securing computer networks for brokers, to facial recognition systems at ATMs, to iris scanning for high-security access points. International Biometric Group projected that U.S. financial services firms would spend \$672 million in 2007 for various biometric deployments. One of the biggest deployments to date has been United Bankers’ Bancorporation (UBB) adoption of U.are.U, a fingerprint recognition system that allows UBB customers to automatically log onto UBB’s Website with finger scans versus passwords. UBB also adopted a fingerprint authentication system for its employees. Wells Fargo, Bloomberg Financial, and Janus Capital Management are other well-known financial firms that have adopted biometric authentication systems for employees and/or customers. Although some financial institutions have selected voice, iris, or facial-scan-based systems, most seem to be choosing finger-scan systems.

29.7.4 Biometrics in the Healthcare Industry. Spurred in part by new regulations that require healthcare institutions to ensure the privacy and security of patient records, healthcare companies have also been at the forefront in the adoption of biometric authentication. Among the major healthcare organizations that have moved to biometric authentication is the Mayo Clinic, which adopted a fingerprint ID system in 2002. The majority of healthcare institutions that have adopted biometric authentication systems have selected finger-scan ID systems. However, deployment of these systems in healthcare organizations has not met with the same success as seen in the financial services industry. Issues involving the potential transmission of illness via physical contact with the fingerprint scanner are not trivial. Additionally, error rates have been higher and accuracy rates much lower than expected. The major reason behind the high incidence of errors appears to be the particulars of the healthcare environment, especially the characteristics of the hands of the doctors, nurses, and other healthcare workers using these systems. Specifically, system performance appears to be undermined by the chronically dry hands of these workers, a condition resulting from

frequent hand washing and the use of alcohol-based hand sanitizers. Another problem has been the resistance to using the fingerprint technology by both nurses and doctors, who feel that it involves a privacy intrusion. Add to this the costs that are associated with tying a single sign on type of authentication to the core hospital system, and the problems escalate even higher. Cerner and EPIC seem to have the top programs in the healthcare industry, and both have been certified for all three Meaningful Use levels required by HIPAA and HITECH. Yet, these programs come at a hefty cost. Even barebones, a recent change for a hospital in Wyoming cost them \$4.5 million. While it was a change that needed to be done, it stretched their budgets to the very maximum, and several cuts were made to accommodate this.

29.7.5 Increased Deployment of Time and Attendance Systems. An increasing number of companies across many different industries are deploying biometric-based time-and-attendance systems. A shift from the past practice is in the increased use of biometric attendance and tracking systems for white-collar workers. Previously, the focus was on blue-collar factory workers. Although some employers are using the traditional hand-scanning systems, there appears to be a shift toward the use of finger-scanning time-and-attendance systems. This shift seems to be related to the more competitive pricing structure for the finger-scanning systems.

29.8 SUMMARY AND RECOMMENDATIONS. There is no universal “best” biometric authentication system. Each of the five leading biometric technologies carries specific advantages and disadvantages. Some biometric technologies are more appropriate for certain applications and environments than their counterparts. An organization in the midst of evaluating potential biometrics authentication implementation must recognize that there will be trade-offs in any selection, such as cost for accuracy, privacy versus user acceptance, and so on, and there are not yet any universal decision factors for selecting a particular biometric technology for a specific application. There is, however, substantial research into many of the advantages and disadvantages of biometrics. Exhibit 29.3 provides a summary comparison of the features of the five leading biometric technologies discussed in this chapter. The features, shown in the extreme left column, were excerpted from various researcher efforts, and the rankings represent an amalgam of the rankings found in the literature.

Although biometric authentication systems promise cost savings and higher levels of security for organizations, they are not a panacea. Many factors affect how well or poorly biometric authentication controls will perform in a given organizational environment. Included among these factors are the users, the administration, the environment, the infrastructure, the budget, the communication system, and the existing security needs. Although many biometric technologies are capable of operating as stand-alone systems, in reality their accuracy and performance levels would be greatly improved by combining them with more conventional authentication methods, such as passwords and keys. Such multifactor systems offer greater security and reliability.

In selecting a biometric authentication system and preparing for an implementation, organizations should focus on the user-technology interface and the conditions in the operational environment that may influence the technology’s performance. For example, the healthcare industry’s unreflective embrace of finger scan technology illustrates the dangers of failing to heed environmental realities. It is important that organizations consider not only the practical impediments to effective implementation but also the potential psychological impediments, such as user fears about the technology. Ethically, the organization also has the obligation to consider carefully the extent to which the

EXHIBIT 29.3 Comparison of Leading Biometric Technologies

	Finger Scan	Facial Scan	Hand Scan	Iris Scan	Voice Recognition
Accuracy	High	Low	Medium	Very high	Low to medium
Ease of Use	High	Medium	High	Low to medium	High
User Acceptance	Medium	High (overt) Low (covert)	High	Low to medium	High
Privacy Concerns	High	Very high (overt)	Medium	High	Very low
Cost	Low to medium	Low to medium	Medium	High	Low
Performance	High	Low	Medium	High	Low
Potential for Circumvention	Medium	High	Low to medium	Very low	High
Distinctiveness	High	Low	Medium	Very high	Low
Barriers to Universality	Worn ridges; hand or finger impairment	None	Hand impairment	Visual impairment	Speech impairment
Susceptibility to Changes in Biometric	Low to medium	Medium to high	Medium	Low	Low to medium
Susceptibility to Changes in the Environment	Low	High	Very low	Low	Medium to high
Error-Causing Factors	Age, trauma, degradation of prints	Lighting, contrast, pose, movement, expression	Hand injury or trauma, inability to place correctly	Positioning, eye angle, glasses, disease	Illness, age, quality of communication system, ambient noise
Mitigations for Potential Errors	Periodic re-enrollment, enrollment of multiple fingers	Frequent re-enrollment, multiple scans, controlled environment	Periodic re-enrollment, enrollment of both hands	Periodic re-enrollment, user training, enroll both irises	Periodic re-enrollment, control ambient noise

implementation of biometric authentication compromises the privacy rights of users. In making this assessment, management must take into account the possibility that the organization may be compelled to release employees' biometric-related information to government authorities.

Recent studies in biometrics include banks and other financial institutions having identified the use of voice biometrics over fingerprint identification as one of the best means to secure its client accounts and financial information. Voice biometrics compares various characteristics drawn from a client's voice such as inflection, pitch, dialect, accent and others, matching it with data previously captured, and securely stored. For this technology to work, however, it will require banks and other financial institutions to register their clients' voice patterns, correlate them to personal data, and place this into a database.⁴⁷ Other studies have reached agreements with major corporations to help within the healthcare industry, such as BIO-Key having executed an OEM agreement with Caradigm for use of BIO-Key's Identity and Access Management suite. Caradigm will offer this suite within its Single Sign On solution to help hospitals and other caregivers writing electronic prescriptions of controlled substances the ability to meet federal and state regulations.⁴⁸ Other areas of study within this field have covered such areas as a wearable biometric tattoo for identification purposes, vein recognition, and mobile platforms being used to promote its acceptance. In a 2011 report released by the Unisys Corporation, acceptance of these and other biometric technologies are gaining, but more slowly than anticipated.⁴⁹ Future use and acceptance may come about as technology advances, people become more accustomed to their use in everyday life, and legislation forces the use for security purposes.

30.1 INTRODUCTION. Today, electronic commerce involves the entire enterprise. The most obvious e-commerce applications involve business transactions with outside customers on mobile devices and the World Wide Web (WWW or Web), yet they are merely the proverbial tip of the iceberg. The presence of e-commerce has become far more pervasive, often involving the entire logistical and financial supply chains that are the foundations of modern commerce. Even the smallest organizations now rely on the Web for access to services and information.

The explosive growth of mobile applications in the past few years has integrated electronic transactions deeply in the minute-to-minute fabric of daily life. Walk down the street in any urban area, mobile devices have become ubiquitous. Nations which lacked wired infrastructure have skipped a technological generation and gone directly to a telecommunications infrastructure based on mobile phone technologies.

The pervasive desire to improve efficiency often causes a convergence between the systems supporting conventional operations with those supporting an organization's online business. It is thus common for internal systems at bricks-and-mortar stores to utilize the same back-office systems as are used by Web customers. It is also common for kiosks and cash registers to use wireless local area networks to establish connections back to internal systems. These interconnections can provide intruders with access directly into the heart of the enterprise.

The TJX case, which came to public attention in the beginning of 2007, was one of a series of large-scale compromises of electronically stored information on back-office and e-commerce systems. Most notably, the TJX case appears to have started with an insufficiently secured corporate network and the associated back-office systems, not a Website penetration. This breach escalated into a security breach of corporate data systems. It has been reported that at least 94 million credit cards were compromised.¹ On November 30, 2007, it was reported that TJX, the parent organization of stores including TJ Maxx and Marshall's, agreed to settle bank claims related to VISA cards for US\$ 40.9M.²

E-commerce has now come of age, giving rise to fiduciary risks that are important to senior management and to the board of directors. The security of data networks, both those used by customers and those used internally, now has reached the level where it significantly affects the bottom line. TJX has suffered both monetarily and in public relations, with stories concerning the details of this case appearing in the *Wall Street*

Journal, the *New York Times*, *Business Week*, and many industry trade publications. Data security is no longer an abstract issue of concern only to technology personnel. The legal settlements are far in excess of the costs directly associated with curing the technical problem.

Protecting e-commerce information requires a multifaceted approach, involving business policies and strategies as well as the technical issues more familiar to information security professionals.

Throughout the enterprise, people and information are physically safeguarded. Even the smallest organizations have a locked door and a receptionist to keep outsiders from entering the premises. The larger the organization, the more elaborate the precautions needed. Small businesses have simple locked doors; larger enterprises often have many levels of security, including electronic locks, security guards, and additional levels of receptionists. Companies also jealously guard the privacy of their executive conversations and research projects. Despite these norms, it is not unusual to find that information security practices are weaker than physical security measures. Connection to the Internet (and within the company, to the intranet) worsens the problem by greatly increasing the risk and decreasing the difficulty, of attacks. Ubiquitous mobile devices only serve to compound the difficulties.

30.2 BUSINESS POLICIES AND STRATEGIES. In the complex world of e-commerce security, best practices are constantly evolving. New protocols and products are announced regularly. Before the Internet explosion, most companies rarely shared their data and their propriety applications with any external entities, and information security was not a high priority. Now companies taking advantage of e-commerce need sound security architectures for virtually all applications. Effective information security has become a major business issue. This chapter provides a flexible framework for building secure e-commerce applications and assistance in identifying the appropriate and required security services. The theoretical examples shown are included to facilitate the reader's understanding of the framework in a business-to-customer (B2C) and business-to-business (B2B) environment.

A reasonable framework for e-commerce security is one that:

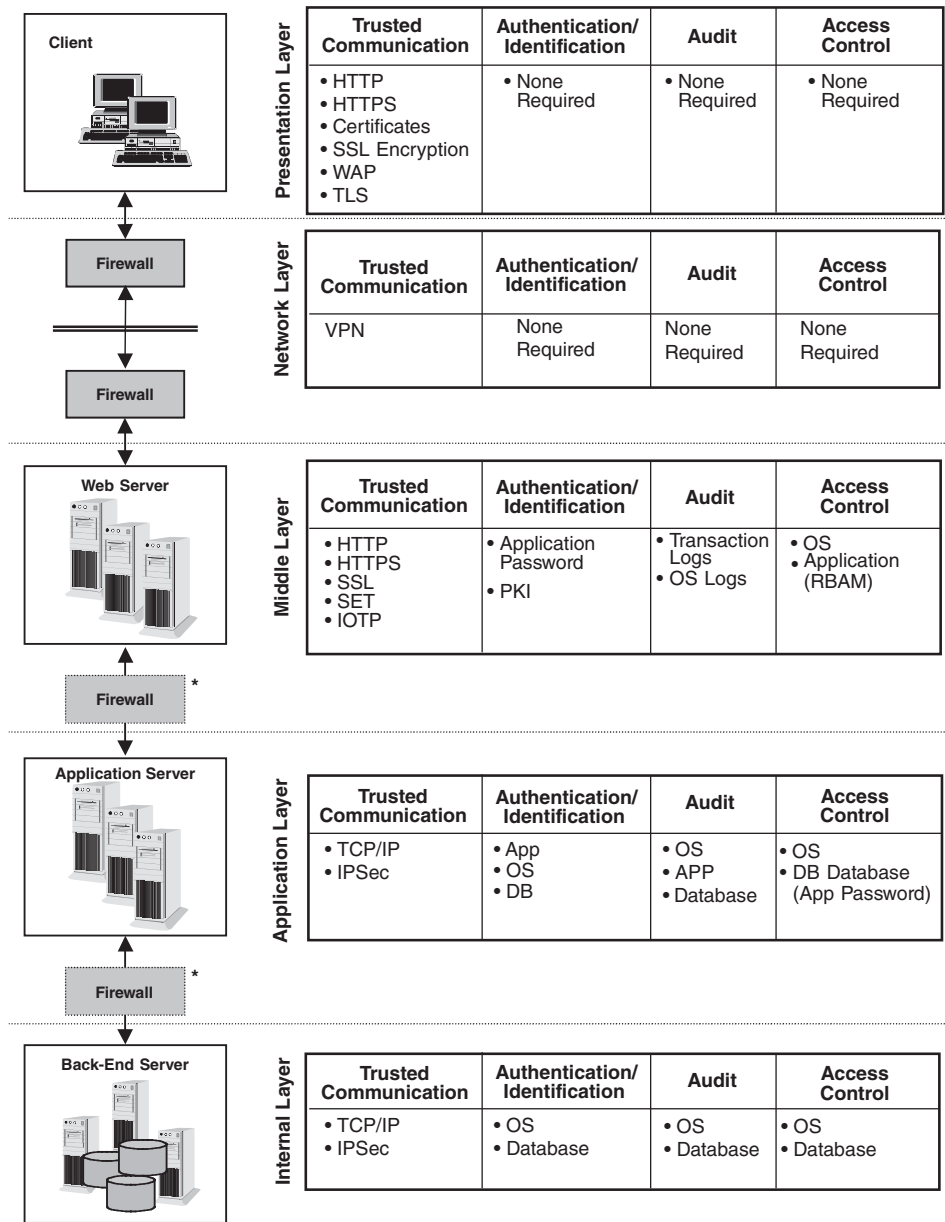

1. Defines information security concerns specific to the application.
2. Defines the security services needed to address the security concerns.
3. Selects security services based on a cost-benefit analysis and risk versus reward issues.
4. Ensures the ongoing attention to changes in technologies and requirements as both threats and application requirements change.

This four-step approach is recommended to define the security services selection and decision-making processes.

30.2.1 Step 1: Define Information Security Concerns Specific to the Application. The first step is to define or develop the application architecture and the data classification involved in each transaction. This step considers how the application will function. As a general rule, if security issues are defined in terms of the impact on the business, it will be easier to discuss with management and easier to define security requirements.

30 · 4 E-COMMERCE AND WEB SERVER SAFEGUARDS

The recommended approach is to develop a transactional follow-the-flow diagram that tracks transactions and data types through the various servers and networks. This should be a functional and logical view of how the application is going to work—that is, how transactions will occur, what systems will participate in the transaction management, and where these systems will support the business objectives and the organization’s product value chain. Data sources and data interfaces need to be identified, and the information processed needs to be classified. In this way a complete transactional flow can be represented. (See Exhibit 30.1.)

*Firewall should be between the web layer/application layer or the application/back-end layers depending on the company’s architecture.

EXHIBIT 30.1 Trust Levels for B2C Security Services

Common tiered architecture points include:

- **Clients.** These may be PCs, thin clients (devices that use shared applications from a server and have small amounts of memory), personal digital assistants (PDAs), and wireless application protocol (WAP) telephones.
- **Servers.** These may include World Wide Web, application, database, and middle-ware processors, as well as back-end servers and legacy systems.
- **Network devices.** Switches, routers firewalls, NICs, codecs, modems, and internal and external hosting sites.
- **Network spaces.** Network demilitarized zones (DMZs), intranets, extranets, and the Internet.

It is important at this step of the process to identify the criticality of the application to the business and the overriding security concerns: transactional confidentiality, transactional integrity, or transactional availability. Defining these security issues will help justify the security services selected to protect the system. The more completely the architecture can be described, the more thoroughly the information can be protected via security services.

30.2.2 Step 2: Develop Security Service Options. The second step considers the security services alternatives for each architecture component and the data involved in each transaction. Each architectural component and data point should be analyzed and possible security services defined for each. Cost and feasibility should not be considered to any great degree at this stage. The objective is to form a complete list of security service options with all alternatives considered. The process should be comparable with, or use the same techniques as, brainstorming. All ideas, even if impractical or farfetched, should be included.

Decisions should not be made during this step; that process is reserved for Step 3.

The information security organization provides services to an enterprise. The services provided by information security organizations vary from company to company. Several factors will determine the required services, but the most significant considerations include:

- Industry factors
- The company's risk appetite
- Maturity of the security function
- Organizational approach (centralized or decentralized)
- Impact of past security incidents
- Internal organizational factors
- Political factors
- Regulatory factors
- Perceived strategic value of information security

Several factors contribute to the services that information security organizations provide. "Security services" are defined as safeguards and control measures to protect the confidentiality, integrity, and accountability of information and computing resources. Security services that are required to secure e-commerce transactions need to be based on the business requirements and on the willingness to assume or reduce the risk of the

information being compromised. Information security professionals can be subject-matter experts, but they are rarely equipped to make the business decisions required to select the necessary services. Twelve security services that are critical for successful e-commerce security have been identified:

1. **Policy and procedures** are a security service that defines the amount of information security that the organization requires and how it will be implemented. Effective policy and procedures will dovetail with system strategy, development, implementation, and operation. Each organization will have different policies and procedures; best practice dictates that organizations have policies and procedures based on the risk the organization is willing to take with its information. At a minimum, organizations should have a high-level policy that dictates the proper use of information assets and the ramifications of misuse.
2. **Confidentiality and encryption** are a security service that secures data while they are stored or in transit from one machine to another. A number of encryption schemes and products exist; each organization needs to identify those products that best integrate with the application being deployed. For a discussion of cryptography, see Chapters 7 and 37 in this *Handbook*.
3. **Authentication and identification** are a security service that differentiates users and verifies that they are who they claim to be. Typically, passwords are used, but stronger methods include tokens, smart cards, and biometrics. These stronger methods verify what you have (e.g., token) or who you are (e.g., biometrics), not just what you know (password). Two-factor authentication combines two of these three methods and is referred to as strong authentication. For more on this subject, see Chapter 28 in this *Handbook*.
4. **Authorization** determines what access privileges a user requires within the system. Access includes data, operating system, transactional functions, and processes. Access should be approved by management who own or understand the system before access is granted. Authorized users should be able to access only the information they require for their jobs.
5. **Authenticity** is a security service that validates a transaction and binds the transaction to a single accountable person or entity. Also called nonrepudiation, authenticity ensures that a person cannot dispute the details of a transaction. This is especially useful for contract and legal purposes.
6. **Monitoring and audit** provide an electronic trail for a historical record of the transaction. Audit logs consist of operating system logs, application transaction logs, database logs, and network traffic logs. Monitoring these logs for unauthorized events is considered a best practice.
7. **Access controls and intrusion detection** are technical, physical, and administrative services that prevent unauthorized access to hardware, software, or information. Data are protected from alteration, theft, or destruction. Access controls are preventive—stopping unauthorized access from occurring. Intrusion detection catches unauthorized access after it has occurred, so that damage can be minimized and access cut off. These controls are especially necessary when confidential or critical information is being processed.
8. **Trusted communication** is a security service that assures that communication is secure. In most instances involving the Internet, this means that the communication will be encrypted. In the past, communication was trusted because it

was contained within an organization's perimeter. Communication is currently ubiquitous and can come from almost anywhere, including extranets and the Internet.

9. **Antivirus** is a security service that prevents, detects, and cleans viruses, Trojan horse programs, and other malware.
10. **System integrity controls** are security services that help to assure that the system has not been altered or tampered with by unauthorized access.
11. **Data retention and disposal** are a security service that keeps required information archived, or deletes data when they are no longer required. Availability of retained data is critical when an emergency exists. This is true whether the problem is a systems outage or a legal process, whether caused by a natural disaster or by a terrorist attack (e.g., September 11, 2001).
12. **Data classification** is a security service that identifies the sensitivity and confidentiality of information. The service provides guides for information labeling, and for protection during the information's life.

Once an e-commerce application has been identified, the team must identify the security issues with that specific application and the necessary security services. Not all of the services will be relevant, but using a complete list and excluding those that are not required will assure a comprehensive assessment of requirements, with appropriate security built into the system's development. In fact, management can reconcile the services accepted with their level of risk acceptance.

30.2.3 Step 3: Select Security Service Options Based on Requirements. The third step uses classical cost-benefit and risk-management analysis techniques to make a final selection of security service options. However, we recommend that all options identified in Step 3 be distributed along a continuum, such as shown in Exhibit 30.2, so that they can be viewed together, and compared.

Gauging and comparing the level of security for each security service and the data within the transaction will facilitate the decision process. Feasible alternatives can then be identified and the best solution selected based on the requirements. The most significant element to consider is the relative reduction in risk of each option, compared with the other alternatives. The cost-benefit analysis is based on the risk versus reward issues. The effectiveness information is very useful in a cost-benefit model.

Four additional concepts drive the security service option selection:

1. Implementation risk or feasibility
2. Cost to implement and support
3. Effectiveness in increasing control, thereby reducing risk
4. Data classification

Implementation risk considers the feasibility of implementing the security service option. Some security systems are difficult to implement due to factors such as product maturity, scalability, complexity, and supportability. Other factors to consider include skills available, legal issues, integration required, capabilities, prior experience, and limitations of the technology.

Cost to implement and support measures the costs of hardware and software implementation, support, and administration. Consideration of administration issues is

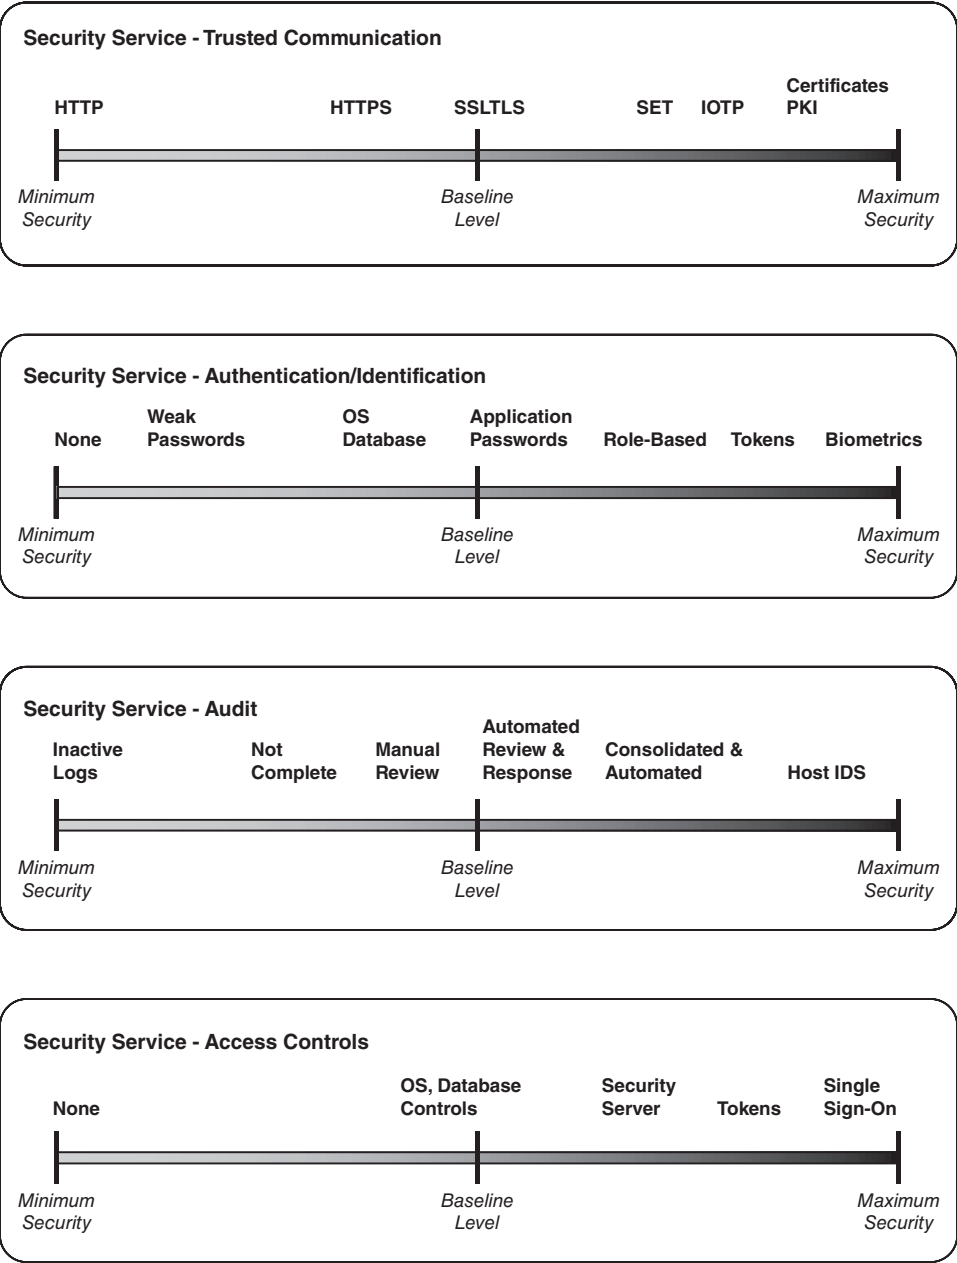

EXHIBIT 30.2 Continuum of Options

especially critical because high-level support of the security service is vital to an organization's success.

Effectiveness measures the reduction of risk proposed by a security service option once it is in production. Risk can be defined as the impact and likelihood of a negative event occurring after mitigating strategies have been implemented. An example of a negative event is the theft of credit card numbers from a business's database. Such an event causes not only possible losses to consumers but also negative public relations

that may impact future business. Effective security service options reduce the risk of a negative event occurring.

Data classification measures the sensitivity and confidentiality of the information being processed. Data must be classified and protected from misuse, disclosure, theft, or destruction, regardless of storage format, throughout their life (from creation through destruction). Usually, the originator of the information is considered to be the owner of the information and is responsible for classification, identification, and labeling. The more sensitive and confidential the information, the more information security measures will be required to safeguard and protect it.

30.2.4 Step 4: Ensures the Ongoing Attention to Changes in Technologies and Requirements. The only constant in this analysis is the need to evolve and to address ever-increasing threats and technologies. Whatever security approaches the preceding steps identify, they must always be considered in the context of the continuing need to update the selected approaches. Changes will be inevitable, whether they arrive from compliance, regulation, technological advances, or new threats.

30.2.5 Using the Security Services Framework. The next two sections are examples to demonstrate the power of the security services methodology. The first example is a B2C model; the business could be any direct-selling application. The second example is a B2B model. Both businesses take advantage of the Internet to improve their product value chain. The examples are a short demonstration of the security services methodology, neither complete nor representative of any particular application or business.

30.2.5.1 Business-to-Customer Security Services. The B2C company desires to contact customers directly through the Internet, and allow them to enter their information into the application. These assumptions are made to prepare this B2C system example:

- Internet-facing business
- Major transactions supported
- External customer-based system, specifically excluding support, administration, and operations
- Business-critical application
- Highly sensitive data classification
- Three-tiered architecture
- Untrusted clients, because anyone on the Internet can be a customer

Five layers must be secured:

1. The *presentation layer* is the customer interface, what the client sees or hears using the Web device. The client is the customer's untrusted PC or other device. The security requirements at this level are minimal because the company will normally not dictate the security of the customer. The identification and authentication done at the presentation level are those controls associated with access to the device. The proliferation of appliances in the client space (e.g., traditional

30 · 10 E-COMMERCE AND WEB SERVER SAFEGUARDS

PCs, thin desktops, and PDAs) makes it difficult to establish a uniform access control procedure at this level. Although this layer is the terminal endpoint of the secure connection, it is not inherently trustworthy, as has been illustrated by all too many incidents involving public computers in cafes, hotels, and other establishments.

2. The *network layer* is the communication connection between the business and the customer. The client, or customer, uses an Internet connection to access the B2C Web applications. The security requirements are minimal, but sensitive, and confidential traffic will need to be encrypted.
3. The *middle layer* is the Web server that connects to the client's browser and can forward and receive information. The Web server supports the application by being an intermediary between the business and the customer. The Web server needs to be very secure. Theft, tampering, and fraudulent use of information needs to be prevented. Denial of service and Website defacement are also common risks that need to be prevented in the middle layer.
4. The *application layer* is where the information is processed. The application serves as an intermediary between the customer requests and the fulfillment systems internal to the business. In some examples, the application server and database server are the same because both the application and database reside on the same server. However, they could reside within the Web server in other cases.
5. The *internal layer* is comprised of the business's legacy systems and databases that support customer servicing. Back-end servers house the supporting application, including order processing, accounts receivable, inventory, distribution, and other systems.

For each of these five levels, we need four security services:

1. Trusted communications
2. Authentication/identification
3. Audit
4. Access controls

Step 1: Define Information Security Concerns Specific to the Application. Defining security issues will be particular to the system being implemented. To understand the risk of the system, the best starting place is with the business risk; then defining risks at each element of the architecture.

Business Risk

- The application needs high availability, because customers will demand contact at off-hours and on weekends.
- The Web pages need to be secure from tampering and cyber-vandalism, because the business is concerned about the loss of customer confidence as a result of negative publicity.
- Customers must be satisfied with the level of service.
- The system will process customer credit card information and will be subject to the privacy regulations of the Gramm-Leach-Bliley Act, 15 USC §§ 6801–09.

Technology Concerns

Of the five architectural layers in this example, four will need to be secured:

1. The *presentation layer* will not be secured or trusted. Communications between the client and the Web server will be encrypted at the *network layer*.
2. The *network layer* will need to filter unwanted traffic, to prevent denial of service (DoS) attacks and to monitor for possible intrusions.
3. The *middle layer* will need to prevent unauthorized access, be tamper-proof, contain effective monitoring, and support efficient and effective processing.
4. The *application layer* will need to prevent unauthorized access, support timely processing of transactions, provide effective audit trails, and process confidential information.
5. The *internal layer* will need to prevent unauthorized access, especially through Internet connections, and to protect confidential information during transmission, processing, and storage.

Step 2: Develop Security Services Options. The four security services reviewed in this example are the most critical in an e-commerce environment. Other services such as nonrepudiation and data classification are important but not included in order to simplify the example. Services elected are:

- Trusted communication
- Authentication and identification
- Monitoring and auditing
- Access control

Many security services options are available for the B2C case, with more products and protocols on the horizon. There are five architectural layers for each of the services defined in Step 1.

1. **Presentation layer.** Several different options can be selected for trusted communication. While the most common application-level protocol is the Hypertext Transfer Protocol (HTTP); the ever increasing need for privacy and assurance of integrity argues for the use of its more secure encrypted sibling, Transport Layer Security,³ the successor to Secure Socket Layer (SSL) protocol,⁴ in conjunction with certificates in a Public Key Infrastructure (PKI), to authenticate and cryptographically secure the communications pathway. The use, or possible use, of wireless connections somewhere in the path only increases the importance of secured, encrypted paths. Because the client is untrusted, the client's authentication, audit, or access control methods cannot be relied on.
2. **Network layer.** Virtual private networks (VPNs) are considered best practice for secure network layer communication. Firewalls are effective devices for securing network communication. The client may have a personal firewall. If the client is in a large corporation, there is a significant likelihood that a firewall will intervene in communications. If the client is using a home or laptop computer, then a personal firewall may protect traffic. There will also be a firewall on the B2C company side of the Internet.

3. **Middle layer.** The Web server and the application server security requirements are significant. Unauthorized access to the Web server can result in Website defacement by hackers who change the Web data. More important, access to the Web or application server can lead to theft, manipulation, or deletion of customer or proprietary data. Communication between the Web server and the client needs to be secure in e-commerce transactions. HTTP is the most common form of browser communication. In 2000, it was reported that over 33 percent of credit card transactions were using unsecured HTTP.⁵ In 2007, VISA reported that compliance with the Payment Card Industry Data Security Standard (PCI DSS) had improved to 77 percent of the largest merchants in the United States,⁶ still far from universal. This lack of encryption is a violation of both the merchant's agreement and the PCI, but episodes continue to occur. In the same vein, it is not unusual for organizations to misuse encryption, whether it involves self-signed, expired, or not generally recognized certificates. (See Chapter 37 in this *Handbook*.) HTTPS (HTTP over TLS) is the most common secure protocol solution, but the encryption key length and contents are critical: The larger the key, the more secure the transaction is from brute-force decryption (see Chapter 7). Digital certificates in a PKI and digital signatures are not as common, but they are more effective forms of security.
4. **Application layer.** The application server provides the main processing for the Web server. This layer may include transaction processing and database applications; it needs to be secure to prevent erroneous or fraudulent processing. Depending on the sensitivity of the information processed, the data may need to be encrypted. Interception and the unauthorized manipulation of data are the greatest risks in the application layer.
5. **Internal layer.** In a typical example, the internal layer is secured by a firewall protecting the external-facing system. This firewall helps the B2C company protect itself from Internet intrusions. Database and operating system passwords and access control measures are required.

Management can decide which security capability is required and at what level. This format can be repeated to discuss security services at all levels and all systems, not just e-commerce-related systems.

Step 3: Select Security Service Options Based on Requirements. In Step 3 the B2C company can analyze and select the security services that best meet its legal, business, and information security requirements. There are four stages required for this analysis:

1. Implementation risk or feasibility
2. Cost to implement and support
3. Effectiveness in increasing control, thereby reducing risk
4. Data classification

Implementation risk is a function of the organization's ability to effectively roll out the technology. In this example, we assume that implementation risk is low and resources are readily available to implement the technology.

Costs to implement and support are paramount to the decision-making process. Both costs need to be considered together. Unfortunately, the cost to support is difficult

to quantify and easily overlooked. In this example, resources are available to both implement and support the technology.

Effectiveness in increasing control is an integral part of the benefit and risk-management decisions. Each component needs to be considered in order to determine cross-benefits where controls overlap and supplement other controls. In this case, the control increase is understood and supported by management.

Data classification is the foundation for requirements. It will help drive the cost-benefit discussions because it captures the value of the information to the underlying business. In this example, the data are considered significant enough to warrant additional security measures to safeguard the data against misuse, theft, and loss.

There are many technology decisions required to secure the example environment. Management can use this approach to plot the security levels required by the system. For example, for system audit services, in order of minimal service to maximum:

- The minimal level of security is to have systems with a limited number of system events logged. For example, the default level of logging from the manufacturer is used but does not contain all of the required information. The logs are not reviewed but are available for forensics in the event of a security incident.
- A higher level of security is afforded with a log that records more activities based on requirements and not, for example, the manufacturer's default level. As in the minimal level of security, the activities are logged and available to support forensics but are not reviewed. In this case, more types of information are recorded in the system log, but it still may not contain all that is required.
- A sufficient log is kept on each server and is manually monitored for anomalies and potential security events.
- The log is automatically reviewed by software on each server.
- System logs are consolidated onto a centralized security server. Data from the system logs are transmitted to the centralized security server, and software is then used to scan the logs for specific events that require attention. Events such as attempts to gain escalated privileges to root or administrative access can be flagged for manual review.
- The maximum service level is a host-based intrusion detection system (IDS) used to scan the system logs for anomalies and possible security events. Once detected, action needs to be taken to resolve the intrusion. The procedure should include processes such as notification, escalation, and automated defensive response.

30.2.5.2 Business-to-Business Security Services. The second case study uses the security services framework in a B2B example. Following is a theoretical discussion of how the framework can be applied to B2B e-commerce security. These assumptions may be made in this B2B system example:

- Internet-facing.
- Supports major transactions.
- Descriptions will be external and customer based (excluding support, administration, and operations security services).
- Trusted communication is required.

30 · 14 E-COMMERCE AND WEB SERVER SAFEGUARDS

- Three-tier architecture.
- Untrusted client.
- Business-critical application.
- Data are classified as highly sensitive.

There are five layers in this example that need to be secured:

1. The *presentation layer* is the customer interface and is what the client sees or hears using the Web device. The client is the customer's untrusted PC, but more security constraints can be applied because the business can dictate enhanced security. As noted previously, the security of the presentation layer is complicated by the wide range of potential client devices that may be employed.
2. The *application layer* is where the information is processed. The application serves as an intermediary between the business customer's requests and the fulfillment systems internal to the business (the back-end server). The application server is the supporting server and database.
3. The *customer internal layer* is the interface between the application server supporting the system at the customer's business location, and the customer's own internal legacy applications and systems.
4. The *network layer* is the communication connection between the business and another business. The Internet is used to connect the two businesses. Sensitive and confidential traffic will need to be encrypted. Best practice is to have the traffic further secured using a firewall.
5. The *internal layer* is the business's legacy systems that support customer servicing. The back-end server houses the supporting systems, including order processing, accounts receivable, inventory, distribution, and other systems.

The four security services are:

1. Trusted communications
2. Authentication/identification
3. Audit
4. Access controls

Step 1: Define Information Security Concerns Specific to the Application. Defining security issues will be particular to the system being implemented. To understand the risk of the system, it is best to start with the business risk; then define risk at each element of the architecture.

Business Risk

- Communication between application servers needs to be very secure. Data must not be tampered with, stolen, or misrouted.
- Availability is critical during normal business hours.
- Cost savings realized by switching from electronic data interchange (EDI) to the Internet is substantial, and will more than cover the costs of the system.

Technology Concerns

There are six architectural layers in this example, five of which need to be secured:

1. The *presentation layer* will not be secured or trusted. The communication between the client and the customer application is trusted because it uses the customer's private network.
2. The *application server* will need to be secure. Traffic between the two application servers will need to be encrypted. The application server is inside the customer's network and demonstrates a potentially high, and perhaps unnecessary degree of trust between the two companies (see Section 30.6.5).
3. The *customer's internal layer* will be secured by the customer.
4. The *network layer* needs to filter out traffic that is not required, prevent DoS attacks, and monitor for possible intrusions. Two firewalls are shown: one to protect the client and the other to protect the B2B company.
5. The *application layer* will need to prevent unauthorized access, support timely processing of transactions, provide effective audit trails, and process confidential information.
6. The *internal layer* will need to prevent unauthorized access (especially through Internet connections) and protect confidential information during transmission, processing, and storage.

Step 2: Develop Security Services Options. There are four security services reviewed in this example. Others could have been included, such as authenticity, nonrepudiation, and confidentiality, but they have been excluded to simplify this example. Elected security services include:

1. Trusted communication
2. Authentication/identification
3. Audit
4. Access control

Many security services options are available for B2B environments.

- **Presentation layer.** Several different options can be selected for communication. HTTP is the most common. The communications between the presentation layer residing on the client device and the application server, in this example, are internal to the customer's trusted internal network and will be secured by the customer. Past episodes involving this scenario include the previously mentioned TJX affair and the episode involving Hannaford.⁷ Recently, Bashas', a chain of grocery stores in Arizona, was compromised by malware on their Point of Sale network.⁸ These compromises of internal networks argue for the use of HTTPS (HTTP over TLS) as a presentation layer, even on "internal" networks where information transmitted may include personally identifiable information (PII) in some form. As a matter of safety, when in doubt it is far safer to run an encrypted infrastructure as a guard against exposing PII than it is to discover at a later date that some data in certain circumstances is protected PII. Encrypting unsensitive data does accrue excessive costs; failing to encrypt even a small amount of PII could lead to a significant liability.

30 · 16 E-COMMERCE AND WEB SERVER SAFEGUARDS

- **Application layer.** Communication between the two application servers needs to be secure. The easiest and most secure method of peer-to-peer communication is via a VPN.
- **Customer internal.** Communications between the customer's application server and the customer's back-end server are internal to the customer's trusted internal network and will be secured by the customer.
- **Network layer.** It is common in a B2B environment that a trusted network is created via a VPN. The firewalls will probably participate in these communications, but hardware solutions are also possible.
- **Application layer.** The application server is at both the customer and B2B company sites. VPN is the most secure communication method. The application server also needs to communicate with the internal layer, and this traffic should be encrypted as well.
- **Internal layer.** The internal layer may be secured with another firewall from the external-facing system. This firewall helps the B2B company to protect itself from intrusions and unauthorized access. In this example, a firewall is not assumed, so the external firewall and DMZ need to be very secure.

Intrusion detection, log reading, and other devices can easily be added and discussed with management. This format can be repeated to discuss security services at all levels and all systems, not just e-commerce-related systems.

Step 3: Develop Security Service Options. In Step 3, the B2B company can analyze and select the security services that best meet its legal, business, and information security requirements. The biggest difference between B2C and B2B systems is that the B2C system assumes no level of trust. The B2B system assumes trust to some degree, but additional coordination and interface with the B2B customer or partner is required. Trustworthiness is not an either/or question and should not be presumed (see Section 30.6.4). This coordination and interoperability must not be underestimated, because they may prove difficult and expensive to resolve. There are four stages required for this analysis:

1. Implementation risk or feasibility
2. Cost to implement and support
3. Effectiveness in increasing control, thereby reducing risk
4. Data classification

Implementation risk is a function of the organization's ability to effectively roll out the technology. In this example, we assume that implementation risk is low and resources are readily available to implement the technology.

Cost to implement and support are paramount to the decision-making process. Both businesses' costs need to be considered. Unfortunately, the cost to support is difficult to quantify and easily overlooked. In this example, resources are available both to implement and to support the technology.

Effectiveness in increasing control is an integral part of the benefit and risk-management analysis. Each security component needs to be considered in order to determine cross-benefits where controls overlap and supplement others. In this example, increased levels of control are understood and supported by management.

Data classification is the foundation for requirements and will help drive the cost-benefit discussions because it captures the value of the information to the underlying business. In this example, the data are considered significant enough to warrant additional security measures to safeguard the data against misuse, theft, and loss.

Each security service can be defined along a continuum, with implementation risk, cost, and data classification all considered. Management can use this chart to plot the security levels required by the system. This example outlines the effectiveness of security services options relative to other protocols or products. Each organization should develop its own continuums and provide guidance to Web developers and application programmers as to the correct uses and standard settings of the security services. For example, for authentication/identification services, in order of minimal service to maximum:

- The minimal level of security is to have no passwords.
- Weak passwords (e.g., easy to guess, shared, poor construction) are better than no passwords but still provide only a minimal level of security.
- Operating system or database level passwords usually allow too much access to the system but can be effectively managed.
- Application passwords are difficult to manage but can be used to restrict data access to a greater degree.
- Role-based access distinguishes users by their need to know to support their job function. Roles are established and users are grouped by their required function.
- Tokens are given to users and provide for two-part authentication. Passwords and tokens are combined for strong authentication.
- Biometrics are means to validate the person claiming to be the user via fingerprints, retina scans, or other unique body function.

For more information on identification and authentication, see Chapters 28 and 29 in this *Handbook*.

30.2.6 Framework Conclusion. Internet e-commerce has changed the way corporations conduct business with their customers, vendors, suppliers, and business units. The B2B and B2C sectors will only continue to grow. Despite security concerns, the acceleration toward increased use of the Internet as a sales, logistics, and marketing channel continues. The challenge for information security professionals' is to keep pace with this change from a security perspective, but not to impede progress. Another equal challenge is that the products that secure the Internet are new and not fully functional or mature. The products will improve, but meanwhile, existing products must be implemented, and later retrofitted, with improved and more secure security services. This changing environment, including the introduction of ever more serious and sophisticated threats, remains difficult to secure.

The processes described in this section will allow the security practitioner to provide business units with a powerful tool to communicate, select, and implement information security services. Three steps were described and demonstrated with two examples. The process supports decision making. Decisions can be made and readily documented to demonstrate cost effectiveness of the security selections. The risk of specific decisions can be discussed and accepted by management. The trade-offs between cost and benefit can be calculated and discussed. Therefore, it becomes critical that alternatives be

reviewed and good decisions made. The processes supporting these decisions need to be efficient and quickly applied. The information security services approach will allow companies to implement security at a practical pace. Services not selected are easily seen. The risk of not selecting specific security services needs to be accepted by management.

30.3 RULES OF ENGAGEMENT. The Web is a rapidly evolving, complex environment. Dealing with customers electronically is a challenge. Web-related security matters raise many sensitive security and privacy issues. Attacks against Websites are not private incidents; they are often public and must always be taken seriously. Correctly differentiating “false alarms” from real attacks is an ongoing challenge with little hope of clean solutions. Distinguishing a popularity spike from a Distributed Denial of Service (DDoS) attack is imprecise and error prone. Indeed, a single traffic surge could be both simultaneously. The Victoria’s Secret online lingerie show in February 1998 was popular beyond even the most optimistic expectations of its creators, and the volume of visitors caused severe problems. Obviously, the thousands of people were not attacking the site; they were merely a virtual mob attempting to access the same site at the same time. Similar episodes have occurred when sites were described as interesting on Usenet newsgroups or on social networking sites (e.g., YouTube, Facebook, Twitter, and others). Request tsunamis often occur with little or no warning. Physical mobs are limited by transportation, timing, and costs; virtual mobs are solely limited by how many can attempt to access a resource simultaneously, from locations throughout the world. A recent example was the debut of a limited Missoni product set by Target on September 13, 2011, which generated a demand surge that rendered Target’s Website effectively inaccessible (93 percent of requests were refused) for hours.^{9,10}

30.3.1 Website-Specific Measures. Protecting a Website means ensuring that the site and its functions are available 24 hours a day, seven days a week, and 365 days a year. It also means ensuring that the information exchanged with the site is accurate and secure.

This section focuses on issues specific to Web interactions with customers as well as supply and distribution chains. Practically speaking, the Website is an important, if not the most important, component of an organization’s interface with the outside world.

Website protection lies at the intersection of technology, strategy, operations, customer relations, and business management. Website availability and integrity directly affect the main streams of cash flow and commerce: an organization’s customers, production chains, and supply chains.

Availability is the cornerstone of all Web-related strategies. Idle times have become progressively more sparse. Depending on the business and its markets, there may be some periods of lower activity. In the financial trading community, there remain only a few small windows during a 24-hour period when updates and maintenance can be performed. As global business becomes the norm, customers, suppliers, and distributors increasingly expect information, and the ability to effect transactions, at any time of the day or night, even from modest-size enterprises. On the Internet, “nobody knows that you are a dog” also means “nobody knows that you are *not* a large company.” The playing field has indeed been leveled, but it was not uniformly raised or lowered. Expectations have increased while capital and operating expenses have dramatically dropped.

Causation is unrelated to impact. The overwhelming majority of Web outages are caused by unglamorous problems. High-profile, deliberate attacks are much less

frequent than equipment and personnel failures. The effect on the business organization is indistinguishable. Having a low profile is no defense against random scanning attack or someone looking for a springboard from which to attack a third party.

Additionally, while an individual firm's assets may not be an attractive target, the firm can still be a useful springboard for an attack against a third party. Such attacks may occur because of a relationship (e.g., vendor or supplier) or may merely be opportunistic attempts at recruitment (e.g., recruiting, or perhaps more appropriately, press-ganging desktop computers for botnets).

External events and their repercussions can also wreak havoc, both directly and indirectly. The September 11, 2001, terrorist attacks that destroyed New York City's World Trade Center complex had worldwide impact, not only on systems and firms located in the destroyed complex. Telecommunications infrastructure was damaged or destroyed, severing Internet links for many organizations. Parts supply and all travel was disrupted when North American airspace was closed for several days. Manhattan was sealed to exits and entries, while within the city itself, and throughout much of the world, normal operations were suspended. The September 11 attacks were extraordinarily disruptive, but security precautions similar to those described throughout this *Handbook* served to ameliorate damage to Web operations and other infrastructure elements of those concerns that had implemented them. Indeed, the existence of the Web and the resulting ability to organize groups without physical presence proved a means to ameliorate the damage from the attacks, even to firms that had a major presence in the World Trade Center. In the period following the attacks on the World Trade Center, Morgan Stanley and other firms with offices in the affected area implemented extensive telecommuting and Web-based interactions first to account for their staffs¹¹ and then to enable work to continue.¹²

Best practices and scale are important. Some practices, issues, and concerns at first glance appear relevant only to very large organizations, such as Fortune 500 companies. In fact, this is not so. Considering issues in the context of a large organization permits them to appear magnified and in full detail. Smaller organizations are subject to the same issues and concerns but may be able to implement less formal solutions. "Formal" does not necessarily imply written procedures. It may mean that certain computer-related practices, such as modifying production facilities in place, are inherently poor ideas and should be avoided. Very large enterprises might address the problems by having a separate group, with separate equipment, responsible for operating the development environment. Incremental staged deployments are an excellent technique to calibrate risk exposure.

30.3.2 Defining Attacks. Repeated, multiple attempts to connect to a server could be ominous, or they could be nothing more than a customer with a technical problem. Depending on the source, large numbers of failed connects or aborted operations coming from gateway nodes belonging to an organization could represent a problem somewhere in the network, an attack against the server, or a blend of both. It could also represent something no more ominous than a group of users within a locality accessing a Web resource through a firewall.

30.3.3 Defining Protection. There is a difference between protecting Internet-visible assets and protecting Websites. For the most part, Internet-visible assets are not intended for public use. Thus, it is often far easier to anticipate usage volumes and to account for traffic patterns. Websites are subject to the vicissitudes of worldwide public usage. A dramatic surge in traffic could be an attack, or it could be an unexpected

display of the site's URL in a television program or in a relatively unrelated news story. Differentiating between belligerence and popularity is difficult, if not impossible.

Self-protective measures that do not impact customers are always permissible. However, care must be exercised to ensure that the measures are truly impact-free. As an example, some sites, particularly public FTP servers, often require that the Internet protocol (IP) address of the requesting computer have an entry in the inverse domain name system, which maps IP addresses to host names (e.g., node 192.168.0.1 has a PTR [pointer record] 1.0.168.192.in-addr.arpa) (RFC1034, RFC1035; Mockapetris 1987a, 1987b) as opposed to the more widely known domain name system database, which maps host names into IP addresses. It is true that many machines have such entries, but it is also true that many sites, including company networks and many ISPs, do not provide inverse DNS information. Whether this entire population should be excluded from the site is a policy and management decision, not a purely technical decision. Even a minuscule incident rate on a popular Website can be catastrophic, both for the provider and for the naïve end user who has no power to understand or resolve the situation.

30.3.4 Maintaining Privacy. Logging interactions between customers and the Website is also a serious issue. A Website's privacy policy is again a managerial, legal, and customer relations issue with serious overtones. Technical staff needs to be conscious that policies, laws, and other issues may dictate what information may be logged, where it can be stored, and how it may be used. For example, the 1998 Children's Online Privacy Protection Act (COPPA) (15 U.S.C. § 6501 et seq.) makes it illegal to obtain name and address information from children under the age of 13 in the United States. Many firms are party to agreements with third-party organizations such as TRUSTe,¹³ governing the use and disclosure of personal information. For more information on legal aspects of protecting privacy, see Chapter 69 in this *Handbook*.

30.3.5 Working with Law Enforcement. Dealing with legal authorities is similarly complicated. Attempts at fraudulent purchases and other similar issues can be addressed using virtually the same procedures that are used with conventional attempts at mail or phone order fraud. Dealing with attacks and similar misuses is more complicated and depends on the organization's policies and procedures, and the legal environment. The status of the Website is also a significant issue. If the server is located at a hosting facility, or is owned and operated by a third party, the situation becomes even more legally complicated. Involving law enforcement in a situation will likely require that investigators have access to the Web servers and supporting network, which may be difficult. Last, there is a question of what information is logged, and under what circumstances. For more information on working with law enforcement, see Chapter 61 in this *Handbook*.

30.3.6 Accepting Losses. No security scheme is foolproof. Incidents will happen. Some reassurance can be taken from the fact that the most common reasons for system compromises in 2001 appear to remain the same as when Clifford Stoll wrote *The Cuckoo's Egg* in 1989. Then and now, poorly secured systems have:

- Management accounts with obvious passwords
- Unprotected system files
- Unpatched known security holes

However, eliminating the simplest and most common ways in which outsiders can compromise Websites does not resolve all problems. The increasing complexity of site content, and of the applications code supporting dynamic sites, means that there is an ongoing design, implementation, testing, and quality assurance challenge. Server-based and server-distributed software (e.g., dynamic www sites) is subject to the same development hazards as other forms of software. Security hazards will slip into a Website despite the best efforts of developers and testers. The acceptance of this reality is an important part of the planning necessary to deal with the inevitable incidents. When it is suspected that a Website, or an individual component, has been compromised, the reaction plans should be activated. The plans required are much the same as those discussed in Chapter 56 in this *Handbook*. The difference is that the reaction plan for a Website has to take into consideration that the group primarily impacted by the plan will be the firm's customers. The primary goal of the reaction plan is to contain the damage. For more information on computer security incident response, see Chapter 56.

30.3.7 Avoiding Overreaction. Severe reactions may create as much, if not more, damage than the actual attack. The reaction plan must identify the decision-making authority and the guidelines to allow effective decisions to be made. This is particularly true of major sites, where attacks are likely to occur on a regular basis. Methods to determine the point at which the Website must be taken offline to prevent further damage need to be determined in advance.

Offline clones should be prepared to enable fast responses. When under time pressure during an emergency, the last thing one wants to do is building production system images.

In summary, when protecting Websites and customers, defensive actions are almost always permissible and offensive actions of any kind are almost always impermissible. Defensive actions that are transparent to the customer are best of all.

30.3.8 Appropriate Responses to Attacks. Long before the advent of the computer, before the development of instant communications, international law recognized that firing upon a naval vessel was an act of war. Captains of naval vessels were given standing orders summarized as *fire if fired upon*. In areas without readily accessible police protection, the right of citizens to defend themselves is generally recognized by most legal authorities. Within the body of international law, such formal standards of conduct for military forces are known as *rules of engagement*, a concept with global utility.

In cyberspace, it is tempting to jettison the standards of the real world. It is easy to imagine oneself master of one's own piece of cyberspace, without connection to real-world laws and limitations on behavior. However, information technology (IT) personnel do not have the legal standing of ships' captains with no communications to the outside world. Some argue that "fire if fired upon" is an acceptable standard for online behavior. Such an approach does not take into account the legal and ethical issues surrounding response strategies and tactics. It may be unsatisfying, but the only response relatively free of legal consequences (criminal, civil, and regulatory) is "Defensive Action Only." Blocking address ranges is defensive; firing back crosses the line into offense.

Any particular security incident has a range of potential responses. Which response is appropriate depends on the enterprise and its political, legal, and business environment. Acceptability of response is also a management issue as well as potentially a political

issue. Determining what responses are acceptable in different situations requires input from management on policy, from legal counsel on legality, from public relations on public perceptions, and from technical staff on technical feasibility. Depending on the organization, it also may be necessary to involve unions and other parties in the negotiation of what constitutes appropriate responses.

What is acceptable or appropriate in one area is not necessarily acceptable or appropriate in another. Often the national security arena has lower standards of proof than would be acceptable in normal business litigation. In U.S. civil courts, cases are decided upon a preponderance of evidence. Standards of proof acceptable in civil litigation are not conclusive when a criminal case is being tried, where guilt must be established beyond a reasonable doubt.

Gambits or responses that are perfectly legal in a national security environment may be completely illegal and recklessly irresponsible in the private sector, exposing the organization to significant legal liability.

Rules of etiquette and behavior are similarly complex. The rights of prison inmates in the United States remain significant, even though they are subject to rules and regulations substantially more restrictive than for the general population. Security measures, as well, must be appropriate for the persons and situations to which they are applied.

30.3.9 Counter-Battery. Some suggest that the correct response to a perceived attack is to implement the cyberspace equivalent of *counter-battery*, that is, targeting the artillery that has just fired upon you. However, counter-battery tactics, when used as a defensive measure against Internet attacks, will be perceived, technically and legally, as an attack like any other.

Counter-battery tactics may be emotionally satisfying but are prone to both error and collateral damage. Counter-battery can be effective only when the malefactor is correctly identified and the effects of the reciprocal attack are limited to the malefactor. If third parties are harmed in any way, then the retaliatory action becomes an attack in and of itself. One of the more celebrated counter-battery attacks gone awry was the 1994 case when two lawyers from Phoenix, Arizona, spammed over 5,000 Usenet newsgroups to give unsolicited information on a U.S. Immigration and Naturalization Service lottery for 55,000 green cards (immigration permits). The resulting retaliation—waves of email protests—against the malefactors flooded their Internet service provider (ISP) and caused at least one server to crash, resulting in a denial of service to all the other, innocent, customers of the ISP.¹⁴

30.3.10 Hold Harmless. Operational policies for Internet operations must adopt a hold harmless position vis-à-vis good faith actions within policy. Dealing with an Internet crisis often requires fast reactions. If employees act in good faith, in accordance with their responsibilities, and within documented procedures, those making the decisions should be immune from reprisal. Punishment for actions undertaken in good faith is counterproductive. If the procedures are wrong, improve the rules and procedures; do not blame the employees for following established policies. Disciplinary actions are manifestly inappropriate in such circumstances.

30.4 RISK ANALYSIS. As noted earlier in this chapter, protecting an organization's Websites depends on an accurate, rational assessment of the risks. Developing effective strategies and tactics to ensure site availability and integrity requires that all potential risks be examined in turn.

Unrestricted commercial activity has been permitted on the Internet since 1991. Since then, enterprises large and small have increasingly integrated Web access into their second-to-second operations. The risks inherent in a particular configuration and strategy are dependent on many factors, including the scale of the enterprise and the relative importance of the Web-based entity within the enterprise. Virtually all high-visibility Websites (e.g., Yahoo!, America Online, cnn.com, Amazon.com, and eBay) have experienced significant outages at various times.

The more significant the organization's Web component, the more critical is availability and integrity. Large, traditional firms with relatively small Web components can tolerate major interruptions with little damage. Firms large or small that rely on the Web for much of their business must pay greater attention to their Web presences, because a serious outage can quickly escalate into financial or public relations catastrophe.

For more details of risk analysis and management, see Chapters 62 and 67 in this *Handbook*.

30.4.1 Business Loss. Business losses fall into several categories, any of which can occur in conjunction with an organization's Web presence. In the context of this chapter, customers are both outsiders accessing the Internet presence and insiders accessing intranet applications. In practice, insiders using intranet-hosted applications pose the same challenges as the outside users.

30.4.2 PR Image. The Website is the organization's public face 24/7/365. This ongoing presence is a benefit, making the firm visible at all times, but the site's high public profile also makes it a prime target.

Government sites in the United States and abroad have often been the targets of attacks. In January 2000, "Thomas," the Website of the U.S. Congress, was defaced. Earlier, in 1996, the Website of the U.S. Department of Justice was vandalized. Sites belonging to the Japanese, U.K., and Mexican governments also have been vandalized.

Attacks against Websites continue to be an ever-increasing problem. On March 21, 2013, a series of malware infections crippled broadcasters and financial institutions in South Korea during a time of increasing tensions over North Korean nuclear and missile testing, including a renunciation by North Korea of the 1953 armistice suspending the Korean War.¹⁵

These incidents continue, with hackers on both sides of various issues attacking the other side's Web presence. While no conclusive evidence of the involvement of nation states in such activities has become generally known, it is inevitable. Surges of such activity have coincided with major public events, including the 2001 U.S.–China incident involving an aerial collision between military aircraft, the Afghan and Iraqi operations, and the Israeli–Lebanese war of 2006, the Russian–Georgian conflict,¹⁶ and Estonia.¹⁷ Such activity has not been limited to the national security arena, however. Many sites were defaced during the incidents following publication of cartoons in a Danish newspaper that some viewed as defaming the prophet Muhammad.

In some cases, companies have suffered collateral damage from hacking contests, where hackers prove their mettle by defacing as many sites as they can.¹⁸ The fact that there is no direct motive or animus toward the company is not relevant; the damage has still been done.

In the corporate world, company Websites have been the target of attacks intended to defame the corporation for real or imagined slights. Some such episodes have been reported in the news media, whereas others have not been the subjects of extensive reporting. The scale and newsworthiness of the episode is unimportant; the damage

done to the targeted organization is the true measure. An unreported incident that is the initiating event in a business failure is more damaging to the affected parties than a seemingly more significant outage with less severe consequences.

Other cybervandals (e.g., *sadmind/IIS*) have used address scanners to target randomly selected machines. Obscurity is not a defense against address-scanner attacks.

30.4.3 Loss of Customers/Business. Internet customers are highly mobile. Website problems quickly translate into permanently lost customers. The reason for the outage is immaterial; the fact that there was a problem is often sufficient to provoke customer flight.

In most areas, there is competitive overlap. Using the overnight shipping business as an example, in most U.S. metropolitan areas there are (in alphabetical order) Federal Express, United Parcel Service, and the United States Postal Service. All of the firms offer Web-based shipment tracking, a highly popular service. Problems or difficulties with shipment tracking will quickly lead to a loss of business in favor of a different company with easier tracking.

30.4.4 Interruptions. Increasingly, modern enterprises are being constructed around ubiquitous 24/7/365 information systems, most often with Websites playing a major role. In this environment, interruptions of any kind are catastrophic.

Production. The past 20 years have seen a streamlining of production processes in all areas of endeavor. Twenty years ago, it was common for facilities to have multiday supplies of components on-hand in inventory. Today, *zero latency* or *just-in-time* (JIT) environments are common, permitting large facilities to operate with minimal inventory. Fiscally, zero latency environments may be optimally cost efficient, yet the paradigm leaves little margin for disruptions of the supporting logistical chain. This chain is sometimes fragile, and subject to disruption by any number of hazards.

Supply Chain. Increasingly, it is common for Web-based sites to be an integral part of the supply chain. Firms may encourage their vendors to use a Web-based portal to gain access to the vendor side of the purchasing system. XML¹⁹-based gateways and *service-oriented architecture* (SOA) approaches, together with other Web technologies, are used to arrange for and manage the flow of raw materials and components required to support production processes. The same streamlining that speeds information between supplier and manufacturer also provides a potential for serious mischief and liability.

Delivery Chain. Web-based sites, both internal and external, human readable and intersystem, have become the vehicle of choice for tracking the status of orders and shipments. Increasingly system-system links, implemented as electronic-documents (e.g., XML or JSON) have become the backbone of many enterprises' delivery chain management and inquiry systems.

Information Delivery. Banks, brokerages, utilities, and municipalities are increasingly turning to the Web as a convenient, low-cost method for managing their relationships with consumers. Firms are also supporting downloading records of transactions and other relationship information in formats required by personal database programs and organizers. These outputs, in turn, are often used as inputs to other processes, which then generate other transactions. Not surprisingly, as time passes, more and more people and businesses depend on the availability of information on demand. Today's Web-based customers presume that information is accessible wherever they can use a smartphone or tablet. This is reminiscent of usage patterns of automatic teller machines in an earlier decade, which allowed people to base their plans on access

to teller machines, often making multiple \$20 withdrawals instead of cashing a \$200 check weekly.

30.4.5 Proactive versus Reactive Threats. Some threats and hazards can be addressed proactively, whereas others are inherently reactive. When strategies and tactics are developed to protect a Web presence, the strategies and tactics themselves can induce availability problems.

As an example, consider the common strategy of having multiple name servers responsible for providing the translation of domain names to IP addresses. It is required before a domain name (properly referred to as a Domain Name System [DNS] zone) can be entered into the root-level name servers, that at least two name servers be identified to process name resolution requests. Name servers are a prime example of resources that should be geographically diverse.

Updating DNS zones requires care. If an update is performed improperly, then the resources referenced via the symbolic DNS names will become unresolvable, regardless of the actual state of the Web server(s) and related infrastructure. The risk calculus involving DNS names is further complicated by the common, efficient, and appropriate practice of designating ISP name servers as the primary mechanism for the resolution of domain names. In short, name translation provides a good example of the possible risks that can affect a Web presence.

30.4.6 Threat and Hazard Assessment. Some threats are universal. Others are specific to an individual environment. The most devastating and severe threats are those that simultaneously affect large areas or populations, where efforts to repair damage and correct the problem are hampered by the scale of the problem. Differences in perspective can impede effective response. What seems a minor outage to a carrier may be a business-threatening outage to a customer.

On a basic level, threats can be divided into several categories. The first is between deliberate acts and accidents. Deliberate acts comprise actions done with the intent to damage the Website or its infrastructure. Accidents include natural phenomena (acts of God) and clumsiness, carelessness, and unconsidered consequences (acts of clod).

Broadly put, a deliberate act is one whose goal is to impair the system. Deliberate acts come in a broad spectrum of skill and intent. For the purpose of risk analysis and planning, deliberate acts against infrastructure providers can often appear to be acts of God. To an organization running a Website, an employee attack against a telephone carrier appears simply as one more service interruption of unknown origin.

No enterprise or agency should consider itself an unlikely target. Past high-profile incidents have targeted the FBI (May 26 and 27, 1999), major political parties, and interest groups in the United States. On the consumer level, numerous digital subscriber line (DSL)-connected home systems have been targeted for subversion as preparation for the launching of DDoS attacks. In 2007, several investigations resulted in the arrest of several individuals for running so-called botnets (ensembles of compromised computers). These networks numbered hundreds of thousands of machines.²⁰ Recently, Aramco was victimized by a major attack²¹; as were major Korean financial institutions.²² The potential for such networks to be used for mischief cannot be underestimated.

30.5 OPERATIONAL REQUIREMENTS. Internet-visible systems are those with any connection to the worldwide Internet. It is tempting to consider protecting

Internet-visible systems as a purely technical issue. However, technical and business issues are inseparable in today's risk management. For example, as noted earlier in this chapter, the degree to which systems should be exposed to the Internet is fundamentally a business risk-management issue. Protection technologies and the policies behind the protection can be discussed only after the business risk questions have been considered and decided, setting the context for the technical discussions. In turn, business risk-management evaluation (see Chapter 62) must include a full awareness of all of the technical risks. Ironically, nontechnical business managers can accurately assess the degree of business risk only after the technical risks have been fully exposed.

Additional business and technical risks result from outsourcing. Today, many enterprises include equipment owned, maintained, and managed by third parties. Some of this equipment resides on the organization's own premises and other equipment resides offsite: for example, at application service provider facilities.

Protecting a Website begins with the initial selection and configuration of the equipment and its supporting elements, and continues throughout its life. In general, care and proactive consideration of the availability and security aspects of the site from the beginning will reduce costs and operational problems. Although virtually impossible to achieve, the goal is to design and implement an automatic system, with a configuration whose architecture and implementation operates even in the face of problems, with minimal customer impact.

That is not to say that a Website can operate without supervision. Ongoing, proactive monitoring is critical to ensuring the secure operation of the site. Redundancy only reduces the need for real-time response by bypassing a problem temporarily; it does not eliminate the underlying cause. The initial failure must be detected, isolated, and corrected as soon as possible, albeit on a more schedulable basis. Otherwise, the system will operate in its successively degraded redundancy modes until the last redundant component fails, at which time the system will fail completely.

30.5.1 Ubiquitous Internet Protocol Networking. Business has been dealing with the security of internets (i.e., interconnected networks) since the advent of internetworking in the late 1960s. However, the ubiquity of Transmission Control Protocol/Internet Protocol (TCP/IP) networks and of the public Internet has exposed much more equipment to attack than in the days of closed corporate networks. In addition, a much wider range of equipment, such as voice telephones based on voice-over IP (VoIP), fax machines, copiers, and even soft drink dispensers, are now network accessible.

IP connectivity has been a great boon to productivity and ease of use, but it has not been without a darker side. Network accessibility also has created unprecedented opportunities for improper, unauthorized access to networked resources and other mischief. It is not uncommon to experience probes and break-in attempts within hours or even minutes of unannounced connection to the global Internet.

Protecting Internet-visible assets is inherently a conflict between ease of access and security. The safest systems are those unconnected to the outside world. Similarly, the easiest to use systems are those that have no perceivable restrictions on use. Adjusting the limits on user activities and access must balance conflicting requirements. As an example, many networks are managed *in-band*, meaning that the switches, routers, firewalls, and other elements of the network infrastructure are managed using the actual network as the connection medium. If the management interfaces were not managed over properly encrypted connections, management passwords would be visible on the

network. An outsider or unauthorized insider may thus monitor the network, gaining sufficient information to paralyze the network. This can result in severe damage and liability to the organization.

30.5.2 Internal Partitions. Complex corporate environments can often be secured effectively by dividing the organization into a variety of interrelated and nested security domains, each with its own legal, technical, and cultural requirements. For example, there are specific legal requirements for medical records (see Chapter 71 in this *Handbook*) and for privacy protection (see Chapter 69). Partners and suppliers, as well as consultants, contractors, and customers, often need two-way access to their corporate data and facilities. These diverse requirements mean that a single corporate firewall is often insufficient. Different domains within the organization will often require their own firewalls and security policies. Keeping track of the multitude of data types, protection and access requirements, and different legal jurisdictions and regulations makes for previously unheard-of degrees of complexity. It is simply not possible to configure a complete set of rules to implement the multiple, different security requirements without creating security gaps or contradictions.

Much has been written about so-called *Advanced Persistent Threats*.²³ While the terminology is relatively new, the concept is not, having been mentioned in earlier editions of this handbook.²⁴ The fundamental underlying change with advanced threats is the degree of targeting and the attacker's intention to remain covert. In these respects a useful historic precedent is involvement in intelligence gathering by submarine forces. During World War II, submarines were first explicitly tasked with intelligence gathering. The orders given can be summarized as "get the information and/or photographs; avoid detection at all costs." The translation is straightforward: No matter how attractive, do not announce your presence by making an attack; your purpose is to stay covert and extract the desired information. This is precisely the model of today's targeted, information extraction attacks.

Damage control is another property of a network with internal partitions. A system compromised by an undetected malware component will be limited in its ability to spread the contagion beyond its own compartment.

30.5.3 Critical Availability. Networks are often critical for second-to-second operations. The side effects of ill-considered countermeasures may be worse than the damage from an actual attack. For example, shutting down the network or even part of it, for maintenance or repair can wreak more havoc than penetration by a malicious hacker. Damage control, often starting with compartmentalization, is a critical part of limiting the impact of an attack.

30.5.4 Accessibility. Users must be involved in the evolution of rules and procedures. Today, it is still not unheard of for a university faculty to take the position that any degree of security will undermine the very nature of their community, compromising their ability to perform research and inquiries. This extreme position persists despite the attention of the mass media, the justified beliefs of the technical community, and documented evidence that lack of protection of any Internet-connected system undermines the safety of the entire connected community.

Connecting a previously isolated computer system or network to the global Internet creates a communications pathway to every corner of the world. Customers, partners, and employees can obtain information, send messages, place orders, and otherwise interact 24 hours a day, seven days a week, 365 days a year, from literally anywhere on

or near Earth. The Space Shuttle had Internet access; as does the International Space Station. Under these circumstances, the possibilities for attack or inadvertent misuse are limitless.

Despite the vast increase in connectivity, some businesses and individuals do not need extensive access to the global Internet for their day-to-day activities, although they may resent being excluded. The case for universal access is therefore a question of business policy and political considerations.

30.5.5 Applications Design. Protecting a Website begins with the most basic steps. First, a site processing confidential information should always support the Secure Hypertext Transfer Protocol (HTTPS), typically using Transmission Control Protocol (TCP) port 443. Properly supporting HTTPS requires the presence of an appropriate digital certificate (see Chapter 37).

When the security requirements are uncertain, the site design should err on the side of using HTTPS for communications. Eavesdropping on the Internet is an ever-present hazard. There have been cases of routing database manipulation and state-sponsored surveillance. The Hannaford and TJ Maxx episodes described earlier in this chapter both involved the application of what can only be described as classic signals intelligence (SIGINT) techniques. Even though details on such attacks are often not made public, the voluminous historical literature on communications intelligence (COMINT) and SIGINT from the World War II period makes one point abundantly clear: Encryption of all potentially sensitive traffic is the only way to protect information.

Encryption also should be used within an organization, possibly with a different digital certificate, for sensitive internal communications and transactions. Earlier, it was noted that organizations are not monolithic security domains. This is nowhere more accurate than when dealing with human resources, employee evaluations, compensation, benefits, and other sensitive employee information. There are positive requirements that this information be safeguarded, but few organizations have truly secured their internal networks against internal monitoring. It is far safer to route all such communications through securely encrypted channels. Such measures also demonstrate a good faith effort to ensure the privacy and confidentiality of sensitive information. Such efforts are an important element of an organization's defense when an incident occurs. Upfront care can significantly reduce legal liability.

Failure to heed these hazards has been at the root of several incidents, including the TJ Maxx and Hannaford affairs.

It is also important to avoid providing all of the authentication information on a single page or, for that matter, in a sequence of pages. When parts of information are suppressed, as, for example, portions of a credit card or account number, the division between suppressed and displayed portions should be maintained. Displaying all of the information, even if it is on different screens, is an invitation to a security breach.

30.5.6 Provisioning. Although today's hardware has unprecedented reliability, any failure of hardware between the customer and the data center will impair an enterprise's Web presence. For a highly available, front-line Website, the effective requirement is a minimum of two diversely located facilities, each with a minimum of two servers. This is not necessarily an expensive proposition. Fairly powerful Web servers can be purchased for less than \$5,000, so the total hardware expenditure for four servers is reasonable, substantially less than the annual cost of a single technician. Cloud-computing, the availability of data center-housed virtual servers as a service (e.g.,

Amazon, Verizon, RackSpace, Google) presents another option with low entry costs. In most cases, the cost of the extra hardware is more than offset by the business cost of downtime, which can sometimes exceed the total cost of the duplicative hardware by a factor as much as 100, in a single episode.²⁵

Duplicate hardware and geographic diversity ensure constant customer access to some degree of functionality. The degree of functionality that must be maintained depends on the market and the customers. Financial firms supporting online stock trading have different operational, regulatory, and legal requirements than supermarkets. The key is matching the support level to the activities. Some degree of planned degradation is generally acceptable. Total unavailability is not an option.

Remote hosting services generally referred to as “cloud computing” do not eliminate risks. While renting time and other resources from a provider does reduce capital and operating costs, there is a corresponding loss of visibility and control. A failure at a remote vendor operated facility can take down a critical service. Depending on your applications, industry, regulatory, and legal environments, the risks of cloud computing may be quantifiable, or they may be immeasurable. Difficulties in vendor relationships can give rise to “hostage data” situations. From a security and information assurance perspective, planning in advance to deal with changes in cloud vendors should be part of planning.

There are also unresolved legal issues surrounding the use of shared computing facilities operated by third parties. If a search warrant is served on an internal facility, the organization will clearly be aware of what has happened. If a shared facilities vendor is served with a warrant, it is an open question whether the vendor has the desire (or capability) to present the defenses clearly available with data stored within the company.

30.5.7 Restrictions. All Web servers should be located behind a firewall in a DMZ, as discussed in Section 30.6.4. Incoming and outgoing services should be restricted using protocols such as HTTP, HTTPS, and Internet Control Message Protocol (ICMP). For troubleshooting purposes, it is desirable to implement ICMP, which is used by PING, an echo requester, as a way to check connectivity. All unused ports should be disabled. Furthermore, the disabled ports should be blocked by the firewalls separating the DMZ from the outside world.

Customer information should, to the extent possible, be stored on systems separate from the systems actually providing Web serving. Many security episodes have exploited file protection errors on Web servers, in order to access databases directly. Segregating customer data on separate machines, and ensuring that the only way to access customer data is through the documented pathways, is likely severely to impede improper attempts to access and modify information.

These safeguards are especially important for high-security information such as credit card numbers. The number of incidents in which malefactors have downloaded credit card numbers directly from Website is an indication of the importance of such precautions. The systems actually storing the sensitive information should never be accessible from the public Internet. Storage and processing of payment card information is also subject to industry guidelines, particularly the PCI DSS.

The TJX case, which came to public attention in the beginning of 2007, was one of a series of large-scale compromises of electronically stored information on back-office and e-commerce systems. Most notably, the TJX case appears to have started with an insufficiently secured corporate network and the associated back-office systems, not

a Website penetration. This breach escalated into a security breach of corporate data systems. It is reported on the TJX Website that at least 45.7 million credit cards were compromised (original reports in *USA Today* and other publications cite 94 million credit card numbers as being compromised). On November 30, 2007, it was reported that TJX, the parent organization of stores including TJ Maxx and Marshall's, had agreed to settle bank claims related to VISA cards for US\$ 40.9M.²⁶ Also, as of March 2008, a class action suit on behalf of customers was in process of being settled. It called for fees to be paid to each of the plaintiffs for credit monitoring and identity theft, and for new driver's licenses, as well as \$6.5 million to plaintiff's counsel. In spite of several such high-profile attacks, the lessons appear not to have been learned. As recently as March 2008, Hannaford Bros. Co. reported that 4.2 million credit card numbers had been exposed, with about 1,800 cases of fraudulent usage reported as of that date. An incident involving the network supporting Sony's PlayStation 3²⁷ disclosed personal information relating to an estimated 70 million subscribers. Clearly, more stringent controls, care, and safeguards are called for.

30.5.8 Multiple Security Domains. The front-line Web servers, and the database servers supporting their activities, comprise two different security domains.

The Web servers, as noted previously, need to be globally accessible via HTTP, HTTPS, and ICMP (while not needed for actual operations, ICMP is often needed for troubleshooting connectivity problems by both customers and providers). In turn, they need to access the application or database servers, and *only* those servers. In a production environment, it is preferable that application or database servers interact with the Web servers using a dedicated, restricted-use protocol. Properly implemented, such a restriction prevents a hijacked Web server from exploiting its access to the application or database server.

These second-tier servers should be in a security domain separated by restrictive firewalls from the externally accessible front-line Web servers. This seems like a significant expenditure, but it is often less expensive and lower risk than the costs associated with correcting a single significant incident.

30.5.9 What Needs to Be Exposed? Publicly accessible Websites need publicly accessible Web servers to perform their functions. The challenge is to provide the desired services to the public without simultaneously providing access that can be leveraged in unauthorized ways to subvert the site. A penetration incident may lead to significant financial losses, embarrassment, and financial and (in some cases) criminal liability.

Generally speaking, Web servers should not be connected to the public Internet (unless it is possible to verify that all other ports are closed to traffic). All connections to the public network should be made through a firewall system, with the firewall configured to pass only Web-related traffic to those hosts. A DMZ guarded by a firewall often creates a more easily controlled security gateway.

Many sites will opt to place externally visible Web servers in a security compartment of their own, on a separate port of the firewall (if not a totally separate firewall), using a separate DMZ from other publicly accessible resources. These precautions may seem excessive, but having improperly secured systems can lead to security breaches that are extremely difficult to correct and can lead to extended downtime while the problems are analyzed and remedied. In this case, an ounce of prevention is worth substantially more than a pound of cure.

30.5.9.1 Exposed Systems. Exposed systems are inherently a security hazard. Systems without access from or to the public network cannot be compromised from the public network. Only systems that absolutely need to be publicly accessible should be so configured. Minimizing the number of exposed systems is generally desirable, but this is best considered in terms of machine roles rather than actual counts of systems. Increasing the load on each publicly accessible server by increasing the size of the server, thus increasing the amount of capacity impacted by a single system outage, is not a benefit. However, this must be balanced against the new trend toward server virtualization, which does not increase the size of a server, but which increases its utilization, in order to lower costs and improve reliability.

The introduction of SSL-based VPN implementations and services supporting remote access via secure HTTPS connections (e.g., gotomypc.com) create an entirely new class of security hazard. SSL and other encrypted techniques have been used to exfiltrate data from security penetrations. While encrypted connections may be difficult or impossible to observe, connections to unexpected locations are a signal of possible security compromise.

30.5.9.2 Hidden Subnets. The servers directly supporting the Website need to be accessed by the outside world, and thus must generally have normal, externally visible Internet addresses. Alternatively, traffic directors, firewalls, or similar devices may map an external port number to an internal address and port number. However, in most cases the other systems supporting the Web servers generally have no legitimate need for unrestricted access from or to the public network.

The safest address assignments for supporting, non–outside-visible systems are the IPv4 addresses allocated for use in private internets²⁸ and their equivalent IPv6 addresses.²⁹ Needless to say, these systems should be in a security compartment separated from the publicly accessible Web servers, and that compartment should be isolated from the publicly accessible compartment with a very restrictive firewall.

30.5.10 Access Controls. Publicly accessible systems are both the focus of an organization's security efforts and the primary target of attempts to compromise that security. The number of individuals authorized to make changes to the systems and the ways in which changes may be made need to be carefully controlled, reported, and monitored. The cleared individuals should use individual accounts, and the access to sensitive functions through such accounts should be immediately invalidated if the individual's access is no longer authorized or if the employee ceases employment, is under investigation for impropriety, or other reason. The most efficient and effective way to implement these requirements is role-based access control, which leverages the underlying operating system protection model to enforce file security.³⁰ The key aspect of role-based protection is that file access is protected by role, not identifier. It is thus possible to remove a user's access to production files with a single command.

Access controls are also not merely a question of traditional role-based control. Increasingly, applications are directly accessed by customers. Such direct access requires more precautions and care than that provided by customer service personnel. It is often appropriate for customer service personnel to have access to most accounts; it is just as inappropriate to give corresponding unfettered access to end customers, who should only have access to their specific account. Applications-level attacks (e.g., SQL injection) become increasingly hazardous.

The transition to Web browser and mobile device-based interfaces needs additional security precautions. Remote clients are subject to compromise and reverse-engineering. As an example, using plaintext, client-supplied information to control access (e.g., cookies or URL-encoded) can easily give rise to an SQL injection (or equivalent) attack, merely by editing the unencoded information. Switching to proper variable, session-based numbering scheme would make tampering far less successful (indeed, the greater number of failures resulting from using an such an opaque number would be easily detectable by applications and security logging systems).

The challenge to such systems is that the safeguards must be implemented within the application. Such safeguards are needed to ensure applications security.

SQL injection attacks of this type have occurred to major organizations. In 2011, details of 200,000 credit card accounts with Citibank were compromised in this way.³¹

For more information on access controls, see Chapters 28 and 29 in this *Handbook*.

30.5.11 Site Maintenance. Maintaining and updating the Website requires great care. The immediate nature of the Web makes it possible for a single-character error in a major enterprise-level application to cause hundreds of thousands of dollars of damage within moments. Web servers need to be treated with respect; the entire enterprise is riding on the electronic image projected by the server. Cybervandalism, which most commonly consists of defacing the home page of a well-known site, requires unauthorized updating of the files comprising the site. In 2000 alone, well-known public and private entities including the FBI, OPEC, World Trade Organization, and NASA, as well as educational institutions including the University of Limerick, have been harmed in this way. These attacks continue to be a danger, both in terms of damage to the organization's image and covertly, as using the WWW site as a launching pad for Web-based exploits.

The Web is inherently a highly leveraged environment. Small changes in the content of a single page percolate throughout the Web in a matter of minutes. Information disseminates easily and quickly at low cost. Leverage helps tremendously when things go right; when things go badly, leverage dramatically compounds the damage. For more information on change control, see Chapters 38, 39, and 40 in this *Handbook*.

30.5.12 Maintaining Site Integrity. Every Website and its servers is a target. Antagonists can be students, activists, terrorists, disgruntled former employees, or unhappy customers as well as state actors. Because Websites are an enterprise's most public face, they represent extremely desirable targets.

Maintaining integrity requires that updates and changes to the site be done in a disciplined manner. Write access to the site must be restricted, and those authorized must use secure methods to access the Web servers. The majority of reported incidents appear to be the result of weak security in the update process. For example, unsecured FTP access from the general Internet is a poor practice. Safer mechanisms include:

- FTP from a specific node within the inner firewall
- KERMIT on a directly wired port or over a secured connection
- Logins and file transfers (e.g., SFTP) over secure authenticated connections via an underlying SSH transport
- Physical media transfers

Most of the technologies do not inherently require that an onsite individual perform server updates, which would preclude remote maintenance. It does mean that in order to get to a machine from which an update can be performed, it is necessary to come through a virtual private network with point-to-point tunneling protocol or Layer2 tunneling protocol (VPN PPTP/L2TP) authenticated by at least one of the secure gateways. For more information on VPNs, see Chapter 32 in this *Handbook*.

30.6 TECHNICAL ISSUES. There are many technical issues involved in protecting Internet-accessible resources. The technologies used to protect network assets include routers, firewalls, proxy servers, redundancy, and dispersion. When properly designed and implemented, security measures produce a positive feedback loop, where improvements in network security and robustness are self-reinforcing. Each improvement makes other improvements possible and more effective.

30.6.1 Inside/Outside. Some visions of the future include a utopian world where everything is directly accessible from anywhere without effort, and with only beneficial results. The original Internet operated on this basis, until a number of incidents (including the 1988 Morris worm) caused people to rethink the perceived inherent peacefulness of the networked world. It is a trend that has only accelerated, as the total number of systems grows ever larger.

The architecture and design of protective measures for a network depend on differentiating inside trustable systems from outside untrustworthy systems. This is equally true for intranets, the Internet, or an *extranet*, so called to distinguish private interconnections of networks from the public Internet. Unfortunately, trust is not a black-and-white issue. A system may be trustworthy from one perspective and untrustworthy from another, thus complicating the security design. In addition, the vast majority of inappropriate computer use is thought to be done by those with legitimate access to some aspect of the system and its data. Alternatively, it is not possible to be strong everywhere. Trusted but compromised systems are a significant danger.

Basic connectivity configuration is one of those few areas that are purely technical, without a business risk element. One of the most obvious elements involves the tables implemented in routers connecting the enterprise to the public carrier-supplied IP connection. The table rules must prevent *IP spoofing*, which is the misrepresentation of IP packet origins. This is also true when originators are within the organization.

There are three basic rules for preventing IP spoofing applicable to all properly configured networks:

1. Packets entering the network from the outside should never have *originator* addresses within the target network.
2. Packets leaving a network and going to the public network must have *originator* addresses within the originating network.
3. Packets leaving a network and going to the public network must not have *destination* addresses within the originating network.

An exception to these rules is in the use of stealth internal networks, those whose internal addresses correspond to legal external addresses.³²

A corollary to these rules is that packets with originator or destination addresses in the most local intranet addresses range³³ or dynamic IP addresses,³⁴ should never be

permitted to enter or leave an internal network. Nested address spaces may deliberately create aliased address spaces.^{35,36}

30.6.2 Hidden Subnets. Firewalls funnel network traffic through one or more choke points, concentrating the security task in a small number of systems. The reasoning behind such concentration is that the likelihood of security breaches of the entire network rises rapidly with the number of independent access points.

Firewalls and proxy servers (see Chapter 26 in this *Handbook*) are effective only in topologies where the firewall filters all traffic between the protected systems and the less-trusted world outside its perimeter. If the protected systems can in any way be accessed without going through the firewall, then the firewall itself has been rendered irrelevant. Security audits often uncover systems that violate this policy; relying on administrative sanctions to preclude such holes in the security perimeter generally does not work. The rule of international diplomacy, “Trust but verify,” applies.

The simplest solution to this problem is the use of RFC 1918³⁷ addresses within protected networks.³⁸ RFC1918 provides a range of IPv4 addresses guaranteed by the Internet Assigned Numbers Authority (IANA) never to occur in the normal, public Internet. The address ranges used for dynamic IP address assignment have similar properties.³⁹ IPv6 networks are similarly governed by RFC 4193.

Filtering these addresses on both inbound and outbound data streams is straightforward and highly effective at stopping a wide range of attacks.⁴⁰ Requiring the use of such addresses, and prohibiting the internal use of externally valid addresses, goes a long way toward preventing the use of unauthorized protocols and connections.

30.6.3 What Need Be Exposed? A security implementation starts with an analysis of the enterprise’s mission, needs, and requirements. All designs and implementations are a compromise between absolute security, achieved only in a powered-down or disconnected system, and total openness, in which a system is completely open to any and all access from the outside.

Although in most cases communications must be enabled between the enterprise and the outside world for normal business functions, total disconnection, known as an *air gap*, is sometimes both needed and appropriate between specific components. Industrial real-time control systems, life-critical systems, and systems with high requirements for confidentiality remain appropriate candidates for total air gaps.

Often, systems that do not need to receive information from outside sources must publish statistical or other information to less secure systems. This requirement can often be satisfied through the use of limited functionality links such as media exchange, or through tightly controlled one-way transfers. These mechanisms can be implemented with IP-related technologies or with more limited technologies, including KERMIT,⁴¹ UUCP, or vendor-specific solutions.

In other cases, restrictions reflect policies for permitted use and access rather than for protection against outside attack. For example, it is reasonable and appropriate for a public library to limit access to HTTP and related protocols while prohibiting access to such facilities as FTP and TELNET. Remote access using the Secured Shell Protocol (SSH) is extremely useful, as it allows for two-way authentication (both client and server can be authenticated against public/private keys). There is a collateral issue of what provisions should be made for systems within the perimeter to connect to outside networks using various protocols. PPTP and L2TP are the most well-known. Whether these methods of accessing outside networks should be permitted or not is

a management question of no small import, equivalent to totally suppressing outside communications.

From a security standpoint, tunnels to the outside world are a perfect storm, potentially permitting unlimited, nonmonitored communications to the outside. From the standpoint of enabling business operations, such access may be a practical necessity. Vendors, contractors, suppliers, and customers all need access to internal systems at their respective organizations, and such access will invariably require the use of a VPN tunnel. Perhaps the best solution is to reverse the traditional inside/outside dichotomy, making the LAN an untrusted network. The LAN then becomes a universal dial tone. Access to internal corporate systems can then be secured separately using VPN technology.

The advent of SSL/HTTP-based tunnels presents another challenge. `gotomypc.com` offers such a service, and individuals have used it to circumvent firewalls and implemented ad hoc remote access. The cost is nominal, often a small fraction of the monthly out-of-pocket outlay for an individual's daily commute to the office. The solution of blocking connections to the IP addresses assigned to such a provider is an often recommended, yet inherently flawed, prophylactic. Blocking one or more such services does nothing to secure the network against an as-yet-unidentified service of this type, such as that hosted on a home server. Limiting the duration of SSL connections is also merely a speed bump to such schemes. These remain a challenge, as does the advent of directly usable SSL/HTTP tunnels communicating using the standard HTTP (TCP Port 80) and HTTPS (TCP Port 443) ports.

In these cases, firewalls are a reasonable solution, so long as their limitations are recognized. For example, firewalls do not prevent mobile code such as Active-X and JAVA from working around prohibited functions. Network attacks using code supplied to browsers for local execution within the local network context have been published. These attacks can persist across time, and are one of the attack classes within the so-called Advanced Persistent Threat spectrum. Such code, in combination with weak security practices on network infrastructure, can cause severe damage (see Chapters 16, 17, 20, and 21 in this *Handbook*).

30.6.4 Multiple Security Domains. Many networks implement security solely at the point of entry, where the organization's network connects to the public Internet. Such *monolithic firewalls* are less than effective choices for all but the simplest of small organizations. As a starting point, systems available to the general population should be outside of the internal security domain in a no-man's land between the public Internet and the private internal net such isolation is referred to as a *demilitarized zone* (DMZ). These systems should be afforded a degree of protection by sandwiching them between an outer firewall (protecting the DMZ from the public network) and an inner firewall (protecting the internal network from the public network and controlling the communications between the publicly accessible servers located in the DMZ to the internal network). Alternatively, the DMZ may be a cul-de-sac attached to a separate port on a single firewall, using a different set of traffic management rules. Such a topology permits implementation of the differing security restrictions applicable to the two networks. Systems located within the DMZ should also be suspect, as they are targets for compromise.

Although the industry as a whole agrees on the need for DMZ configurations, it is less appreciated that such restrictions also have a place within organizations. Different groups, departments, and functions within an organization have different security and access requirements. For example, in a financial services firm, the security

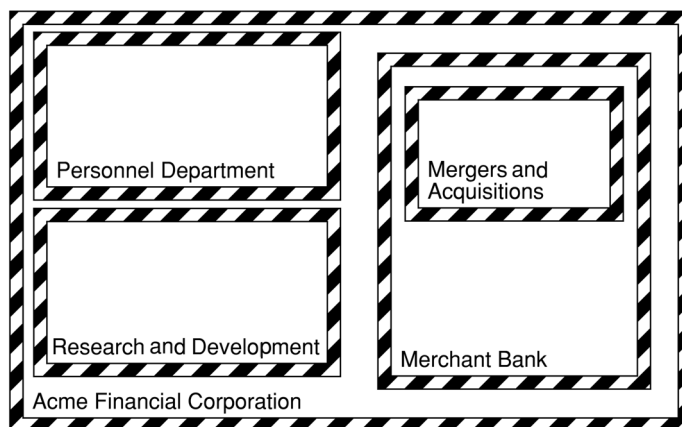

EXHIBIT 30.3 Sibling and Nested Security Domains

requirements differ dramatically among departments. Three obvious examples of departments with different requirements are personnel, mergers and acquisitions, and research and development (see Exhibit 30.3).

The personnel department is the custodian of a wide range of sensitive information about the firm, its employees, and often outsiders who are either regularly on company premises or work regularly with the company on projects. Some of this information, such as residence addresses, pay levels, and license plates, is sensitive for personal or cultural reasons. Other information subjects the organization to legal or regulatory sanctions if it is improperly disclosed or used. In the United States, examples of sensitive data include Social Security numbers, age, sexual orientation, and the presence of human immunodeficiency virus (HIV) or other medical details. Still other information may be subject to specific legal or contractual confidentiality provisions.

The mergers and acquisitions department handles sensitive information of a different sort. Information about business negotiations or future plans is subject to strict confidentiality requirements. Furthermore, the disclosure of such information is subject to a variety of regulations on governmental and securities industry levels. Within the mergers and acquisitions department, access to information often must be on a need-to-know basis, both to protect the deal and to protect the firm from exposure to civil and criminal liability.

Some information in the research and development department is completely open to the public, whereas other information is restricted to differing degrees.

A full implementation of an adequate security environment will require protections that are not only logically different on a departmental basis but also require that different departments be protected from each other. It is difficult, therefore, if not topologically impossible for a single firewall, located at the connection to the outside world, to implement the required security measures. It is difficult to provide assurances that the corporate backbone is free from surreptitious monitoring. In addition, even authorized monitoring can produce communications logs containing sensitive protected information. The network logs then become a hazard in and of themselves.

Securing systems in isolated logical areas is an example of necessary distrust, merely a matter of ensuring that the interactions between the third-party systems and the outside world are allowed to the extent that they are expected. As an example, consider the straightforward situation at Hypothetical Brokerage. Hypothetical Brokerage uses two

trading networks, Omega and Gamma. At first glance, it would seem that that it would be acceptable to place Omega's and Gamma's network gateways on the usual DMZ, together with Hypothetical's Web servers.

However, this grants a high degree of trust to Omega and Gamma and all of their staff, suppliers, and contractors. The most important operative question is whether there is a credible hazard.

Either of the two gateways is well situated to:

- Monitor the communications traffic to and from Hypothetical's Web servers
- Monitor the traffic between Hypothetical and the other, competing network
- Attack the other gateway
- Disrupt communications to and from the other gateway
- Attack Hypothetical's network

Network providers also represent an attractive attack option. A single break-in to a network provider-supplied system component has the effect of compromising large numbers of end user sites. There is ample history of private (PBX) and public (carrier-owned) switches being preferred targets.⁴² Provider-supplied SOHO routers with remote management or Wi-Fi capability can also become an attack vector if the provider-supplied configurations are deficient, or if the provider-generated management passwords are compromised.⁴³

The solution (see Exhibit 30.4) is to isolate the third-party systems in separate DMZs, with the traffic between each of the DMZs and the rest of the network scrupulously checked as to transmission control protocol and user datagram protocol (TCP/UDP), port number, and source and destination addresses, to ensure that all traffic is authorized. One method is to use a single firewall, with multiple local area network (LAN) ports, each with different filtering rules, to recast Hypothetical's original single DMZ into disjoint, protected, DMZs.

30.6.5 Compartmentalization. Breaking the network into separate security compartments reduces the potential for total network meltdown. Limiting the potential damage of an incident is an important step in resolving the problems.

The same rule applies to the DMZs. For example, in a financial trading or manufacturing enterprise, it is not uncommon to have gateways representing access points to trading and partner networks. Where one places these friendly systems is problematic. Many organizations have chosen to place these systems within their regular DMZ.

Sites have belatedly discovered that such gateways have, on occasion, been found to have acted as routers, taking over that function from the intended routers. In other cases, the gateways have experienced malfunctions and impaired the functioning of the rest of the network (or DMZ). As always, the only solutions certain to work are shutdown or isolation.

Compartmentalization also prevents accidents from cascading. A failure in a single gateway is not likely to propagate throughout the network, because the unexpected traffic will be stopped by the firewall isolating the gateway from the network. Such an event can be made to trigger a firewall's attack alarms.

The network problem is not limited to externally provided nodes. An errant system operating within a noncompartmented network, located as it is within the outer security perimeter, can wreak havoc throughout the entire corporation. Constructing the network as a series of nested and peer-related security domains, each protected by appropriate

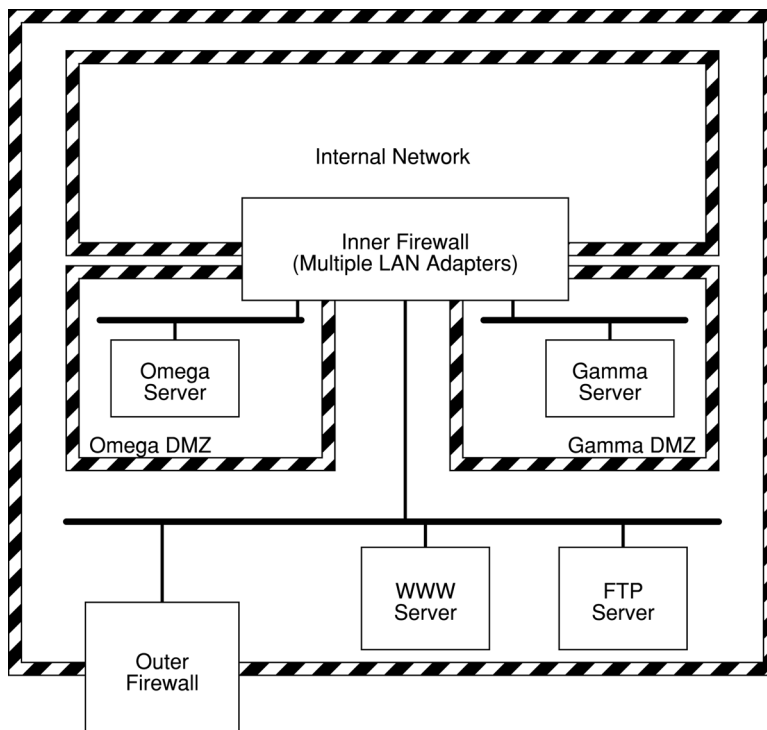

EXHIBIT 30.4 Omega and Gamma Servers in Separate DMZs from Hypothetical's Server

firewalls, localizes the impact of the inevitable incidents, whereas an uncompartimented network permits the contagion to spread unchecked throughout the organization. Larger networks dramatically raise the costs of an incident. It is quite conceivable that the entire budget for compartimenting a corporate network will be less than the cost of a single hour of downtime resulting from the first errant system.

The ready availability of portable storage devices, including USB memory devices and external hard drives, makes compartmentalization an even more serious issue. Exploits have shown the desirability of disabling automatic execution of software stored on plug-in devices.

30.6.6 Need to Access. Sometimes it is easy to determine who requires access, to which resources, and to which information. However, the question of access control often involves painful choices, with many nuances and subtleties. Legal and contractual responsibilities further complicate the question. For example, lack of access may exculpate persons alleged to have misused information.

Physical and logical access controls (see Chapters 23, 28, 29, 32, and 35 in this *Handbook*) need to be implemented for Internet-accessible systems as for any other sensitive and critical system. Controls for such systems must be enforced and respected by all members of the organization. It is important that personnel with restricted access to the network and security infrastructure understand and comprehend the reasons for the security rules and that they not take measures that circumvent those rules. The integrity of an organization's firewalls and network infrastructure is only as good as the

physical and logical security of the personnel, equipment, infrastructure, and systems comprising the firewall and network. Regular auditing of both physical and logical access to infrastructure assets is critical and necessary. Scanning for unauthorized (rogue) Wi-Fi access points is also prudent. As was the past with dial-in modems; rogue Wi-Fi access points can compromise an organization's entire security posture.

The need to maintain information security on communications within organizations argues for the extensive use of security technologies, even when the data packets are never expected to leave the premises. It is sound planning, even within the enterprise, to require applications with privacy or confidentiality requirements to make use of privacy infrastructure such as the Secure Sockets Layer (SSL) for Web-based applications or tunneling such as Layer 2 Tunneling Protocol⁴⁴ and Point-to-Point Tunneling Protocol.⁴⁵ This helps ensure that sensitive information is limited in distribution.

Needless to say, these approaches should employ high-grade encryption and properly signed X.509 certificates from well-accepted Certification Authorities. Self-signed, expired, and not-generally-accepted certificates should not be used.

30.6.7 Accountability. People often talk about impenetrable systems. Despite the castle-and-moat analogies used in many discussions of security, perimeters are imperfect. Given the likelihood of successful attacks, security personnel must use both technical and managerial measures for effective response.

When securing infrastructure, priority should be given to protective measures that ensure accountability for actions. Just as it is desirable to prevent inappropriate activity, it is even more important to ensure that activities can be accounted for.

For example, there are many ways to carry out denial-of-service attacks. The most troublesome are those which are completely legal. Although some of these attacks, such as distributed denial of service, are belligerent or politically and ideologically motivated, involving remote-control *zombie* programs and botnets (described in Chapter 16), many accidental DoSs can occur without malice in the course of software development. For example, two of the most famous worms that inadvertently led to DoSs, the Morris worm and the WANK worm, were detected inadvertently as a result of implementation errors in their replication mechanisms. These errors caused both worms to proliferate extremely rapidly, effectively producing unintended DoS attacks and subsequent detection.

When a compromised machine is analyzed forensically, the presence of the attack may remain undetected. This is particularly true when the attack involves designer malware not in general circulation (see Chapters 16, 17, and 20 in this *Handbook*).

It is important to analyze security breaches to distinguish among attacks, accidents, and experiments. It is better for weaknesses to be uncovered, even accidentally, within an organization than it is to deal with a truly belligerent security breach. Policies and practices should therefore encourage employees to report accidents rather than try to hide them. As for false alarms caused by overenthusiastic security neophytes, management should avoid punishing those who report illusory breaches or attacks. Accountability provides the raw material to determine what actually happened. The resulting information is the critical underpinning for analysis and education, thus enabling the enterprise to evolve to higher levels of security and integrity.

30.6.8 Read-Only File Security. Many sites allow downloads, usually via FTP and HTTP, of large numbers of files. These files may include copies of forms,

30 · 40 E-COMMERCE AND WEB SERVER SAFEGUARDS

manuals, instructions, maps, and service guides. If such file serving is provided, then it is critical to ensure that:

- The servers supporting the downloading service are secure.
- The contents of the publicly accessible file store are read-only and subject to change control.
- The entire contents of the public file store can be restored quickly in the event of a possible compromise.
- There is a clearly designated party with responsibility for maintaining and protecting the public file service.

30.6.9 Going Offline. Internet-connected systems require responsiveness that is directly related to the out-of-service costs. This may be the cost of lost business; in other organizations, the cost may be that of lost professional time, of damaged public relations, and of lowered morale. In any event, the larger the proportion of the organization (or its customers) affected by the problem, the higher the cost, and the greater the urgency to effect repairs.

Today's interconnected world makes Internet disconnection a truly painful option for a network or security manager. Although the cost of disconnection (or partial disconnection) can run into hundreds of thousands of dollars in lost business and productivity, disconnection in certain situations is both necessary and appropriate. At times, disconnection presents the lowest-cost, most effective way to protect users, systems, and the public. On May 4, 2000, during the epidemic of the "I Love You," Microsoft Outlook—exploiting virus attack, network managers at Ford Motor Company disconnected Ford's network from the outside world to limit the entry of contaminated email into Ford's systems and to prevent Ford's systems from spreading the contagion.⁴⁶ The response achieved its goals. Disconnection resulted in less pain than the alternatives. Segmented networks help provide compartmentalization, permitting a more nuanced response than simple disconnection.

The primary issue surrounding disconnection is: What can be disconnected? Who has the authority? Murphy's Law often intervenes. Such important incidents require short response times, inevitably on occasions when senior managers are not available. The best way to provide for this contingency is to furnish guidelines for personnel with authority to defend the systems and a guarantee that actions within the guidelines will be immune from reprisal. If an organization fails to authorize such actions, they also forswear the benefits accruing from the steps to contain damage.

30.6.10 Auditing. In any organization, facilities usage should be monitored and analyzed, including network activity. Because people interested in attacking or subverting the enterprise's networks will attack when they wish, such monitoring and analysis must be part of a continuing process. Ongoing observation and review should include:

- Physical communications infrastructure
- Firewalls, router tables, and filtering rules
- Host security
- File security
- Traffic patterns on backbones, DMZ, and other network segments
- Physical security of systems and communications infrastructure

These areas are both synergistic and independent. They are synergistic in that the combination of all of them is mutually reinforcing in promoting a secure computing environment. They are independent because any one of them may represent a weak point in an otherwise secure environment. For more information on auditing, see Chapter 54 in this *Handbook*.

30.6.11 Emerging Technologies. Emerging technologies continue to recast the challenges in the Internet technology arena. One such challenge is emerging in the use of SSL/TLS-based firewalls.

Using HTTPS as a basis for building encrypted tunnels appears at first impression to be a tremendously enabling technology. Most firewalls permit the initiation of connections from within the protected zone on TCP port 443 for the purpose of allowing connection to the wide variety of Websites that need to secure information, as has been mentioned in other locations throughout this chapter. For privacy and security, such traffic should be opaque to monitoring.

The use of HTTPS as the basis for tunneling also provides a tailor-made technique for abuse. For example, such technologies make it possible for a compromised desktop system to monitor the network, extracting data of interest, and to transmit the resulting data securely to an outside location through the firewall. The opaque nature of the SSL/TLS-based connection makes it impossible to scan the outgoing data.

This technology may well be the death knell of shared-connectivity LANs. It is ever more important to secure the network infrastructure against attacks that allow a rogue machine to accumulate data by monitoring network traffic.

Intrusion detection systems may also need to be repurposed to identify HTTPS connections that have significant traffic volumes, for signs of compromise or abuse. Approaches that treat the entire network as inherently compromised, with the use of IPSec VPN technology from the desktop server, to secure communications infrastructure, may be needed to protect against such attacks and malfeasance. In this context, the use of telnet for console communications is strongly discouraged. SSH and other encrypted protocols should be used.

30.7 ETHICAL AND LEGAL ISSUES. Managing a Website poses a variety of ethical and legal issues, mostly surrounding the information that the site accumulates from processing transactions as well as from performance tracking, problem identification, and auditing. Policies need to be promulgated to ensure that information is not used for unauthorized purposes, and the staff running such systems needs to be aware of, and conform to, the policies. Many of these ethical issues have civil and criminal considerations as well. The topic of information privacy is more completely addressed in Chapter 69 of this *Handbook*. For more information on security policy standards, development and implementation, see Chapters 44, 45, 47, 48, 49, 50, and 66.

30.7.1 Liabilities. The liability environment surrounding Web servers is too new for litigation to have run its course. However, there is no reason to believe that the myriad laws governing the disclosure of personal information will not be fully enforced in the context of Websites.

Websites increasingly handle sensitive information. Financial industry sites routinely handle bank and securities transactions. Email services handle large volumes of consumer traffic, and more and more insurance companies, employee benefits departments, and others are using Websites to deal with extremely sensitive information covered by a variety of regulations.

Part of the rationale for recommending careful attention to the control of Web servers and their supporting systems is the need to create an environment of due diligence, where an organization can show that it took reasonable steps to ensure the integrity, safety, and confidentiality of information.

30.7.2 Customer Monitoring, Privacy, and Disclosure. Customer monitoring is inherently a sensitive subject. The ability to accumulate detailed information about spending patterns, for example, is subject to abuse. A valid use of this information helps to pinpoint sales offerings that a customer would find relevant while eliminating contacts that would be of no interest. Used unethically or even illegally, such information could be used to assemble a dossier that could be the subject of embarrassing disclosure, of insurance refusal, and even of job termination. The overall problem predates the Web. In fact, more than 20 years ago a major network news segment reconstructed someone's life using nothing more than the information contained in their canceled checks, supplemented with publicly available information. The resulting analysis was surprisingly detailed. A similar experiment was reported in 1999, using the Web.⁴⁷

Organizations sometimes violate the most basic security practices for protecting on-line information, when all of the information required to access an account improperly is contained on the single page of a billing statement. There have been repeated incidents (e.g., CDUniverse, CreditCard.com) where extremely sensitive information has been stored unencrypted on Web-accessible systems. These incidents recur with regularity and are almost always the result of storing large amounts of sensitive client information on systems that are Internet accessible. There is little question that it is inappropriate to store customer credit card, and similarly sensitive data, on exposed systems.

The security and integrity of systems holding customer order information is critical. The disclosure of customer ordering information is a significant privacy hazard. Failure to protect customer banking information (e.g., credit card numbers and expiration dates) can be extremely costly, both in economic terms and in damaged customer relations. Firms processing payment cards are also subject to the Payment Card Industry Security Standards Council's PCI DSS; which can create additional liabilities and obligations on the enterprise.

A Website, by its monitoring of customer activity, will accumulate a collection of sensitive material. It may be presumed that the information is useful only for the site, and is inherently valid, but there are a variety of hazards here, most of which are not obvious:

- Information appearing to originate from a single source may indeed be a compilation of data from multiple sources. Shared computers, firewalls, and proxy servers can give rise to this phenomenon.
- Casual correlations may arise between otherwise unrelated items. For example, it is not an uncommon acceptable business practice for one member of a business group to pay for all expenses of a group of traveling colleagues. Failure to correctly interpret such an event could be misconstrued as proof of illicit or inappropriate behavior.
- Individuals often have a variety of societal roles (e.g., parent, domestic partner, professional, nonprofit involvement). Conclusions drawn from such data may not reflect the individual, but can easily be an unrelated consequence of some other involvement (e.g., an inquiry about the SAT or GRE could indicate an intent to attend a college; it could also mean that a child, niece, neighbor, or other acquaintance could have sought counsel).

The problem with casual associations is the damage they can cause. In the national security area, the use of casual associations to gather intelligence is a useful tool, albeit one that is recognized to have serious limitations. In other situations, it is an extremely dangerous tool, with significant potential to damage individuals and businesses. An example:

A California-based married businessman flies to New York City. When he arrives, he checks into a major hotel. A short time later, he makes a telephone call, and shortly a young woman goes up to his room and is greeted warmly. Apparently, a compromising situation. The businessman is old enough to be the woman's father. In fact, he *is* her father. That single fact changes apparently inappropriate behavior into a harmless family get-together. Peter Lewis⁴⁸ of *The New York Times* correctly notes that this single fact, easily overlooked, dramatically changes the import of the information.

The danger with correlations and customer monitoring is that there is often no control on the expansive use of the conclusions generated. The information often has some degree of validity, but it is both easy to overstep the bounds of validity, and it is difficult, if not impossible, to later correct damage, once damage has been done.

30.7.3 Litigation. The increasing pervasiveness of the Web has led to increasing volumes of related litigation. In this chapter, the emphasis is on litigation or regulatory investigation involving commercial or consumer transactions, and the issues surrounding criminal prosecution for criminal activities involving a Website. More detailed information on this subject appears in Chapter 61 of this *Handbook*.

Civil. Website logs and records can become involved in litigation in many ways. In an increasing number of cases, neither the site owner nor the operator is a party to the action; the records merely document transactions and events involved in a dispute. The dispute may be a general commercial matter, a personnel matter, or even a domestic relations matter involving divorce.

It is important that records handling and retention policies be developed in concert with counsel. The firm's management and counsel also must determine what the policy is to be with regard to subpoenas and related requests. Counsel also will determine what materials are subject to which procedures and regulations. For example, in a case of an email provider (e.g., hotmail.com), material may be subject to the Electronic Communications Privacy Act of 1986 (18 U.S.C.A. § 2510 et seq.). Other material may be subject to different legal or contractual obligations.

Regulatory. A wide range of rules is enforced (and often promulgated) by various regulatory agencies. In the United States, such agencies exist at the federal, state, regional, and local level. (Outside the United States, many nations have agencies only at the national and provincial levels.) Many of these agencies have the authority to request records and conduct various types of investigations. For many organizations, such investigations are significantly more likely than civil or criminal investigations. Regulatory agencies also may impose record-keeping and retention requirements on companies within their jurisdiction.

Criminal. Criminal prosecutions receive more attention than the preceding two categories of investigation yet are much less frequent. Criminal matters are expensive to investigate and prosecute and must pass a higher standard of proof than regulatory or civil prosecutions. Relatively few computer-related incidents reach the stage of a criminal prosecution, although because of its seriousness, the process is the most visible.

Logs, Evidence, and Recording What Happened. The key to dealing effectively with any legal proceeding relating to a Website is the maintenance of accurate, complete records in a secure manner. This is a complex topic, some details of which are covered in Chapter 53 of this *Handbook*.

In the context of protecting a Website, records and logs of activity should be offloaded to external media and preserved for possible later use, as determined by the site's policy and its legal obligations. Once offloaded, these records should be stored using the strict procedures suitable for evidence in a criminal matter. The advent of inexpensive CD-ROM and DVD writers greatly simplifies the physical issues of securely storing such media. A cautionary note about CD-ROM and DVD media is in order: When creating such records, care should be taken to use blank media manufactured to archival standards. Archival quality media is more expensive than the more readily available media of lesser quality; however, archival media has a rated life of decades, cheaper media has a lifespan of a few years.

Archival records not intended for evidentiary use also should be stored offline. This should take the form of physically offline, or at least on systems that are not accessible from the public Internet.

The media should be stored in signed, sealed containers in an inventoried, secure storage facility with controlled access. For this reason, the copies archived for records purposes should not be the copies normally used for system recovery. In the event of an investigation or other problem, these records will be carefully examined for possible modification or misuse.

30.7.4 Application Service Providers. In recent years, it has become increasingly common to outsource entire applications services and hosting. External organizations providing such services are known as applications service providers, more commonly referred to as ASPs. More recently, this has been rechristened as *software as a service* (SaaS). Both raise similar security and integrity concerns. In both cases, significant applications and data are stored outside of the organization, with the organization retaining responsibility for the integrity and confidentiality of these records.

A more bare-boned offering, virtual hosting, has experienced an explosion of popularity, often referred to as *Infrastructure as a Service* (IaaS). Many of the same issues with SaaS apply to environments purchased as IaaS. The dividing line for responsibility is different, but the same classes of problems occur.

Conceptually, ASPs are not new. Many organizations have historically outsourced payroll processing and other applications. Theoretically, the ASP is responsible for the entire application. Often, paying a package price for the application seems attractive: no maintenance charges, no depreciation costs, lower personnel costs, latest technology, and moderately priced upgrades. However, just as a ship's captain retains responsibility for the safety of his ship despite the presence of a harbor pilot, an enterprise must not forget that if something goes wrong, the enterprise, not the ASP, will likely bear the full consequences. In short, the ASP must be required to answer the same questions, and held to the same standards, as an inside IT organization regarding privacy, security, and integrity issues.

The security and integrity issues surrounding the use of ASPs are the same as those surrounding the use of an internal corporate service. Questions of privacy, integrity, and reliability remain relevant, but as with any form of outsourcing, there are additional questions. For example, is stored information commingled with that of other firms, perhaps competitors? Is information stored encrypted? What backup provisions exist?

Is there offsite storage of backups? What connectivity does the ASP have? Where are the ASP's servers, and are they dispersed? What are the personnel practices of the ASP? Does the ASP itself own and operate its facilities, or does it in turn contract out to other providers?

The bottom line is that although outsourcing promises speedy implementation, lower personnel costs, and economies of scale, the customer organization will suffer considerable harm if there is a problem with the ASP, with availability, results, or confidentiality.

In the end analysis, the organization retains liability for its operations and its data. While it is comforting to consider that the legal system will accept "My provider did it" as an excuse for lost, compromised, or untrustable data, it remains an untested theory and is not likely to prevail. Recent experiences with major manufacturers, subcontractors, and tainted products would seem to indicate that outsourcing risk remains a serious potential liability.

Legal process requests, either criminal warrants or civil subpoenas, against ASPs for third-party data represent another hazard. If data belonging to third parties is commingled on the ASP's system, care is required to prevent the unauthorized and inappropriate disclosure of unrelated data belonging to third parties other than the one that is the subject of the request.

None of the items cited are sufficient to justify a negative finding on ASPs as a group. They should, however, serve as reminders that each of the issues related to keeping a Web presence secure, available, and effective apply no less to an ASP than they do to an in-house IT organization.

For information about outsourcing and security, see Chapter 68 in this *Handbook*.

30.8 SUMMARY. Availability is the cornerstone of all Web-related strategies. Throughout this chapter, it has been noted that redundant hosting and routing were necessary to ensure 24/7/365 availability. It was also noted that although some providers of services offer various guarantees, these guarantees almost never provide adequate compensation for consequential damage done to the enterprise. In the end, an enterprise's only protection is to take adequate measures to ensure their own security and integrity.

Operating guidelines and authority are also critical to ensuring the availability of Web resources on a 24/7/365 basis. Systems must be architected and implemented to enhance availability on an overall level. Operating personnel must have the freedom and authority to take actions that they perceive as necessary without fear of reprisal if the procedures do not produce the desired outcome.

Privacy and integrity of information exchanged with the Website is also important. The implementation and operation of the site and its components must be in compliance with the appropriate laws, regulations, and obligations of the site owner, in addition to being in conformance with the expectations of the user community.

Protecting Internet and Web assets is a multifaceted task encompassing many disciplines. It is an area that requires attention at all levels, beginning at the highest levels of business strategy and descending successively to ever more detailed implementation and technology issues.

It is also an area where the smallest detail can have catastrophic impact. Recent events have shown that the lessons of communications history apply. Even a small error in network architecture, key management, or implementation can snowball until it is an issue that can be felt in the corporate boardroom.

31.1 INTRODUCTION. The Internet has been called a cesspool, sometimes in reference to the number of virus-infected and hacker-controlled machines, but more often in reference to the amount of objectionable content available at a click of the mouse. This chapter deals with efforts to monitor and control access to some of this content. Applications that perform this kind of activity are controversial: Privacy and free-speech advocates regularly refer to *censorware*, while the writers of such software tend to use the term *content filtering*. This chapter uses *content filtering*, without meaning to take a side in the argument by so doing. For more on the policy and legal issues surrounding Web monitoring and content filtering, see Chapters 48 and 72 in this *Handbook*.

31 · 2 WEB MONITORING AND CONTENT FILTERING

This chapter briefly discusses the possible motivations leading to the decision to filter content, without debating the legitimacy of these motives. Given the variety of good and bad reasons to monitor and filter Web content, this chapter reviews the various techniques used in filtering, as well as some ways in which monitoring and filtering can be defeated.

31.2 SOME TERMINOLOGY

Proxy—a computer that intercedes in a communication on behalf of a client. The proxy receives the client request and then regenerates the request with the proxy's own address as the source address. Thus, the server only sees identifying information from the proxy, and the client's identity remains hidden (at least from a network addressing point of view). Proxies are widely used by organizations to control the outward flow of traffic (mostly Web traffic) and to protect users from direct connection with potentially damaging Websites.

Anonymizing proxy—a proxy that allows users to hide their Web activity. Typically, such a proxy is located outside organizational boundaries, and often used to get around filtering rules.

Privacy-enhancing technologies (PET)—a class of technologies that helps users keep their network usage private. These include encryption, anonymizing proxies, mixing networks, and onion routing.

Encryption—reversible garbling of text (plaintext) into random-looking data (ciphertext) that cannot be reversed without using secret information (keys). See Chapter 7 in this *Handbook* for details of cryptography.

Mixing networks—users encrypt their outbound messages with their recipient's (or recipients') public key(s) and then also with the public key of a "Mix server." The encrypted message is sent to the Mix server, which acts as a message broker and decrypts the cryptogram to determine the true recipient's address and to forward the message.¹

Onion routing—an anonymous and secure routing protocol developed by the Naval Research Laboratory Center for High Assurance Computer Systems in the 1990s. Messages are sent through a network (cloud) of *onion routers* that communicate with each other using public key cryptography. Once the temporary circuit has been established, the sender encrypts the outbound message with each of the public keys of all the onion routers in the circuit.

Specifically, the architecture provides for bi-directional communication even though no one but the initiator's proxy server knows anything but previous and next hops in the communication chain. This implies that neither the respondent nor his proxy server nor any external observer need know the identity of the initiator or his proxy server.²

A third-generation implementation of onion routing is *Tor* (the onion router).³

31.3 MOTIVATION. As a general concept, an individual or group chooses to monitor network activity and filter content through an authority relationship. The most common relationships leading to monitoring and filtering are:

- Governments controlling their citizenry
- Parents and schools protecting their children
- Organizations enforcing their policies

- Governments enforcing their laws
- Governments monitoring terrorists and other nation states

31.3.1 Prevention of Dissent. Probably the most common reason for the opposition to content filtering is that many repressive governments filter content to prevent dissent. If citizens (or subjects) cannot access information that either reflects badly on the government or questions the country's philosophical or religious doctrines, then the citizens probably will not realize the degree to which they are being repressed.

In countries such as the United States, where the Constitution guarantees freedoms of speech and the press, many people feel that only those with something to hide about their activities would fight against censorship. This notion, combined with objectionable content so readily available on the Internet, may be why efforts to question the use of filtering software in libraries and other public places have met with resistance or indifference. Chapter 72 gives many examples of countries using filtering products to limit the rights of their citizens. These examples should be a cautionary tale to readers in countries that are currently more liberal in information policy.

31.3.2 Protection of Children. For the same reasons that convenience stores, at least partially, hide adult magazines from view, the government has required that some classes of information on the Internet be off-limits to children in public schools. This stems from the perception of the schools' role as a surrogate parent and government liability involved in possible failure in that role. A variety of regulations have required the use of content monitoring and filtering in schools and libraries, on the theory that such public or publicly supported terminals should not be using taxpayers' money to provide objectionable content to children. The U.S. Supreme Court has ruled several of these efforts unconstitutional after extreme protest from libraries. Most recently, the Child Internet Protection Act (CIPA)⁴ required school districts that receive certain kinds of government funding to use filtering technologies. Most schools have implemented Web filtering, aggressively limiting the Web content available to students. Estimates of the amount of blocked content vary widely, but one school district claims to filter about 10 percent of its total Web traffic due to questionable content.⁵

The obvious target of filtering technology in schools is to keep students from viewing material considered *harmful to minors*. Another less-publicized reason to filter Web content is to prevent students from doing things on the Web that they might not do if they knew that someone was watching. The hope is to keep students from getting a criminal record before they even graduate from high school, protecting them from their bad judgment while they are learning to develop good judgment and learning the rules of society. Arguably, this is the job of a parent and not the job of a school, but schools providing Internet access nonetheless must provide this kind of protection.

High school students and kindergarteners generally have differing levels of maturity, and a reasonable filtering policy would include a flexible, gradual degree of filtering depending on age. Schools could use less-intrusive methods of controlling access to Web content as well, such as direct supervision of students using computers. Parents also have the opportunity to filter the content that their children view at home.

31.3.3 Supporting Organizational Human Resources Policy. Organizations have a variety of reasons for monitoring and filtering the Web content accessed by their employees. The simplest is a desire to keep employees doing work-related activity while at work. Despite studies indicating that the flexibility to conduct limited personal business, such as banking or email, from work produces happier, more

31 · 4 WEB MONITORING AND CONTENT FILTERING

productive workers, managers sometimes view personal use of business computers as stealing time from the company.

A more pragmatic reason to filter some Web content is to prevent “hostile workplace” liability under Equal Employment Opportunity laws. The problem with this approach is that many kinds of content would potentially be offensive to coworkers, so it is difficult to use filtering technology to guarantee that no one will be offended while still allowing reasonable work-related use of the Internet.

Some organizations choose to monitor Web traffic with automated systems, rather than blocking anything, and to notify users of the monitoring. The notification could be in general policy documents or in the form of a pop-up window announcing that the user is about to view content that might violate policy. Either way, the notion is that the organization might avoid liability by having warned the user, but might also avoid privacy and freedom-of-speech complaints. The monitor-and-notify approach also sends the message that the organization trusts its employees, but wants to maintain a positive and productive work environment.

31.3.4 Enforcement of Laws. Law enforcement agencies rarely engage in content filtering, but traffic monitoring is an often-utilized tool for investigating computer crime. Gathering evidence for these investigations often involves catching the traffic as it actually arrives at its destination, so filtering would be counterproductive. In this case, proving identity is the key to getting usable evidence, so privacy-enhancing technologies are real problems. In some cases, the logs of Web proxies—which would identify the real source address of the client machine—are available with a subpoena. Investigations of this sort often target child pornography, drug production, or the theft of computer hardware protected by asset-recovery software.

31.3.5 National Security Surveillance. While government law enforcement agencies work to control activity that violates the nation’s laws, other government agencies are concerned with the growth of information and communications technologies as tools of terror and international conflict. From the threat of eventual cyber-war to the more immediate concern with terrorism, governments are exploring ways to detect the use of email, cell phones, social media platforms, and even online games to communicate and coordinate plans for hostile activities. Monitoring these media has become a pressing, expensive, and risky priority for national governments.

As this edition was going to press, secret information was leaked about communications-monitoring activities of the U.S. Government’s National Security Agency, rekindling a perennial debate on the balance between privacy and safety in a democratic republic. Despite long-standing precedent and assurances about constitutional protection from unreasonable search, the revelations about the NSA’s PRISM and related programs have made it clear that networked communication is fair game in a nation’s efforts to stay one step ahead of its adversaries (whether they are real, potential, or even imagined ones).⁶ Furthermore, as the U.S. citizenry has discovered, it is very difficult for a government to effectively eavesdrop on hostile foreign electronic communications without gathering *all* communications, at the risk of violating privacy expectations of citizens and allies alike.

31.4 GENERAL TECHNIQUES. Filtering of networked communication can employ two basic tactics: examination of *metadata* and examination of the actual content of a message. The U.S. news media rediscovered the concept of metadata in the wake of the PRISM leak, as NSA representatives insisted that actual message content would

only be examined after filtering out irrelevant communications by looking at phone numbers, call durations, IP addresses, and other transactional information that reveals the source, destination, and temporal context of a conversation.⁷ Based on the overwhelming volume of communications traffic traversing the copper wires, fiber-optic cables, and wireless frequencies, it is indeed a daunting task to make filtering (or legal or military) decisions based on examining every word of every message. It is much more efficient, for most purposes, at least to start with these metadata and make assumptions about the relevance or danger of a particular computer, human, or organizational communication partner. Direct examination of the full content of messages is much more resource-intensive, though advances are being made in effective and efficient automated processing of text and images.

31.4.1 Matching the Request. The simplest technique used by filtering technologies is the matching of strings against lists of keywords. Every Web request uses a uniform resource locator (URL) in the general form:

`protocol://server.organization.top-level-domain/path-to-file.file-format`

Filtering a request for a URL can examine any portion of the string for a match against prohibited strings:

- Filters can match the *protocol* field to enforce policies about the use of encrypted Web traffic (HTTP versus HTTPS). This is more of a general security concern than it is a Web filtering issue, although an organization worried about the need to analyze all traffic could prevent the use of encrypted Web traffic by blocking all HTTPS requests.
- The *server* and *organization* fields describe who is hosting the content. Filtering based in these strings is a broad approach, as it leads to blocking either an entire Web server or an entire organization's Web traffic. See the discussion of server blocking in Section 31.4.2.
- The *top-level-domain* field can be used to filter content; see Section 31.4.3 for attempts to set up an .xxx domain.
- The *path-to-file* field includes the actual title of the requested Web page, so it varies most between individual requests. Whether it is more likely than other fields to contain information useful in filtering depends on the naming convention of the server. This field (and the *file-format* field) is optional, as shown in the request for `www.wiley.com`, which directs the server to display its default page.
- The *file-format* field tells the Web browser how to handle the text displayed in the page, whether in straight html format or encoded in some other file format (e.g., doc, pdf), or whether to allow dynamic generation of content (e.g., asp). Few filtering products use this field to filter traditional kinds of objectionable content, although enforcing other policies regarding dynamic code in high-security environments can require matching this field.

31.4.2 Matching the Host. Some filtering systems attempt to distinguish between acceptable and unacceptable sources on the Web by inspecting the particular servers or general information portals such as search engines.

31.4.2.1 Block Lists of Servers. Objectionable content tends to be concentrated on individual servers. This naturally leads some organizations to block access to those servers. The two methods of blocking servers are by Internet Protocol (IP) address and by name.

Blocking by IP address simply denies all traffic (or all HTTP traffic) to and from certain addresses. This tactic involves several difficulties based on how addresses are used. First, IP addresses are not permanent. While the numeric addresses of most large commercial servers tend to remain the same over time, many smaller servers have dynamically assigned addresses that may change periodically. Thus, blocking an IP address may prevent access to content hosted on a completely different server than intended. Second, commercial servers often host content for many different customers, and blocking the server as a whole will block all of the contents rather than just the objectionable ones. This is a particular problem for very large service providers like AOL, which grants every user the ability to host a Website. Blocking the AOL servers because of objectionable content would potentially overblock large numbers of personal Web pages. Third, address-based blocking creates the possibility of malicious listing, a practice in which an attacker (or a competitor) spoofs the address of a Web server and provides objectionable content likely to land the server on blocking lists. Some filtering products allow users to submit “bad” sites, providing another opportunity for malicious listing.

Blocking by name involves the Domain Name System (DNS), in which a human-readable name (e.g., www.wiley.com) maps to a computer-readable IP addresses (in this case, 208.215.179.146). DNS allows an organization to change the physical address of its Web server by updating the DNS listing to point to the new IP address, although this does rely on the system as a whole propagating the change in a reasonable amount of time. A device that monitors or filters traffic based on a domain name needs to be able to periodically refresh its list of name-to-address mappings in order to avoid blocking sites whose addresses periodically change. As with address-based blocking, name-based blocking also risks malicious listing as well as both under- and overblocking. Many organizations register multiple names for their servers, for a variety of reasons. For instance, an organization might register its name in the .net, .com, .org, and .biz top-level domains to prevent the kind of misdirection described in Section 31.44 (whitehouse.com). Other reasons for registering a name in multiple domains include preventing competitors from using name registration to steal customers and preventing speculative buying of similar names by individuals hoping to sell them for significant profit. Web hosting companies also provide service to many different organizations, so a variety of URLs would point to the IP address of the same hosting server. Thus, blocking by server name could underblock by not accounting for all the possible registered names pointing to the same server and overblock by matching the server name of a service provider that hosts sites for many different customers who use the provider’s server name in the URL of their Web pages.

31.4.2.2 Block/Modify Intermediaries. The Web has become an enormous repository of information, requiring the development of powerful search tools to find information. Early search engines gave way to more sophisticated information portals like Yahoo!, Google, AOL, and MSN. By allowing advanced searches and customized results, these portals give users easy access to information that would be difficult or impossible to find using manual search techniques. Portals have become wildly popular tools for accessing the Internet as a whole; Google claimed 100 million search queries

per day at the end of 2000; in 2013, its site index was estimated to contain over 48 billion pages.⁸ Information access at this scale makes portals natural targets for monitoring and filtering. Few commercial organizations prevent their employees from using popular portals, since they have become so much a part of the way people use the Internet. Some countries, however, have blocked access to certain portals for their citizens, hoping to control access to information that might tend to violate national laws (e.g., access to Nazi memorabilia in France) or inspire citizen resistance to the government (e.g., access to information about the Tiananmen Square massacre in China). For further discussion of these issues, see Chapter 72 in this *Handbook*.

31.4.3 Matching the Domain. From 2004 until its final decision in 2011, the Internet Corporation for Assigned Names and Numbers (ICANN) considered and rejected requests for a new top-level domain, .xxx, which would allow providers of sexually related content to voluntarily reregister their sites. Such a domain, it was argued, would be easy to filter in the URL of the request, which presumably would appeal to supporters of Web filtering. It would also allow content providers to show that they were complying with laws preventing children from accessing inappropriate material, by enabling more effective parental filtering. Nevertheless, the move met resistance on both fronts. Conservative religious groups feared that establishing a .xxx domain would legitimize pornography, while not all sexual content providers agreed that the perceived benefit would outweigh either the increased filtering of their sites or the easier monitoring of their clients' traffic.

ICANN rejected several revisions of the .xxx domain proposal over the years, citing the lack of unanimity in the sex content provider community as well as the fear that ICANN might be placed in the position of regulating content, which is outside the organization's charter. Ultimately, however, in 2011, the .xxx domain was approved.⁹

31.4.4 Matching the Content. String matching is simple to do, but difficult to do without both over- and underblocking. For instance, one of the most common categories for content filtering (particularly in the United States) is sex. Blocking all content exactly matching the word "sex" would fail to match the words "sexy" and "sexual." To avoid this kind of underblocking, word lists need to be very long to account for all permutations. A slightly more effective tactic is to block all works containing the string "sex," but this would overblock the words "Essex," "Sussex," and "asexual." Looking for all strings beginning with the combination "sex" would overblock "sexton," "sextet," and "sextant." Simple string matching also ignores context, so blocking "sex" would match in cases where a survey page asked the respondent to identify gender using the word "sex" or in pages describing inherited sex traits or gender roles or sexual discrimination lawsuits.

Other difficulties in string matching involve the vagaries of language. URLs can be displayed in any language whose character set a computer recognizes, so a filter will underblock requests in a language for which it lacks word lists. More generally, in any language it is possible to obfuscate the contents of a site with a seemingly benign URL to avoid filtering. The classic example of this is the pornography site www.whitehouse.com, presumably set up to catch visitors who mistakenly typed "com" when trying to reach the U.S. White House Website (www.whitehouse.gov). More recently, spam marketing campaigns have been setting up Websites linked in email, with meaningless strings of numbers and characters in the URL (e.g., <http://2sfh.com/7hioh>), making the sites difficult to filter.

In a 2006 study, Veritest compared three of the industry-leading Web filter products (WebSense, SmartFilter, and SurfControl). The winning product underblocked 7 sites, overblocked 8 sites, and miscategorized 10 sites, from a preselected list of 600 URLs. The two competing products fared worse, underblocking 23 and 14 sites, and overblocking 9 and 12 sites out of 600.¹⁰ A meta-study of filtering effectiveness studies performed in 2010 determined that from 2001 through 2008, the average accuracy of filtering products was 78 percent, with some increasing success: During 2007 and 2008, surveys found that the success rate had risen to 83 percent.¹¹ If this is the performance of the industry's leading edge, then clearly the technology is still developing.

Given the difficulties of accurate matching based on text or address related to the Web page request, a natural alternative is to examine the page content itself. Of course, content matching needs to have access to the unencrypted data in transit, so encrypted Web sessions cause a real problem for this tactic. Some organizations allow (or require) that HTTPS sessions terminate on the organization's own proxy server, potentially allowing the proxy to decrypt the data and perform content analysis.

31.4.4.1 Text. It is possible, although resource intensive, to watch the network traffic stream and look for text that matches a list of undesired content. This sort of matching typically does little analysis of context and so is prone to the same kind of false positives (overblocking) and false negatives (underblocking) described in Section 31.4.2. Moreover, as an increasing amount of Web content involves pictures and sounds, text matching becomes less effective.

31.4.4.2 Graphics. A promising new technique, with applications in visual searching as well as visual content blocking, breaks a graphic image into smaller objects by color or pattern. The technique then evaluates each object against a database of reference images for matching with desired criteria. In the case of blocking objectionable sex content, objects can be evaluated for skin tone and either blocked outright or referred to administrators for manual review if the match is inconclusive. Although content-based filtering has not yet developed into a commercial product, the tools exist and the technology seems applicable not only to still images, but also to video and even audio content.¹² In 2006, the NASA Inspector General's office used an image-search program called Web ContExt to snare an employee who had been trafficking in child pornography.¹³

31.5 IMPLEMENTATION. With the exception of content-based matching, which has not yet reached the market in any significant way, most filtering—whether of address, domain, or keyword—involves matching text lists.

31.5.1 Manual “Bad URL” Lists. Many firewalls provide the capability for administrators to block individual URLs in the firewall configuration. Entered manually, these rules are good for one-time blocking when a security alert or investigation identifies sites hosting viruses or other malware. This approach is also useful for demonstrating the general filtering abilities of the firewall and for testing other Web-blocking technologies. For instance, in an organization using a commercial blocking solution on a Web proxy, a simple URL-blocking rule on the organization's border firewall would provide some easy spot testing of the effectiveness of the commercial solution. Given the extreme size and constant growth of the Web, however, the manual approach does not scale well to protect against all the possible sources of objectionable material.

31.5.2 Third-Party Block Lists. With the enormous size of the Web, the more typical approach is to use a third-party block list. Most of these are commercial products with proprietary databases, developed through a combination of automated “Web crawlers” and human technicians evaluating Websites. Some companies have attempted to prevent researchers from trying to learn about blocking lists and strategies, but the U.S. Copyright Office granted a Digital Millennium Copyright Act (DMCA) exemption in 2003 for fair use by researchers studying these lists.¹⁴ Web-filter companies continue to oppose such exemptions. Two open-source filtering alternatives also exist, with publicly viewable (and customizable) block lists that run on caching proxies: SquidGuard¹⁵ and DansGuardian.¹⁶

31.6 ENFORCEMENT. Filtering of Web traffic typically occurs either at a network choke point, such as a firewall or Web proxy, or on the individual client machine. Economies of scale lead organizations to filter on a network device, while products designed for parental control of children’s Internet use usually reside on individual home computers.

31.6.1 Proxies. A proxy server is a device that accepts a request from a client computer and then redirects that request to its ultimate destination. Proxies serve a variety of purposes for an organization, including reduction of traffic over expensive wide-area network links and Internet connections, increased performance through caching frequently accessed Web pages, and protection of internal users through hiding their actual IP addresses from the destination Web servers. Proxies also represent a natural locus of control for the organization, enabling authentication and tracking of Web requests that go through this single device. Most browsers support manual configuration of a proxy for all Web traffic as well as automatic discovery of proxies running on the organization’s network. Organizations that use Web proxies typically allow outbound Web traffic only from the IP address of the proxy, thus forcing all HTTP traffic to use the proxy. Use of an encrypted Web session (HTTPS) is possible through a proxy, although either at the expense of the ability to monitor content (if the proxy merely passes the traffic through) or at the expense of the end-to-end privacy of the encrypted link (if the proxy decrypts and re-encrypts the session).

Individuals also use proxies to maintain the privacy of their activities on the network, as described in Section 31.7.4. Thus, in addition to serving as a natural vehicle for content-filtering applications, proxies also represent a serious threat to those same applications.

31.6.2 Firewalls. A firewall’s job is to analyze information about the traffic passing through it and apply policy rules based on that information. Maintaining acceptable response time and throughput requires that the firewall do its job quickly and efficiently. In order to do so, most firewalls merely look at network-layer information, such as source and destination addresses and ports. More recently, firewall vendors have been adding more features to increase security and product appeal. Many companies now call their more advanced firewalls “service gateways” or “security gateways” as the notion of Unified Threat Management (UTM) becomes more popular. These UTM devices combine many features that formerly required individual devices, such as anti-virus, intrusion detection, and filtering of both junk email and Web content.

Sophisticated traffic examination increases the demand on firewall hardware. In order to reduce the performance hit caused by increased packet inspection, many

firewalls allow the administrator to define particular rules or protocols for advanced checking. For instance, since viruses are most prevalent in email, Web, and peer-to-peer connections, the firewall administrator might need to configure only anti-virus checking on rules applying to these protocols. Similarly, if the firewall needs only to monitor outbound HTTP requests from a single IP address, the Web proxy, then the extra processing load of the monitoring function can be constrained to that traffic profile.

The decision between filtering Web traffic at the proxy server (letting the firewall just pass the traffic from that address) and filtering Web traffic at the firewall (having the firewall do the URL inspection) depends on the amount of Web traffic and the budget (one device or two). The decision also affects the strength of the assertion that the organization is successfully filtering objectionable content. If the organization's border firewall performs the filtering, then this assertion depends on the firewall being the only way for traffic to leave the organization's network. Other traffic vectors, including wireless networking, protocol tunneling, and anonymizing proxies, may come into play. If the organization relies on client computers to use a Web proxy by policy, then the degree to which users can circumvent this policy should also be a consideration.

31.6.3 Parental Tools. Although client-based Web filtering is not common in large organizations because of the expense and management of such services on a large scale, products enabling parents to block content for their children at home have become a big business. Many large ISPs, such as AOL and MSN, offer parental content-blocking tools as a free feature of their services. Other companies sell stand-alone products that install on a home computer, with password-protected parental administrative access to content-blocking functions. Net Nanny, CYBERsitter, and CyberPatrol are some of the more popular offerings. These products typically reside on individual computers rather than on a network device, although if a home computer is set up as a hub for network connectivity (such as with Microsoft's Internet Connection Sharing), then the controls can filter traffic in the same way as an organizational proxy server. Many of these products also filter other traffic, including email, peer-to-peer file sharing, and instant messaging, as well as offering foreign language filtering, destination-address blocking, and time-of-day access rules.¹⁷

31.7 VULNERABILITIES. No security scheme, whether physical or logical, is completely free of vulnerabilities, and Web filtering is certainly no exception to this rule. Users who want to access blocked content have a variety of tactics available to them, although solutions vary in ease of use. IP spoofing, protocol tunneling, and some forms of encryption are not trivial practices, and therefore are the tools of technically adept users in reasonably small number. Other technologies, however, such as anonymizing proxies, translation sites, and caching services, are easy ways for the average user to defeat filtering. Web-filtering vendors are constantly striving to make their products more effective, while privacy and free-speech advocates support ongoing efforts to defeat what they call censorware.

31.7.1 Spoofing. In an organization that performs Web filtering on a proxy server, the organization's border firewall must allow outbound HTTP requests from the IP address of that proxy. A user who can configure traffic to look as though it is coming from the proxy's IP address might be able to get traffic through the firewall without actually going through the proxy. This tactic, known as address spoofing, takes advantage of lax routing policies on routers that forward all unknown traffic to default gateways without checking to see if that traffic came from a direction consistent with

its reported source address. The drawback of spoofing, from the attacker's point of view, is that a large organization with significant amounts of Web traffic traversing the network will notice the temporary unavailability of the proxy caused by the spoofing.

An organization can defeat spoofing by configuring internal routers to check their routing tables, to see if the address of a packet coming into an interface is consistent with the networks available via that interface. The router drops packets with source addresses inconsistent with their actual source. This tactic, called *reverse-path filtering*, requires a more capable (and expensive) router, so it is generally not available for the home user trying to set up network-based protection for parental control.

31.7.2 Tunneling. A more problematic tactic, because it relies on the behavior of applications rather than on subverting network-layer protections, is protocol or application tunneling. An application can encapsulate any other application's information as a packet of generic data and send it across the network. Virtual private network (VPN) clients use this approach to send traffic through an encrypted tunnel.

Protocol tunneling (sometimes called dynamic application tunneling)¹⁸ relies on applications that send data on commonly allowed ports. For example, a user might tunnel a Web session through the secure shell (SSH) application, which uses TCP port 22. SSH often is allowed through firewalls, and because it uses both authentication and encryption, it can be hard to monitor the difference between a legitimate SSH session and a covert tunnel. In this example, the Web browser issues a request for an HTTP page on TCP port 80, and another application running on the client system captures and redirects the port 80 request into an SSH-encrypted tunnel. The other end of the SSH tunnel could be the destination server or a proxy server somewhere between the client and server. The client application (in this case, the Web browser) is unaware of the traffic diversion and needs no altered configuration. This is similar to the approach used by traditional VPNs. A final form of protocol tunneling has come into limited use as IPv6 has become more broadly available. Still in its infancy as an Internet-wide protocol, it nevertheless is available in some pockets of the world, and tunnel brokers offer connections that tunnel IPv6 traffic over the IPv4 Internet backbone. This can become problematic if a home or site believes that it is filtering outbound requests but is only looking for content in IPv4 packets.

Application tunneling (also called static application tunneling)¹⁹ requires reconfiguration of the client application to redirect requests through a different port on the client machine. Typically, the user redefines the destination address for the application to a *localhost* address (in the 127.0.0.x range, referring to the local device), and an application then sets up a connection from that local port to the destination on an allowed network port. This approach requires alteration of the client application's configuration. Some Secure Sockets Layer (SSL) VPN products use this approach to tunnel one or more protocols, or all traffic, across an encrypted HTTP tunnel.

Tunneling via protocol or application generally requires access to either configure existing application settings or install extra software. Thus, tunneling is unavailable to users in organizations that give end users limited control over their computers. Tunneling is more of a problem for parents, whose technically adroit children can install tunneling applications to get around parental controls.

31.7.3 Encryption. Security professionals generally encourage the use of encryption, since it protects sensitive information in transit across a network. However, when users encrypt data to hide transactions that violate organizational policy, encryption can become a liability instead of an asset from the organization's perspective.

In an encrypted Web session using HTTPS (which is HTTP over SSL), the contents of the session are encrypted and thus unavailable for monitoring or filtering based on URL or data content. However, the source and destination IP addresses of the session, which are visible to TCP as the session is set up, remain visible on the network. This is necessary for routers to be able to get the encrypted data packets from one end of the transaction to the other. Thus, while an HTTPS session is immune to filtering by URL text matching or content-based filtering, blocking the destination server is still effective.

As mentioned in the previous section, VPN technologies represent another use of encryption to protect the content of a transaction. Again, although the VPN encrypts the contents of the transaction, the IP addresses of the endpoints must remain visible in order to transport the data to their destination.

Another more complicated version of encryption, called *steganography*, actually embeds data inside other information to avoid detection. For instance, a user could embed a text message within the information used to encode a picture. For more details on steganography and other types of encryption, see Chapter 7 in this *Handbook*.

31.7.4 Anonymity. Most Web monitoring and content filtering relies on the identity of the user. Content filtering can happen without identity information, but unless an organization or country chooses to impose draconian broad-based filtering of all Web requests (and some do choose this approach), the organization might like to enforce filtering requirements for only some users. For instance, a school district might wish to impose stricter filtering on elementary school students than on high school students and use a more permissive policy for teachers and administrative employees.

The bane of this approach is anonymity. When privacy concerns by individuals lead to the use of anonymizing technologies on a scale that makes identity of users difficult to determine, then the only way to comply with policies and laws requiring filtering of content for some groups is to filter for all groups at the level of the strictest requirement. In the case of a school district, if the network cannot distinguish between student traffic and teacher traffic, then the district must impose the requirements of student content-filtering on teachers as well. In fact, many school districts have made this choice, due to both the extreme numbers of hard-to-find anonymizing proxies and the technical difficulty of separating student and teacher use of a common school network infrastructure. Even so, external anonymizing proxies bedevil network administrators' attempts to force compliance with filtering regulations.

Other uses of privacy-enhancing technologies (PET) include network-based anonymity schemes, such as mixing networks and onion routing. The project, known as Tor (originally an acronym for the onion router), has been gaining popularity in recent years. For more information about anonymity and identity, see Chapter 70 in this *Handbook*. For more about PET, see Chapter 42 in this *Handbook*.

31.7.5 Translation Sites. Language-translation sites, such as BabelFish (formerly at <http://babelfish.yahoo.com>),²⁰ also offer the possibility of avoiding content filters. The user enters a URL and clicks a button to request a translation of the text of the site. The user's session is between the client computer and Yahoo!, with the requested URL merely passed as keystroke data within the HTTP session, so the potentially blocked site is made available so long as the user can get to Yahoo! This is a special case of a proxy, in that the request typed into BabelFish generates a request to the server at the other end, but the client does not receive the exact results of that reply; the display, instead, includes all the graphics of the original, but the text is translated

into the requested language. So, from the point of view of a monitoring tool, the client is always connected with Yahoo!, and even a content filter looking at text within HTTP packets could be stymied by the foreign language. Recognizing the potential for abuse, Yahoo! published a Terms of Use document for the BabelFish site prohibiting using the service for “items subject to US embargo, hate materials (e.g. Nazi memorabilia), ...pornography, prostitution, ...[or] gambling items,”²¹ among many other classes of activities or products.

Translation sites are also annoying to system administrators because translation of a site in a particular language *into* that language usually results in unchanged content. For example, a translation of an English-language Website from French into English simply passes the content through without alteration.

31.7.6 Caching Services. One of the primary uses for proxy servers has been to reduce network traffic by saving local copies of frequently requested pages. This behavior can circumvent Web filtering, so long as the user can get to the caching server. Google, for example, caches many pages in an effort to provide very fast response to search requests. Large graphic and video files take up the most bandwidth, so Google’s Image Search feature often caches them. Often, graphic files are available even for sites that no longer exist. Users wanting to bypass blocks on sexually explicit content often use Google Image Search. Google does provide a feature called Safe Search, with three levels of voluntary filtering. The default (middle) setting filters “explicit images only,” while the strict setting filters “both explicit text and explicit images.”²² Google notes, “no filter is 100% accurate, but Safe Search should eliminate most inappropriate material.”²³ The Safe Search feature is configurable per user, and offers no password protection, so it is not a Web-filtering technology so much as it is a voluntary sex-based search filter.

31.8 THE FUTURE. As more ways of communicating and distributing content emerge, the content-filtering industry will doubtless evolve to cover the new technologies. At present, vendors sell filtering products for email, Web chat, newsgroups, instant messaging, peer-to-peer file sharing, and FTP, as well as filtering of Web requests. New features will appear in “traditional” Web filtering as well, including filtering of IPv6 tunneled traffic. The latest versions of the home filtering products Net Nanny and McAfee Parental Controls now offer the ability to force safe search options in the major search engines (like Google Safe Search, described in Section 31.7.6), and provide “object recognition,” which recognizes certain versions of Web objects (like visit counters) that are commonly used in pornography sites.²⁴

Supporters of content filtering, and those who are required to use it and need a reliable product, will be encouraged by the growth of the industry but perhaps disappointed that the problem never seems to be completely solved. Advances in image recognition could provide much better filtering, but may well spawn new ways to alter content to circumvent these tools. Those who decry these products as censorware will point out that, historically, most attempts to censor speech have failed in the end. Eventually, the two sides will probably work out an uneasy compromise, as has happened regarding sales of “adult” content in print and video. As long as some people insist on their right to distribute information that other people find offensive, this conflict is likely to continue. The debate about the balance between freedom and safety will probably become increasingly colored by concerns with illegal activity, terrorism, and cyberwar, which could lead to advances in available tools as well as attempts to define and regulate appropriate use of those tools.

31.9 SUMMARY. For a variety of reasons, some better than others, groups of people with power over, or responsibility for, other groups of people want to control the kind of information to which the other groups has access and to gain knowledge of who is trading information. Monitoring and content-filtering products (or censorware) provide this kind of control using computer technology to examine information flowing across the Internet. Free speech and privacy advocates argue that content filtering prevents legitimate, legal access to information. Even should one grant the legitimacy of filtering in some cases, current technologies are prone to error, both failing to block some objectionable content and blocking some sites that contain no such content.

Most filtering techniques involve examining metadata, matching a string of text or numbers to determine the source or destination of a request or message, or some characteristic of the communication context. This metadata can be used to block access: servers can be blocked by address or by server name. The recent addition of a .xxx domain has opened the possibility of filtering entire top-level domains. Other methods focus on blocking content, examining text or nontextual parts of a Web page, including graphics. Research into image recognition and flesh-tone matching is progressing, and government agencies have used some image-recognition tools in prosecuting cases, but image recognition has not yet entered the commercial market in a large way.

With every protective, or overprotective, strategy comes a group of people dedicated to its defeat. Content filtering has a number of vulnerabilities, chief among which is the use of anonymity via privacy-enhancing technologies such as anonymizing proxies and onion routing. Other ways to defeat Web filtering include the use of protocol and application tunneling, encryption, Web translation sites, and caching services. Filtering technologies have been improving over the years, as has the inventiveness of those dedicated to thwarting them. As information outlets continue to proliferate and new communications media appear, this kind of conflict between protective technologies and privacy-enhancing circumvention is likely to continue.

32.1 INTRODUCTION. The rise of the Internet created a new chapter in human civilization. People are no longer tied to slowly updated information sources such as libraries. The exponential growth in the number of people looking for wide varieties of content also spurred the desire for mobility. If a person can search for information residing half way around the world from home, why not be able to do the same from the local coffee shop or while traveling during a business trip? This information revolution offered an opportunity to provide information and services to consumers, businesses, and employees at virtually any point on the globe and on a multitude of mobile platforms.

The days of focusing on protection at the network perimeter are over and have been for longer than people may realize. Laptops lead the charge of the initial mobile force. Although access to the full processing power of the laptop is useful in some instances, even the lightweight versions are bulky to travel with and have relatively limited battery

32 · 2 VIRTUAL PRIVATE NETWORKS AND SECURE REMOTE ACCESS

life. Smartphones and tablets, fitting in the palm of a hand, a pocket, or a purse, now provide the power to access more commonly used applications.

32.1.1 Borders Dissolving. Widespread Internet access redefined the dynamics of network and perimeter protection. Previously, companies focused on protecting the internal network and systems exposed to the Internet. A perimeter firewall was sufficient to keep the digital predators at bay. The greater challenge is now maintaining the security of the internal network when employees use mobile technologies from home or while traveling. Further complicating the issue is how to allow other business partners—but not intruders—secure access to the systems and information you are responsible for protecting.

Organizations large and small cannot expect to maintain a competitive advantage by restricting employee network and information access to the confines of the workplace. Traveling employees can now maintain direct communications with those at the office. Employees stranded at home due to inclement weather or illness can continue to function, with direct access to necessary information. This mobility provides organizations a viable method to maintain a geographically diverse workforce that allows people to work in closer proximity to customers and partners.

Organizations are also deploying flexible mobile solutions capable of working on smart phones and tablets. Instead of bringing a corporate laptop on a customer visit, a sales associate can use a tablet to present product information, input/change order information, and access other internal resources. There is also a considerable movement to allow employees to use their personal laptop or smart device to access internal resources—and evidence that this policy may actually increase information technology costs instead of decreasing them.¹ This trend increases the potential risk profile, as the organization must provide security at different layers with little to no control over the security protections of the personal device(s) that may connect to internal resources. *Bring Your Own Device* (BYOD) is of increasing importance in discussions of productivity and of security.²

As an organization's network of vendors, suppliers, and partners grows, so does the necessity to share information. The organization must look for methods that allow these outside entities to access relevant information without exposing nonrelevant information. Information sharing is not the limit of partner involvement. There may be situations where in-house staff does not have the necessary experience to develop or support certain information systems. Although having a consultant on-staff or on-call may be cost-prohibitive, the organization may opt to allow a vendor to access specific parts of the internal network remotely, to provide the necessary levels of service. These parts of the network are called *extranets*.

Customers continue to demand increasing levels of convenience. The banking industry is a useful example of how consumer demands increase, and how business responds to meet these needs.³ Instead of having to go to a local bank, the ability to conduct certain inquiries and transactions were possible over the telephone. The limitations of this technology demanded an even greater opportunity, provided by Internet access to accounts and other banking services. Now, the consumer has a visual, point-and-click/touch interface instead of a computerized voice and numeric menus. These same convenience requirements are present in the sale of goods and services. Consumers may not want to go to a brick-and-mortar store to make purchases, but by having an online presence, an organization can meet this demand by providing an e-commerce Website that gives the consumer the ability to view and purchase items at the consumer's time and place of choosing.

32.1.2 Secure Remote Access. Although the implications of not meeting partner and/or consumer demands are obvious, organizations conduct a great deal of planning and review to ensure that meeting these demands does not jeopardize the underlying safety of the information systems that drive the business. The two primary technologies leading to secure remote access are the virtual private network (VPN) and the extranet.

A VPN is a virtual network overlaying an existing set of physical and logical networks. A common VPN implementation is a secured connection allowing a remote client to access an organization's internal network through an *encrypted tunnel*. VPNs also have the ability to extend all or only selected portions of the network to other locations in the organization.

An extranet meets some of the same goals as the VPN with the emphasis being information sharing and e-commerce. Instead of connecting to the internal network, the client establishes an encrypted connection to a Web application server residing in an external service zone. Extranets can introduce additional complexity because the outward-facing systems normally require access to one or more information assets within the internal network.

32.1.3 VPNs. The essence of a VPN is simple: Create an encrypted tunnel into the internal network to protect the transmitted data. However, the concepts underlying VPN technologies are complex and require a great deal of planning to ensure the best possible implementation. VPNs normally fall into two categories: remote access VPNs and site-to-site VPNs. Each VPN type has multiple avenues of implementation, with each having unique requirements.

Allowing people to access internal network resources remotely has significant information-assurance implications. The main information assurance goals of VPNs are securely extending the internal network, protecting data during transmission, and minimizing the security impact of the process.

Smart phones and tablets often also have the ability to establish a VPN tunnel. No matter the type of mobile device, the organization must meet the requirements for remote access while accomplishing the least amount of additional risk.

When properly architected, managed, monitored, and secured, the internal network can provide a relatively safe environment for sharing data. However, the Internet is a hostile environment. The mobile device can no longer count on the internal network protections as a digital comfort zone. Internet hotspots for public access, such as those in restaurants, airports, and hotels, create even greater challenges to information assurance. These public locations (many configured for open access) create sites for malicious actors to intercept network traffic to gather information such as credentials, financial information, and intellectual property. Properly deployed and managed VPNs and extranets have the ability to thwart this type of monitoring by sending data through encrypted channels.

As the need to increase stricter security measures continues, so does the potential to interfere with the end-user experience. It does not take long for a user to figure out that disabling local security measures can have perceived advantages. Without the client firewall running, the connection speed may increase. Worse yet, by disabling security protections, the user may be able to install and run software otherwise blocked from use. The goal of the security managers must be to maintain high security that is transparent to the user. The process of establishing a VPN tunnel or accessing internal resources should seem easy to the authorized user, with the background security infrastructure

32 · 4 VIRTUAL PRIVATE NETWORKS AND SECURE REMOTE ACCESS

providing the necessary levels of protection without interfering with legitimate users' productivity.

This chapter provides a foundation for understanding of the different types, terminologies, and uses for VPNs and extranets.

32.2 REMOTE ACCESS VPNs. The most common use of a VPN is for secure, client remote access. This allows an authorized user to connect to a VPN and gain access to internal resources from anywhere with an Internet connection, while maintaining the security of the transmission. Remote Access VPNs are waging an on-going battle between traditional Internet Protocol Security (IPsec) and the increasingly popular and powerful Transport Level Security/Secure Sockets Layer (TLS/SSL) VPNs. Each VPN type has distinct advantages and each warrants thorough investigation prior to selecting the technology that best fits organizational needs.

32.2.1 IPsec. IPsec is a suite of network layer protocols designed to set up and protect VPN transmissions. Traditional IPsec VPN implementations use a client-resident application or embedded operating-system service to establish a VPN tunnel into to the internal network.

32.2.1.1 Key Exchange and Management. One of the most complex aspects of IPsec is key exchange and management. IPsec uses Internet Key Exchange (IKE) to facilitate the establishment and management of a Security Association (SA).⁴ Key points of IKE Phases 1 and 2 include the following⁵:

- Phase 1 can use main mode or aggressive mode to create the initial IKE Security Association. Main mode—consisting of three pairs of packets—is the most common implementation.
- The first pair negotiates the four-parameter protection suite:
 - Encryption algorithm (e.g., Advanced Encryption Standard, AES),
 - Integrity protection algorithm (e.g., Hashed Message Authentication Mode [HMAC] with Secure Hash Algorithm, SHA-256),⁶
 - Authentication method (e.g., pre-shared key or PKI certificate), and
 - Diffie-Hellman group⁷
- The second pair exchanges encryption keys using Diffie-Hellman.
- The third pair authenticates each side of the connection to the other.
- Aggressive mode accomplishes the same task by only using three packets:
 - The first two messages negotiate the IKE SA parameters and perform a key exchange.
 - The second and third messages authenticate the endpoints to each other.
- Internet Key Exchange Version 2 (IKEv2), defined in RFC 5282,⁸ is an updated version, though not interoperable with version 1. This new version attempts to correct some of the shortcomings of the original implementation of IKE.
- Some of the improvements of IKE version 2 include:
 - Substantially fewer RFCs,
 - A reduced number of message exchanges,
 - Fewer cryptographic methods,

- Built-in denial-of-service (DoS) protections,
- State detection and management, and probably most importantly,
- Network Address Translation (NAT)⁹ traversal via User Datagram Protocol (UDP).¹⁰

If an organization largely depends on IPsec, one or more of these improvements may make IKEv2 extremely beneficial and create a much more resilient, higher functioning of VPN service.

- Phase 2 uses quick mode to establish the IPsec source addresses (SAs).
- Each side of the connection will maintain an IPsec SA in its Security Association Database (SAD).
- The initiating device creates and sends its SA proposal to the VPN device.
- The VPN device replies with its SA selection and another hash to authenticate the connection.
- The initiating device then replies with the hash it generates from the previous request.
- If the hash matches the challenge from VPN device, the SA goes into the SAD and the connection proceeds.

32.2.1.2 Authentication Header versus Encapsulating Security Payload. IPsec provides two security protocols for protecting encapsulated data. Authentication Header (AH) protects the integrity of the packet header and payload by using cryptographic hashing to ensure data does not change. Encapsulating Security Payload (ESP) is the more common implementation because it not only provides the integrity protection of AH but also protects the confidentiality by encrypting the entire original packet and creating a new IP header.

AH and ESP can transmit data in either *transport* or *tunnel* modes:

- Transport mode preserves the original IP header information while providing payload integrity and confidentiality payload protection.
- Tunnel mode provides integrity and confidentiality protection for the IP header and payload.

Since transport mode uses the original IP header information, this mode creates incompatibilities with Network Address Translation (NAT) because of layer-four integrity checks. NAT causes the IP address of the packet to change during transit, and in turn, will cause the integrity check to fail. Thus, tunnel mode is the primary method for host-to-gateway and gateway-to-gateway VPN connections.

32.2.2 Transport Layer Security. The Transport Layer Security (TLS) protocol provides a method for protecting client/server communications. One of the most identifiable implementations of TLS is *Secure Sockets Layer* (SSL), which provides the basis for the HTTPS protocol. Although this chapter uses TLS and SSL interchangeably as many products support both, there are some differences. TLS is the next evolution of the Netscape-developed SSL because it is an open-standards protocol supported by the Internet Engineering Task Force (IETF) and provides enhanced security capabilities.¹¹

32 · 6 VIRTUAL PRIVATE NETWORKS AND SECURE REMOTE ACCESS

The implementation of TLS/SSL is much less complicated (though not necessarily more secure) than IPsec and provides up to 256-bit encryption capabilities that already exist on virtually all Internet-connected systems. The client provides SSL-related parameters to negotiate an HTTPS connection with the server. The server then replies with the negotiated SSL-related parameters as well as its digital certificate. The client then uses the certificate to authenticate the server. If authentication is successful, the client and server establish the encryption keys used to protect the session and begin encrypted communications.

Although very specific conditions must be present, it is possible to conduct a man-in-the-middle (MITM) attack during the described negotiation process, rendering the encryption ineffective. See Section 32.3.3.1.7 for more information.

32.2.3 User-Authentication Methods. Before being allowed unfettered access to internal resources, the client must identify and authenticate to the VPN termination device. The simplest authentication method is the password associated with the username as identifier. Some typical methods for validating user credentials are through Remote Authentication Dial-In User Service (RADIUS),¹² Lightweight Directory Access Protocol (LDAP),¹³ native Microsoft Active Directory (AD),¹⁴ or Kerberos.¹⁵ To combat the ease of stealing or guessing user names and passwords, most vendors provide alternative or complementary authentication mechanisms. An existing Public Key Infrastructure (PKI)—see Chapters 7 and 37 of this *Handbook*—opens the possibility for using dual-factor authentication by requiring a user or machine PKI certificate. Another multifactor option is to use a cryptographic token such as an RSA SecurID¹⁶ or smartcard.

Access to internal resources should not be wide-open to remote VPN users, nor should a one-size-fits-all mechanism be deployed for VPN users post-authentication. Often applied to remote access VPNs, user authorization based on the extended directory attributes of the authenticated user can further control the level of access to internal assets. For example, based on the user's group membership or role in an LDAP directory, VPN connectivity should be granted only to specific resources on the internal network. Further, a certain class of users or department should be assigned a defined, specific subnet of VPN address space.

Further protections such as downstream firewalls or host-based firewalls may control the remote users' access to resources that should or should not be accessed from off-site by policy. Access control lists (ACLs) applied to the VPN endpoint itself can limit what resources on the internal network may be accessed by remote users as well. VPN users should never be considered of equal security levels; all possible points of control, especially in a role-based access control environment, should be applied.

32.2.4 Infrastructure Requirements. VPN networks are an opportunity to use the External Service Zone. Since the VPN connection device must be Internet facing, zoning requires two different networks connected to the firewall. The external, Internet-facing (VPN untrusted) interface would contain inbound and outbound encrypted traffic only. The second network (VPN trusted) is for unencrypted traffic moving to and from the internal network. By using this principle, the firewall policy would restrict the external, inbound connections to the VPN connection device using only the few required protocols. The firewall policy would restrict all external connections to the unencrypted network while allowing authenticated VPN clients the appropriate level of access into the internal network. This unencrypted network also provides a security inspection point that is unimpeded by encryption.

32.2.5 Network Access Requirements. IPsec and TLS/SSL remote access VPNs provide avenues for secure remote access, but each has unique challenges and opportunities.

32.2.5.1 IPsec. IPsec VPNs typically provide full access to the internal network upon successful connection and authentication. IPsec client VPN implementations using IP protocol 50 (ESP) or IP protocol 51 (AH) do not behave well behind an NAT device, which often limits usefulness for users in hotels, coffee shops, and the like. However, configuring the IPsec to use NAT transversal via UDP or TCP connection may overcome the original limitations.

It is also possible to restrict access to internal hosts and networks through a RADIUS policy, VPN connection device, and/or a firewall policy. One consideration that affects client traffic is *Split Tunneling*.¹⁷ With Split Tunneling enabled, only traffic destined for the internal network flows through the encrypted tunnel. Network traffic bound for the Internet takes the most direct route instead of traveling through the tunnel. This can help to reduce bandwidth by not having nonessential traffic flowing through the tunnel. However, the main disadvantage is losing the ability to inspect the Internet-bound network traffic.

32.2.5.2 TLS/SSL. The original implementation of TLS/SSL VPN was far from its IPsec predecessor. These early VPN connections focused on network pass-throughs to specific hosts and protocols, as well as crude, difficult-to-configure portal of simple links to internal files shares and Websites. The portal concept for remote access is unique to the TLS/SSL VPN. The current portals are more robust and flexible, allowing the administrator to feed specific content and network access depending on a user's classification. The true breakthrough for TLS/SSL VPNs was its match of IPsec's ability to allow full network access, without the necessity for a full client-resident VPN application.

The popularity of these VPNs increased rapidly because they reduce overhead, typically behave well with NATed networks, and are easier to configure than IPsec. Most modern SSL VPN implementations now also support a lightweight remote-access client, some of which are built into current smartphones and tablet devices that replicate the fully managed client/server environment traditionally used in IPsec remote access VPN deployments.

32.3 SITE-TO-SITE VPNs. VPNs are not purely for client remote access. Site-to-Site (S2S) VPNs provide the ability to facilitate internal communications needs. VPN Technologies exist that can create meshed, virtual wide-area networks (WANs) in addition to providing alternatives to traditional WAN implementations.

32.3.1 Multiprotocol Label Switching. Multiprotocol Label Switching (MPLS)¹⁸ continues to extend its dominance in the WAN world. Though it is not a traditional encrypted VPN, it does provide a similar type of service. This section will not cover most MPLS intricacies because deployment must meet organizational requirements, and because each service provider has different offerings. However, MPLS does have several distinct, advantageous characteristics.

Purpose. MPLS creates a meshed, routed virtual WAN network at the service provider level. The MPLS network is then free to route packets directly from one WAN endpoint to another within the confines of its virtual network. WAN sites are able to

32 · 8 VIRTUAL PRIVATE NETWORKS AND SECURE REMOTE ACCESS

communicate directly, increasing the WAN's resilience by eliminating one location from creating as a single point of failure. MPLS networks may also provide multiple levels of quality of service (QoS). QoS provides the ability to prioritize network traffic, allowing certain protocols more bandwidth during high utilization periods. It is also possible to establish IPsec tunnels through the MPLS network to increase the confidentiality of traversing data.

Requirements. As with all WAN routing technologies, the routing hardware and software must support the necessary routing and/or MPLS protocols. In addition, the service provider must already have the technology available. Moving to MPLS may require a significant re-architecture of the existing routing infrastructure.

32.3.2 Remote-Site VPNs. Another common use of an IPsec VPN is for intersite (site-to-site, S2S) communications through the Internet.

Purpose. Although geographic diversity provides the organization closer proximity to customers and materials, traditional WAN implementations may not be available or practical. Remote-site VPNs provide an avenue for bridging this gap.

Alternative WAN. It can be cost-prohibitive to run a traditional WAN connection (e.g., T1/T3, Metro Ethernet, etc.) into a leased or owned location. In addition, even a lower-bandwidth leased line may be overpriced and underpowered to provide direct WAN connectivity to a small branch office. This type of S2S VPN may provide the necessary level of connectivity without the high cost of a leased line. Since this S2S VPN will travel over an Internet connection, it may be possible to provide a higher bandwidth for the price. However, the increased bandwidth may come at the detriment of less predictable network performance such as no end-to-end QoS.

Backup. A S2S VPN over the Internet is also an alternative means for WAN backup. Although a cellular backup card can provide increased bandwidth at a lower cost point than Integrated Services Digital Network (ISDN), the cellular networks typically have higher latency and may be infeasible depending on the building location in relation to a cell tower or provider. For isolated locations, a satellite connection may be feasible but typically has even higher latency than a cellular card. These solutions may be insufficient if the site requires heavy access to systems and information across the WAN. An S2S VPN over the Internet provides a means for higher bandwidth using existing hardware. The S2S connection provides additional redundancy by providing a standby, routable link. If architected properly, the site should notice little to no outage if the primary WAN link fails.

Vendor/Partner Connections. Business needs may necessitate the interconnection of the internal network with a vendor/partner network. It is essential to conduct proper planning, configuration, maintenance, and monitoring of these connections to ensure neither side introduces a negative situation leading to compromise and/or information loss. This setup will typically sit behind a GSD to control access to only necessary protocols, networks, and systems. However, depending on the protocols necessary (e.g., Remote Desktop Protocol, or RDP), it can be difficult to track what occurs from here. The RDP system can act as a jump-off point to other portions of the network not necessarily protected to the same level as they may exist on the internal network.

Requirements. Remote site VPNs require an Internet connection as well as VPN and encryption-enabled endpoints. A typical S2S deployment could be between two routers. Other potential deployments include a router to a VPN-enabled Gateway Security Device (GSD), or from GSD to GSD.

32.3.3 Information-Assurance Considerations. Although the ability for people and remote sites to connect to internal resources provides mobility and increases productivity, the organization must carefully consider the information-assurance caveats. Each implementation will have its own unique requirements, but addressing the main concerns presented in the following sections can provide for more informed decisions.

32.3.3.1 Remote-Access VPN Considerations. Remote-access VPNs provide the most incremental risk. All uncontrolled networks deserve treatment as insecure, thus hostile, computing environments. Since there is uncertainty as to the security of the network the end-user system will be using to connect, it is imperative that the host have sufficient self-protection mechanisms to make up for the loss of the additional defense-in-depth layers provided by the internal network. This understanding will require the security administrator(s) to focus on the necessary precautions to protect all of the organization's systems.

32.3.3.2 Fidelity of the Mobile Device. Since there is no absolute control when mobile systems leave the confines of the internal network, the fidelity of the mobile device is a concern. The risk of compromise at every level—from physical to operating system to applications and beyond—can expose the internal network to increased risk during a VPN session.

There are several ways to reduce the likelihood of a loss of fidelity. Protections may include any combination of host-based security software (e.g., firewall, antimalware, intrusion prevention), current patch levels, and secure configurations. Proper deployment and configuration of these protection measures will help to reduce the possibility of compromise.

Even if the fidelity of the device is acceptable during the initial connection, that does not ensure this status will not change at a later time during the connection. Another method for ensuring the health of the device is through Network Access Control (NAC).¹⁹ NAC provides the ability to interrogate a connecting device before and during the connection to determine such information as patch levels, status of security protections, and memory-resident malware. Unfortunately, NAC is not just a plug-and-play proposition. There are many other implications and requirements—such as determining what to evaluate and/or enforce, inline versus passive deployments and client-based versus client-less solutions—associated with effectively deploying NAC at any point in the network.

32.3.3.3 VPN Client Management. Client administration plays a crucial role in the success of a VPN solution.

IPsec requires the use of a client-side application or embedded operating system mechanism. The primary implications of this include configuring and maintaining the client. The intricacies surrounding a hard-client installation include the necessity of local administrative permissions, potential user interaction, and dealing with a corrupt VPN client application. As with all other applications, updates are necessary due to new enhancements, unsupported older versions, and vulnerabilities. In keeping with the goal of minimizing negative user experience, administrators need a way to update client software with little to no user interaction or side effects. One primary question is to determine whether the VPN vendor has a mechanism to push configuration and other client software updates on connection. Without this functionality, it becomes

more difficult to change client-side parameters. For example, a VPN using a preshared key for VPN authentication gets hard-coded into the VPN software configuration. This makes it difficult to change it without having the end-user enter a new key, in addition to being an avenue for compromise if the key is recoverable.

TLS/SSL VPN clients do not have the same pitfalls as IPsec client management. Instead of a hard client, the TLS/SSL VPN normally uses a small Java or ActiveX-based dynamic client or a lightweight OS-specific installation. In certain VPN systems, the administrator may have the choice to leave the dynamic client resident or remove it on disconnection. If the client becomes corrupted, the user can delete the control, and it will automatically download on the next successful connection.

Having the dynamic client remain resident has two advantages. First, this may provide the ability to have a local, encrypted workspace to store working documents and other files, or to provide access to other resources. Second, this keeps the remote system from having to download the client with each connection. The TLS/SSL client also has an advantage by always checking to see if a resident client is current. If not, the VPN system will force a download of the newest client, helping to minimize client-side management.

Proper monitoring of remote access VPNs is also essential. A compromised VPN connection or credential is extremely dangerous and an increasingly more popular target for attackers. Organizations should monitor logs and connections for suspicious activity and have procedures in place for such problems. For example, if a user ID logs in from the main office in California and less than two hours later the same user ID logs in from halfway around the world, it is likely the second connection is not intended or legitimate. This is especially true of single sign-on (SSO) environments.

32.3.3.4 Protection of the VPN Device. The heart of being able to provide VPN services revolves around the existing network security infrastructure and has direct implications regarding perimeter protection, since the VPN connection devices must be Internet *and* internal facing. These devices must also follow the external service zone discussed in Chapter 26 of this *Handbook*. The device itself is another part of the overall network security profile.

It is important to remove all ancillary exposures. The primary protection method is to configure the firewall to allow access only to the necessary ports on the VPN device. All unnecessary protocols, services, and configuration options should be shut down. If a network management tool uses ICMP and/or SNMP to monitor the VPN device, firewall rules or onboard ACLs should only allow access to these protocols from a specific set of monitoring hosts. Although network reconnaissance and attacks are still possible on these ports, this method drastically reduces the attack profile.

Administrative device access should never use insecure protocols such as Telnet, FTP, or HTTP. Instead, administration should only occur using properly configured encrypted protocols such as Secure Shell (SSH) and Hypertext Transfer Protocol Secure (HTTPS). Administrative access should at a minimum be protected with a user name and strong password, or better yet, add dual factor authentication using a certificate or token combined with a PIN or password. To minimize administrative access, only specific network(s) or host(s) should be able to access the administrative console directly, and if possible, never allowed on any Internet-facing interfaces. To reduce administrative exposures further, it may be possible to use a jump host for all administrative access. However, this creates the potential for a single point of administrative failure if the jump host is not available.

32.3.3.5 Cryptographic Options. Without carefully controlling the VPN's cryptographic protocols, it is possible to choose a combination that creates additional risk of compromise or information disclosure. The strength and proper implementation of the VPN tunnel's cryptographic protection is essential to protecting the data-in-motion and must be sufficient to meet the organization's security requirements. The selection of the available cryptographic protocols for IPsec occurs during the IKE negotiation. The cipher suite determines which cryptographic protocols are available to protect VPN sessions. For example, if 3DES and SHA1 are considered insufficient protection, these and all other weaker alternatives must be removed from the negotiable IKE or cipher suite options. This ensures that incompatible clients are unable to connect and only sufficient protections are in-use during the VPN session.

32.3.3.6 Traffic Inspection. Inspection of network traffic plays a crucial role in keeping the internal network secure. Since the goal of the VPN is to provide secure data transport, this is a hindrance when attempting to evaluate inbound, encrypted traffic. Network traffic inspection can occur on the VPN connection device or on the unencrypted side leading to the internal network. Although the network traffic is one step closer to the internal network, this provides a valid inspection point in which to detect and protect against malicious traffic. Certain VPN devices and GSDs may provide the ability to view data inside the tunnel, evaluate network traffic (providing a troubleshooting point), and inspect data before passing onto the unencrypted network. However, doing all of the inspection on the VPN device can have significant performance implications.

32.3.3.7 Processing Power. Encryption and decryption of VPN tunnels requires sufficient processing power. This issue escalates as the number of clients increases. For situations where there are only a few remote-access clients, it may be possible to use a router to terminate VPN connections and provide security services. The higher the number of remote-access clients, the greater the need for dedicated VPN devices (including GSDs). It is possible to install hardware encryption accelerators to offload cryptographic calculations and management from the shared CPU to a dedicated processing device within the router or GSD, thus easing the processing demands on these units. Larger organizations may have thousands of concurrent users, requiring multiple VPN devices.

32.3.3.8 Interception. Since VPN sessions traverse uncontrolled networks, it is possible for malicious actors to intercept the encrypted communications; however, the datagram protocol underlying TCP/IP makes capturing sequential packets difficult anywhere but the source and destination of the session. If the attackers can capture the data stream, it is increasingly feasible for them to crack the encrypted communications using distributed computing environments with massively parallel processing. However, a more practicable method is an MITM attack while the VPN session is being established. Both IPsec and TLS/SSL VPNs are potentially susceptible to MITM attacks. These MITM attacks typically start with the malicious actor on the same network as the victim and conducting an Address Resolution Protocol (ARP)–poisoning attack²⁰ to have all traffic flow through the actor's system before being passed on to the rest of the network.

The main IPsec MITM vector is a preshared key (typically a group name and password) to authenticate the IPsec connection itself. This key is typically readily

recoverable from the VPN client configuration file(s), although this approach requires the malicious actor to exploit access to the client side to determine this information. With the group name and password determined, a tool such as *Fiked* will emulate the VPN termination device, authenticate the IPsec connection, and collect the user's credentials as it attempts to authenticate to gain access to the full VPN connection.²¹ Although this step is not a compromise of the confidentiality of data-in-motion, it provides the actor the ability to connect to the internal network at will with the harvested credentials. It is possible to defend against this attack using a client or computer certificate for the IPsec authentication.

The ability to compromise the confidentiality of TLS/SSL with relative ease became reality in 2009 with the introduction of *SSLStrip*.²² *SSLStrip* uses the ARP-poisoning attack to intercept the client's request to use TLS/SSL. Once intercepted, the tool will establish a valid TLS/SSL session with the server and create a rewritten, unencrypted HTTP session with the client. This method does not cause a certificate error message that may alert the user to their being an issue with the connection. The tool also uses a padlock favicon to deceive the user into believing the connection is secure even though the URL is actually using HTTP, not HTTPS. It is possible to mitigate this attack by only allowing direct TLS/SSL connections instead of redirecting from HTTP to HTTPS. In addition, previously established TLS/SSL sessions are not susceptible to this attack.

32.3.3.9 Site-to-Site VPN Considerations

32.3.3.9.1 Infrastructure Design. MPLS can be a wholesale change in how the WAN functions as well as introducing troubleshooting and security implications.

Since an MPLS network can provide any-to-any, mesh functionality, it becomes more difficult to troubleshoot network issues. In a hub-and-spoke WAN topology, it is possible to deploy centrally located probes to monitor and troubleshoot WAN issues. It is unlikely that organizations using MPLS with many locations would invest the time and money to deploy these types of monitors in all locations. However, the service provider may be able to provide additional services that provide this type of troubleshooting capability for an additional fee.

MPLS networks also add to the overall network security burden by requiring an increase in the number of network security devices to provide protection at each individual location. This is largely because the sites can establish direct communications instead of going to a hub first.

MPLS places the security of the WAN infrastructure in the service provider's hands. Ensure the MPLS provider has a robust network and strict processes for keeping MPLS networks separate. One added protection against provider-side errors is to deploy Border Gateway Protocol (BGP)²³ routing security, where both sides of the connection would authenticate before becoming part of the routing table.

Remote site VPNs create additional risk by placing the Internet directly against the internal network at remote sites. If the Internet connects directly to the site's router, there are several protection options. An ACL can restrict communication to this interface only by the other side of the remote site VPN connection. Another option would be to enable additional security features on the router. However, this may require a code upgrade and increase the processing demands on the router. A more secure but expensive option would be to deploy a GSD that provides security and VPN services—creating an additional another layer of protection between the Internet and the internal network.

Multipoint VPNs are also an important design consideration. Where it has become common, if not necessary, for highly available, high-bandwidth VPN connections, the typical central-site or hub-and-spoke VPN design may not be desirable. Many designs rely on a central point to establish a one-to-many mesh of VPN connections. However, if the central point is unavailable, the entire VPN mesh is down.

Multipoint VPNs remove the dependency on the central VPN endpoint. If the central endpoint becomes temporarily unavailable, the other endpoints are able to communicate and negotiate connections among themselves without the presence of the central (or master) node. This allows the rest of the VPN mesh to stay operational and reroute traffic to other endpoints that would otherwise be unavailable without the central endpoint.

32.3.3.9.2 Cost. MPLS adds cost on many fronts. These include the cost of new or converted circuits and additional services such as QoS or monitoring capabilities. In addition, the equipment running the network must be able to support the new MPLS and routing architecture. There also may be a significant time investment required to redesign the network routing infrastructure.

S2S VPNs using routing devices require sufficient processing power (e.g., random-access memory—RAM—and encryption modules). In certain cases, it may cost more to get to a level of code that supports encryption. The cost of S2S VPN deployments using GSDs increases as the number of security services increases, as well as the number of clients that can connect. If deploying GSDs to remote sites, there is not only a monetary cost, but also higher administrative costs for managing this new piece of the routing and security infrastructure.

32.3.3.9.3 Availability. VPNs are less of a convenience and more of a necessity. A VPN outage can cause severe interruptions for a highly mobile workforce. Even with layers, it can be difficult to eliminate all points of failure due to the associated costs. If the organization considers VPN as a necessity, high-availability solutions are a requirement.

One possible solution is to load-balance inbound connections to distribute them across multiple devices. If one device fails, the other devices will continue to service previously connected clients and will provide a place for new clients to connect. Another option is active/standby failover: If one device fails, the other will be available for new connections. A preferable method would be for the active member to replicate connection information to the standby member. If the active member fails, the standby member can continue servicing the existing VPN tunnels and can accept new connections. This whole strategy also hinges on the main VPN connection points having redundant Internet links, uninterruptable electric power, environmental controls, and back-end network infrastructure.

Cloud-based VPN is also becoming a popular alternative to provide primary or backup availability of VPN remote access.²⁴ These services eliminated the need for a dedicated VPN infrastructure to be built and maintained by organization. Instead, a network may be extended logically to a cloud provider that integrates these connections into a distributed, highly scalable VPN infrastructure hosted in the cloud. This class of service is popular when there are many geographically diverse VPN endpoints or remote users, where low latency is necessary or uptime is critical.

32.3.3.10 Implications of Elusive VPNs. VPNs and VPN-like services occur in more places than most people realize. These unseen VPNs range from legitimate

VPN services such as GotoMyPC²⁵ to malicious VPNs such as botnet command-and-control channels and reverse tunnels. Although VPN sites such as GoToMyPC can be useful, it is up to the organization to decide if this is an acceptable means of *ad hoc* remote access. Some of the key issues to consider with this type of VPN service are that it bypasses internal security controls such as packet and content inspection, and the third party is creating and managing the VPN connection.

Malicious VPNs are a source of continuing concern. Botnet command and control channels can use encryption to evade network defenses that protect information. A reverse tunnel works by redirecting network traffic destined for a listening port to the same port on another host. For example, if a compromised FTP server had an active reverse tunnel, any user attempting to connect to that FTP server would redirect to another FTP server. Beyond the compromised host theory, malicious people already on the internal network may establish an outgoing VPN connection in an effort to hide network traffic.

The most elusive of all are applications that provide embedded VPN-like services. Peer-to-Peer (P2P) networks tunnel file sharing through proprietary and encrypted protocols. Skype²⁶ not only has the ability to create encrypted voice calls, but also has VPN-like capabilities that allow encrypted file transfers. Network defenses should be able to detect the setup of these sessions and stop them before the connection is completed.

It is up to the organization to develop internal network security defenses and policies necessary to protect against all elusive VPNs.

32.3.3.11 Impact of IPv6. Mass migration to IPv6 is still occurring at a slower pace than one may expect, even though IPv6 was developed in the late 1990s and the allocation of the last remaining available IPv4 address blocks to regional Internet registries occurred in 2011. As of the writing of this *Handbook* in early 2013, only about 12 percent of networks in global BGP tables are advertising IPv6 prefixes. Although most organizations continue to ignore the risks and ramifications of delaying enterprise IPv6 transition plans, it is likely that the protocol is already in their environment. Almost all modern operating systems have dual IPv4 and IPv6 network stacks, usually enabled by default, and typically prefer IPv6 by default. IPv6 and its associated transition technologies have specific implications for VPNs.

Without ubiquitous end-to-end IPv6 connectivity, there are several IPv6 transition technologies (such as *6to4*²⁷ and *Teredo*²⁸) that allow IPv6 capable systems at both ends to tunnel communication over legacy IPv4 networks. The 6to4 method encapsulates the IPv6 packet in the payload of IPv4 protocol type 41 packets and requires the use of relay routers along with at least one globally assigned IPv4 address.²⁹ Teredo encapsulates IPv6 packets in the payload of UDP datagrams and also uses relay routers. UDP allows for better traversal of environments using NAT.

These technologies lessen the barrier to adoption of IPv6 by enhancing reachability of IPv6-enabled services; however, these technologies are also often not well understood or managed. Most network and security administrators learn the hard way that when working as designed, a connection (VPN or local) to an IPv6-enabled resource over a transition technology may traverse the organization's border more than once—adding severe latency and passing data through several relay routers not controlled by the organization.

These transition technologies have serious security impacts on both the local network and VPN connection—misconfigurations and lack of experience being the most

dangerous. Without properly configuring (and testing) both endpoints, it is possible for the IPv6 traffic to take an unsecure path before (or even after) entering the VPN tunnel, putting data in the clear and therefore at risk. It is critical for network administrators and VPN users to have a valid, tested IPv6 configuration to ensure IPv6 traffic (both native and tunneled) is traversing *only* the secured VPN tunnel and not traversing any encapsulated tunnel not controlled by the organization. Unless this threat is managed, data may be vulnerable even when an organization thinks its VPN is providing added security to a remote site or worker.

These transition technologies, many of which enabled by default, also tend to set up tunnels and connections automatically. Endpoint configuration, especially on client workstations, must be centrally configured or managed to disable these automatic connections or to specify specific configurations so that unintended tunnels are not configured.

IPv6 also has native support for IPsec (both AH and ESP) through the use of extension headers³⁰ (versus proprietary IPsec clients), though its use is optional. Configuration and use of IPsec in an IPv6 environment requires the same discipline in choosing and configuring cryptographic options as IPv4. It is also possible to use IPv4 IPsec to protect IPv6 transition technology tunnels, as unencrypted tunnel sessions would otherwise be vulnerable to interception and/or manipulation without this protection. Both of these options are generally misunderstood and often unconfigured on networking and VPN devices. Organizations should only consider native IPsec for IPv6 after a thorough education and planning process.

32.4 EXTRANETS. As the necessity for convenient access to data increases, so do the challenges associated with providing the protections required to secure this type of access.

32.4.1 Information-Assurance Goals. Allowing external entities to access internal data remotely has major information-assurance implications. The main information-assurance goals of extranets are protecting shared information assets, preventing information exposure, and minimizing ancillary risks.

Protecting Shared Information Assets. Much of the current information security market focuses on protecting hosts and networks from digital threats. Although the loss of a server or portion of the network undoubtedly causes issues, there may be areas of greater concern. Organizations develop and sustain competitive advantage by manipulating data collected or created into valuable and actionable information. By mitigating the risks associated with external access, there is less chance for a breach of information security to occur.

Preventing Information Exposure. The concept of least privilege is essential when designing system access. One would not expect a financial analyst to have access to proprietary product specifications. The same concepts hold true when assigning access to external entities. Identity management provides an accountability mechanism for providing rights and monitoring actions of issued accounts. Access management provides the enforcement mechanism that keeps those accounts from viewing or changing data not explicitly necessary. The fusion of these two principles reduces the risk of inappropriate or unexpected access.

Minimize Ancillary Risks. It does not take long for Internet-facing systems to come under attack. Minimizing Internet attack vectors occurs from the Network Layer to the Application Layer. The extranet servers are not all-purpose systems. The network protection policies should restrict access to these services so that the Internet

community only has access to the specific service(s) advertised. Extranet services require greater consideration, as network security devices still lag in protecting the protocols and customizations routinely occurring at the Application Layer.

32.4.2 Extranet Concepts. *External Service Zone.* As described in Chapter 26 of this *Handbook*, extranet networks are another opportunity to use zoning, largely because extranets require robust protections and make extensive use of resources in other zones. Zoning allows administrators to be more granular on the services allowed into the network, as well as providing another location for additional security mechanisms.

N-Tier Architecture. If an extranet system provides all aspects of a service, there exists a single point of failure and compromise. N-Tier architecture provides the ability to distribute different aspects of the service offering to additional systems. The extranet system will provide the front-end user interface; the application server facilitates the logic and processing necessary to access data; and the back-end database server stores and provides the data. Since the extranet server resides on an external service zone, the firewall policy must allow that server to connect to its next tier servers on the internal network. When possible, restrict access from the extranet server to the internal network to only necessary systems and services. This architecture helps to create a more robust infrastructure that reduces unnecessary exposures.

TLS/SSL Encryption. The most visible marker of TLS/SSL encryption is the little golden padlock favicon that appears in an Internet browser when connecting to a server using HTTPS. When a host attempts to connect to an extranet server, several steps occur before the encrypted session can begin. The connecting host provides SSL-related parameters to negotiate a HTTPS connection with the server. The server then replies with the negotiated SSL-related parameters and a digital certificate. The client then uses the certificate to authenticate the server. If authentication is successful, the client and server establish the encryption keys used to protect the session and begin encrypted communications.

32.4.3 Types of Extranet Access. The type of systems and services able to go onto the extranet continues to grow. Providing extranet services is always subject to the needs of the organization, and the following sections provide some common examples of extranet systems.

Vendor/Partner Information Sharing. Businesses survive and thrive on competitive advantage, and increasingly need to share information with strategic partners. By providing access to internal information, these partners can better understand and meet the organizational needs. Enterprise Resource Planning (ERP) systems contain the data that serves as the digital lifeblood of an organization. On the extranet, vendors and business partners could have access to work with information stored in the ERP system.

E-Commerce. Conducting business transactions digitally can create efficiencies and reduce costs. E-commerce occurs at the business and consumer level. Businesses can use Electronic Data Interchange (EDI), which allows two entities to exchange standardized, digital versions of documents such as a purchase order and payments without human interaction. The extranet provides a means to allow business partners to exchange EDI data without granting access to the internal servers that actually process and store data. Consumers access e-commerce Websites to view and purchase goods and services.

Employee Productivity. Providing extranet services is not restricted to business partners and consumers. It is possible to enhance employees' access to specific internal services and systems by allowing access without requiring a full VPN connection. Email is the universal business tool, and providing Webmail services can allow employees to access email from almost anywhere in the world on any device with an Internet browser. Employees may find it helpful to be able to access and change benefits information from home. This may also be an opportunity to allow access to intranet information through a content management system.

Outsourced. Enterprises not possessing the requisite internal human or technological expertise to achieve the organization's IT goals have long looked to outsourced solutions to meet their needs. Software as a service (SAAS) provides offerings such as productivity applications, collaboration, and email (e.g., Microsoft Office365) and CRM (e.g., salesforce.com). Infrastructure and platform as a service (IAAS and PAAS, respectively) provide on-demand storage and computing (Amazon Web Services—S3/EC2 or Rackspace Open Cloud). Each of these outsourced offerings continues to mature and redefine how enterprises develop, manage, and present their information.

32.4.4 Information Assurance Considerations

32.4.4.1 Technical Security. Securing an extranet is not possible at a single layer or point in the network. Each layer is interdependent and requires specific protections to ensure the security of the extranet network.

32.4.4.2 Infrastructure. Since the extranet sits behind a GSD, network layer security measures are normally the protections encountered first.

Traffic Inspection. As reiterated in multiple parts of this and other chapters, some security devices have a distinct inability to evaluate encrypted network traffic. Extranets can create additional issues as the encrypted session may travel from the client directly to the extranet server. This potentially requires traffic inspection to occur on the extranet server. Although possible, this method will increase the processing requirements of the server.

Another option is to terminate the SSL connections on an upstream device. This device would then use unencrypted protocols on the downstream side when communicating with the actual extranet server. This method adds an additional layer of complexity when troubleshooting, but it can relieve the extranet server of the encryption and security inspection processing burdens.

Internal Network Exposure. Although the compromise of an extranet server is significant, it should not provide unfettered access to internal resources. Although the firewall policy allows access to specific extranet services from the Internet, the firewall policy must also granularly restrict access from the extranet server to internal systems.

32.4.4.3 Server. Server-level protections are the true first line of defense. It is difficult for network-layer security mechanisms to protect a server that is advertising a vulnerable service. System hardening is an approach to reducing the overall risk profile of the server. Nonessential protocols and services are shutdown. The operating system (OS) may have additional parameters such as file and account permissions that further reduce the risk profile. A script can help to ensure these changes occur in a consistent manner. One well-known system-hardening script is Bastille Linux.

Due to the complexities of operating systems and applications, vulnerabilities will occur. The simplest method of remediating vulnerabilities is to update the server with a patch. It is important to test patches for adverse effects before deployment to the production environment. This practice will help to reduce the potential for unexpected results and downtime.

Vendors can take weeks and months to develop and release a patch. In certain cases, third-party patches will become available for unpatched, actively exploited vulnerabilities. Although the ability to use these patches is an option, it is inadvisable due to the inability to verify their integrity and safety.

Even though the goal is to minimize the risk profile of the server through all of these means, it may also be necessary to provide additional server-level protections, including host-based firewall and intrusion-prevention software. These protections have the advantage of being contextually aware of operating systems and application functions, unlike those residing at the network layer.

Virtualization is already a deeply entrenched aspect of internal server infrastructures and on the extranet. Although virtualization provides economies of scale by allowing multiple extranet systems to run on a single server or cluster, there are many security implications. Without clustering, a single point of failure exists if the physical server goes down. Since the virtual switch directs most of the layer 2 traffic generated by the VMs, there is minimal native visibility and security enforcement of the network traffic generated between the VMs. VM-embedded security enforcement is continuing to become more readily available to protect at the hypervisor level. There are also ongoing concerns of escaping virtual sessions and allowing unauthorized access to another virtual session.

32.4.4.4 Application. Some common application layer vulnerabilities include buffer overflows, Structured Query Language (SQL) injection, and cross-site scripting (XSS). Buffer overflows existed decades ago but continue to be a favorite amongst malicious code developers. This condition exists because the application does not do proper bounds checking on input fields, or uses functions that fail to do the same. SQL injection is a malicious attempt to insert an SQL query into server-side requests. By failing to check for and protect against this type of attack, the back-end server may return the information the malicious query requests. XSS is a type of code injection commonly used for phishing. A malicious actor may send an unsuspecting person a link that redirects some or all content elsewhere.

Vulnerabilities at the application layer can easily defeat even the most secure network layer configurations. Applications developed by multibillion-dollar organizations can be just as vulnerable as something developed internally in a small facility. Developers must understand and follow secure coding practices to help minimize the number and severity of application vulnerabilities. See Chapters 38, 39, and 52 in this *Handbook* for discussions of programming and application security, and Chapters 30 and 31 for Web-based security.

32.4.4.5 Policies. Since extranets provide external entities access to internal information and systems, it is advisable to have a policy that governs the use of these systems. The policy may include information about requirements such as needing a confidentiality agreement before allowing a business partner access to the extranet or mandating the use of TLS/SSL encryption for all extranet communications. Policies do not provide an active protection mechanism but do establish expectations when using extranet systems and consequences of not following those requirements.

32.4.4.6 Access and Identity Management. Access management is crucial to ensuring that only necessary and relevant information gets to the requesting user. The permissions given to this user will dictate the data the user is able to access and should follow the concept of least privilege. Identity management ensures that only properly credentialed entities can gain access to the extranet and underlying systems.

Typically, an external user will authenticate using a username and password. Unfortunately, this is a poor way to validate an entity's identity because of the ease of stealing or guessing passwords. A more reliable method for identifying an external entity would be to require multifactor authentication using a username/password combination and issuing the user a digital certificate. The certificate would then become a part of the connection and authentication process. Although not impossible, it is vastly more difficult to spoof and/or steal a digital certificate.

Federated Identity Management (FIdM)³¹ is a common method to provide single sign-on authentication capabilities between two or more partner organizations. Protocols such as Security Assertion Markup Language (SAML)³² create a standards-based method for each side to communicate and validate authentication information. Due to the intricate details of FIdM, this chapter only mentions its potential use as an authentication mechanism for extranet services. Since each federated organization must place a certain level of trust in the other, it is important to go through a thorough planning process to identify and mitigate the risks associated with this technology.

Chapters 28 and 29 of this *Handbook* contain detailed information about identification and authentication.

32.4.4.7 Availability. Extranet systems are an important part of business operations. When extranet access is unavailable, certain transactions do not occur that can cause issues at points throughout the organization. Extranet availability is a function of the network and server infrastructures.

A single Internet connection has an implied single point of failure if that connection goes down. If the network infrastructure leading to the extranet only has a single path to follow, this becomes another single point of failure. By adding redundancy to the network infrastructure, such as a second Internet connection and secondary routing paths, there is less likelihood of downtime.

Server infrastructures also have the same potential to be a single point of failure. Instead, using a single server to provide an extranet service, it is possible to deploy a cluster of servers and load balancing. The cluster will protect the availability of the service if one or more servers go down. In addition, this provides the ability to perform server maintenance with little to no effect on availability. Load balancing helps to optimize the number of connections going to each cluster member.

32.4.4.8 Impact of IPv6. The largest impact of IPv6 on the extranet is infrastructure and application support. As noted previously, operating systems and applications must be able to accept, process, and reply to the IPv6 packets; the routing infrastructure must be able to communicate using IPv6 natively or through an IPv6 transition tunneling mechanism (e.g., Teredo or 6to4); and lastly, the security infrastructure must be able to evaluate IPv6 packets. A breakdown in any one of these will render the extranet vulnerable or inaccessible.

32.5 CONCLUDING REMARKS. VPNs and extranets have many powerful features that can enhance an organizations ability to conduct and improve employee mobility and business functionality. Support and input must come from all levels of the organization to ensure that the secure remote access systems meet the organization's specific needs and expectations. Most important, these systems must adhere to and enhance, not diminish, the organization's overall security profile.

33.1 INTRODUCTION. IEEE 802.11 wireless local area networks (LANs) are now ubiquitous and have major benefits such as mobility, flexibility, rapid deployment, and cost reduction over traditional wired networks. However, as with any network-
ing technology, wireless LANs create opportunities for unauthorized individuals to potentially access the enterprise network and the information carried over it.

This chapter provides an overview of wireless LAN technologies, security threats and attacks, and how to address them. It is structured as follows:

- 802.11 history and technological overview
- 802.11 security fundamentals
- Detailed coverage of 802.11 security covering both the original legacy functionality and the upgraded system first defined in 802.11i-2004
- Fundamental wireless-medium security threats
- Specific technical wireless-LAN security attacks
- Technical mitigating controls for specific security attacks
- Overarching secure enterprise design principals

33.1.1 Scope. The scope of this chapter is the security of ANSI/IEEE standard 802.11 wireless LANs. This chapter does not consider any other wireless systems, such as mobile telephone networks, or other wireless standards such as HomeRF, Bluetooth, WiMax, or HiperLAN. This chapter provides a high-level overview of fundamentals with technical deep dives in specific areas necessary to comprehend threats. Many of the basic terms and concepts are documented in Chapter 32 in this *Handbook*.

33.1.2 Corporate use of Wireless LANs. Corporations have been using wireless LANs since the 1990s. However, to begin with, the market was fairly small and the technologies proprietary. In the late 1990s and early 2000s, the groundwork was laid for the mass adoption of wireless LANs. The starting point was the publication of ANSI/IEEE standard 802.11 that provided a baseline design enabling manufacturers to develop interoperable products at lower costs.¹

33.1.3 Functional Benefits of Wireless. The main advantages of implementing wireless networks are mobility, flexibility, and cost reduction.

- **Mobility:** Wireless technologies enable staff to access network information via mobile terminals as they move around the office campus; examples include warehouses, shop floors, and hospitals. Within an office environment, wireless technologies provide a flexible alternative or addition to the wired network. Often, desks and meeting rooms have a limited number of Ethernet connections; wireless technologies can cost effectively provide additional network connections as required.
- **Flexibility:** Public wireless networks (hotspots) allow staff to utilize idle time between meetings, in airports, coffee shops, and even on airplanes in flight.² Typical uses include access to the corporate LAN, along with information on the Internet. Public hotspots can also be trunked over the enterprise wireless LAN to provide internet access for consultants and visitors.
- **Cost Reductions:** Costs can be lowered by not having to install physical network links between buildings separated by a road, river, railway tracks, or even a city block. A wireless link can be set up between two buildings provided there is an uninterrupted line of sight between them. In addition, economies of scale can be realized with a wireless medium. A single access point (AP) (thick or thin) can service one or many end users and scale appropriately by bumping excessive users to neighboring APs. This capability is exclusive to wireless. A wired network has a fixed capacity for per-port access and virtual LAN (VLAN) assignment. The use of wireless with Service Set Identifier (SSID) VLAN support can reduce the networking hardware volume. In the case of dynamic VLAN assignment within a wired LAN, endpoint or server moves require proper VLAN pruning at the switch layer to retain security yet provide the required VLANs. Cost savings can be realized within a wireless LAN by reducing network-management tasks and overall complexity to maximize resources and hardware usage.

33.1.4 Security Benefits of Wireless

- **Physical Security:** An AP and supporting hardware can be hidden from end users to protect it from physical attack. A wireless AP can be hidden above the ceiling in contrast to physical endpoint network jacks, which must be accessible by all users who need access to the internal network. This leaves the door open for unauthorized access to a network port in the absence of enterprise wide 802.1X port security.
- **Segmentation Visibility:** Wired networks commonly assign VLANs on a per-port basis, or in advanced configurations, using one per Media Access Control (MAC) address. In port-based VLAN assignment, management relies heavily on proper access-layer switch configuration and the pruning of sensitive VLANs not necessary for a specific business unit or location. MAC address-based VLAN assignment requires the use of MAC authentication-aware switch hardware and a backend authentication and RADIUS server for MAC → VLAN mappings. MAC-based VLAN assignments can improve management capability and oversight, but pose a significant security risk as they are susceptible to MAC-address spoofing.

In a wireless environment, VLANs can be assigned on a per-SSID basis and administrative efforts can be greatly reduced. A user is no longer confined to a particular

33 · 4 802.11 WIRELESS LAN SECURITY

physical location for access to a necessary VLAN, as long as the SSID is available on accessible APs. In the event of expansion, deploying a new AP in close proximity will deliver the necessary VLANs with the corresponding SSID that a client supplicant profile is configured to search for. Since VLAN assignment can be controlled through minor client supplicant configurations and backend RADIUS privileges, segmentation can be determined during the asset-provisioning process and require relatively minor management thereafter.

In an environment which relies heavily on access-layer switches for endpoint connectivity, it is not uncommon to find switching or upstream router protocols making their way to access-layer switch ports. These include protocols such as Dynamic Trunking Protocol (DTP), VLAN Trunking Protocol (VTP), Hot Standby Router Protocol (HSRP), Cisco Discovery Protocol (CDP), Open Shortest Path First (OSPF) routing, and so on. A user with port access can exploit multiple known vulnerabilities in these protocols.

33.1.5 Centralized Management. Thin-client AP environments leverage wireless controllers to provide a central configuration for all associated APs. Thin-client APs are configured on the controller, and intelligence is provided by a backend user directory (Extensible Authentication Protocol–Remote Authentication Dial In User Service, or EAP-RADIUS) and controller itself. The widespread yet central connection of a mesh of APs can additionally be leveraged for security monitoring of the wireless airwaves in a Wireless IDS fashion as described in Section 33.4.

33.1.6 Overview and History of the IEEE 802.11 Standards. The first IEEE 802.11 standard was published in 1999. Following publication, work continued on developing 802.11 with amendments published on a regular basis. The publication of the 802.11b standard increased WLAN bandwidth from 2Mb/s to 11Mb/s, making it a possible technical replacement for a wired LAN. Following that were the 802.11a and 802.11g standards that increased throughput further to 54Mb/s.

These and other amendments were then brought together in the revised standard 802.11-2007. Development continued via further amendments, which were once again brought together with the issue of 802.11-2012.³

The first version of the standard contained authentication and confidentiality services in an attempt to provide similar levels of security as wired LANs. The authentication service consisted of two systems called *Open Authentication and Shared Key Authentication*, and the data confidentiality service was called *Wired Equivalent Privacy (WEP)*. These services are often referred to as the *legacy security services*.

In 2004 the 802.11i standard was released and defined the *Robust Security Network (RSN)* system, which provided enhanced authentication and confidentiality services. The authentication service has two options: the first is the use of pre-shared keys targeted for homes and Small Office Home Office (SOHO) users and the second uses the 802.1X/EAP framework for enterprise use.

Following the issue of the 802.11-2007, amendments were introduced to provide security mechanisms for mesh wireless networks and the use of 802.11 for transportation applications. There were also enhancements to the core 802.11i algorithms to secure some management frames, and enable fast transition to other APs for time critical services such as Voice over IP (VoIP). Throughput was further improved to a maximum of 600Mb/s by the release of 802.11n-2009.

Exhibit 33.1 provides an overview of the development of the 802.11 standard, the amendments, and identifies those with security functionality using shading.

EXHIBIT 33.1 802.11 Standards

Standard	Description	Security Functionality Description
802.11-1999	The original ANSI/IEEE standard 802.11, 1999 edition. Wireless LAN Medium Access Control (MAC) and Physical Layer (PHY) Specifications.	Defined open and shared key authentication and WEP
802.11a-1999	An extension to the 802.11 standard that provides an improved throughput of up to 54Mb/S in the 5GHz frequency band.	None
802.11b-1999	The ANSI/IEEE 802.11b specification is an extension to the 802.11 standard that specifies a higher speed physical layer (up to 11Mb/s).	None
802.11d-2001	802.11d extends the original 802.11 standard to define physical layers, for adoption in additional countries.	None
802.11e-2005	802.11e extends the original 802.11 MAC to provide quality of service support for time-critical applications.	None
802.11g-2003	This standard provides an improved throughput of up to 54Mb/S in the 2.4GHz band.	None
802.11h-2003	802.11h provided spectrum and transmit-power enhancements to the 802.11a 5GHz standard to allow its use in Europe.	None
802.11i-2004	802.11i enhanced the 802.11 MAC to provide improvements in security. This standard defined the RSN security system. The two main encryption algorithms are also known as WPA and WPA2.	Defined the RSN security system
802.11j-2004	802.11j enhanced the 802.11 standard, to add channel selection for 4.9 GHz and 5 GHz in Japan.	None
802.11-2007	The ANSI/IEEE standard 802.11-2007 rolled up all the above amendments into a revised standard.	Security functionality defined in 802.11i-2004
802.11k-2008	802.11k enhanced 802.11-2007 to improve the management and performance of wireless networks. Access Points collect information from clients to control channel selection, roaming, and transmit power control.	None
802.11n-2009	802.11n provides an improved throughput of up to 600Mb/S in both the 2.4 and 5GHz bands.	None
802.11p-2010	802.11p enhanced the 802.11 standard for intelligent transportation system applications.	Dedicated security functionality defined in the standard

(continued)

33 · 6 802.11 WIRELESS LAN SECURITY

EXHIBIT 33.1 (Continued)

Standard	Description	Security Functionality Description
802.11r-2008	802.11r provided fast transitions between APs and to establish the required Quality of Service before the transition.	Redefined the security key negotiation protocol to avoid the lengthy 802.1X process
802.11s-2011	802.11s defines a self-configuring multihop wireless distribution system to provide Mesh networking.	Defines a password-based authentication and key establishment protocol known as SAE
802.11u-2011	802.11u provided improvements to the user experience with wireless hotspots, addressing issues such as enrollment, network selection, and authorization for roaming.	None
802.11v-2011	802.11v extends the management of attached wireless clients established in 802.11k to include the ability to configure the clients.	None
802.11w-2009	802.11w introduced protection for some wireless management and control frames to address potential denial of service deauthentication spoofing attacks through the use of a Message Integrity Code (MIC).	Extended 802.11i to also protect some management frames
802.11y-2008	802.11y produced an enhancement to the existing 802.11 standard to enable high-powered wireless LAN operations in the 3650-3700 MHz band for the USA.	None
802.11z-2010	802.11z defines Tunneled Direct Link setup that enables client devices to establish a direct link with each other whilst remaining associated to an AP. This can more than double throughput between the clients.	None
802.11-2012	The ANSI/IEEE standard 802.11-2012 rolled up all the above amendments to 802.11-2007 into a revised standard.	RSNA defined in 802.11i and mechanisms designed in the above amendments

33.2 802.11 SECURITY FUNDAMENTALS. This section describes the underlying 802.11 security fundamentals in preparation for the details covered in later sections.

33.2.1 Terminology. To better understanding this chapter, readers will find clarification of a few commonly misunderstood 802.11 terms. Section 0 has a more extensive glossary.⁴

Authentication: Authentication is the first step in a two-step process of client connection to an AP. This step validates the client's authority to start associating

with the AP. Network-based authentication such as username and password takes place after layer 2 authentication and association.

Association: Association is the process of the AP accepting the client connection and allocating resources for it. This includes things such as adding client specific information such as supported data rate, data protocol 802.11 b/g/n, and MAC address information.

802.1X: 802.1X provides the encapsulation of Extensible Authentication Protocol (EAP) implementations within 802 communication mediums. 802.1X does not define a specific authentication method, but provides a vehicle for EAP implementations and their underlying methods. 802.1X and ultimately 802.11i are major components of the modern 802.11 RSN system. 802.1X allows or denies client access to requested resources until the client is successfully authenticated.

RADIUS: *Remote Authentication Dial In User Service* (RADIUS) is a network protocol used for authentication, authorization, and accounting (AAA). Historically, RADIUS servers leveraged a flat-file directory for user-based access decisions, but modern implementations leverage a dedicated directory such as Windows Active Directory, Lightweight Directory Access Protocol (LDAP), or a relational database such as Microsoft SQL Server or Oracle. In a Robust Security Network (RSN), a RADIUS server is only responsible for brokering the authentication/authorization of a user requesting access to an AP. Authentication data is transparently sent from the client to the RADIUS server by the AP, and the RADIUS server leverages an external directory to determine a response.

SSID versus BSSID: An SSID is a unique identifier used by a client to establish connectivity to a particular wireless network. An AP can provide multiple SSIDs on the same channel through the use of the same or multiple interfaces. A BSSID is the unique identifier for a Basic Service Set (BSS). A BSS consists of an AP and associated clients or clients.

An **Extended Service Set (ESS)** is a series of BSSIDs (AP interfaces) sharing the same SSID. This helps enable a wireless client to seamlessly move between APs using the same SSID. A BSSID is a separate interface with its own MAC address; multiple SSIDs can share the same interface and MAC address. On a commercial AP the first SSID/VLAN pair will use the BSSID interface/MAC address and each SSID after that will use a virtual MAC address, which increments the BSSID by a small value for each SSID. A BSSID can be used to reference a unique interface or AP (assuming the AP only has one interface). Depending on the vendor of a particular AP, a single BSSID will send broadcast beacons with all SSIDs in one sweep. If an SSID is placed on its own BSSID, it will have a dedicated beacon, which may improve compatibility.

33.2.2 Authentication and Access Control. In the absence of 802.1X port security, wired-LAN access control is primarily reliant on physical security. To access the LAN, an attacker first needs to have physical access to a connection point. In contrast, the nature of wireless LANs means any wireless client within radio range can potentially connect to the internal LAN network, bypassing physical controls.

33 · 8 802.11 WIRELESS LAN SECURITY

To address this issue 802.11 provides an optional native-authentication service. The legacy 802.11 standard includes two protocols, open authentication and shared key authentication. Neither of these protocols was adequate for secure access.

Open authentication is a null-authentication service allowing any and all clients to connect and associate. Shared key authentication (SKA) requires the client to use a cryptographic key to successfully authenticate. This method did put a lock of sorts on the network, but it was soon exploited by attackers who acquired keying material to help compromise the system.⁵ SKA lacked unique authenticated user tracking, and forced an out-of-band key management process. SKA has since been deprecated and should not be used, except for necessary backwards compatibility with older devices. The legacy 802.11 security system did not provide any access-control functionality. Although most equipment included access filtering based upon MAC address, this control was not part of the standard and the legacy service is therefore easily defeated.

The RSN defined by 802.11i is a much stronger system, and provides multiple mechanisms to authenticate the device and the user.⁶ The system defines a personal profile for home/SOHO use based on PSKs, as well as an enterprise profile based upon the 802.1X/EAP framework, which allows the use of a backend authentication server. The 802.1X authentication system also allows for access control decisions to be taken by the network to restrict network resources available to an authenticated user through technologies such as VLAN segmentation.

33.2.3 Data Confidentiality. Data confidentiality on a wired network is provided by physical security and layer-2 boundaries, which limit the accessibility of the data. Unless an attacker is physically connected to the wired LAN and logically resides between a sender and recipient on the network, through ARP poisoning or physical position, the data traveling over the network cannot be captured. A wireless LAN uses a physically public medium for data transfer; therefore, every packet traveling between a wireless client and an AP is transmitted via radio signals and can be captured by any client within radio range. Although captured data may be encrypted and not readily viewable, it should be noted that any client can obtain the ciphertext in some manner despite layer-2 or logical boundaries.

To address this issue the 802.11 standard provides a data confidentiality service. The legacy system provided the Wired Equivalent Privacy (WEP) protocol, which encrypted each message with a symmetric key before transmission. However, this protocol was successfully attacked and automated tools built to enable WEP keys to be cracked by anyone with basic IT skills and access to the freely available toolset.⁷ Overtime, improvements have been made to the WEP protocol, moving it toward a more respectable enterprise solution, but these fell short and were soon superseded by newer, ground-up protocols. Additional controls are needed to protect the network if WEP must be used, such as with older existing equipment.

The RSN system provides two new data confidential protocols called *Temporal Key Integrity Protocol* (TKIP)⁸ and *Counter Mode with Cipher-Block Chaining Message Authentication Code Protocol* (CCMP).⁹ As well as confidentiality, both protocols provide message integrity as well.

33.2.4 Key Management. Secret-key encryption itself is a relatively simple process designed to protect data long enough for the encryption keys to be changed at a determined interval. Designers start by choosing a suitable proven algorithm, protocol, and key length that they are confident will protect user data for a defined

period. The user (or user program) then provides that algorithm with the plaintext data and an encryption key, and the data are then encrypted and ready for transmission. Due to the rapidly advancing speed of processing (of individual CPUs and CPUs running in parallel), no level of any encryption can provide definitive protection for an unlimited period of time—the time required for brute-force testing of all possible keys in the keyspace—necessitating the need for a key scheduling and management system.

Securely and repeatedly establishing mutual encryption keys is the single most complex issue plaguing cryptographic communications between two parties in physically separate locations. The repeatable process of creating keys, mutually (and securely) exchanging different keys or independently deriving the same key, and finally destroying them, is key management.

The legacy 802.11 algorithms did not provide any specific key-management functionality and vendors were left to design their own. The most common system in early standalone APs was to manually enter a defined-length static WEP key into each client and AP. For home users, the RSN system defines the manual entry of a common variable length PSK or passphrase in the client and AP. From this PSK, a key-management process derives working cryptographic keys, which are changed for each message.

For enterprises, RSN uses the 802.1/EAP framework to establish a secure channel during the user- and device-authentication phase, allowing a pairwise master key (PMK) to be set up between the client and the AP. From this PMK, a key-management system establishes working cryptographic keys which are changed for each message.

33.3 IEEE 802.11 ROBUST SECURITY NETWORK. In June 2004, the IEEE released the 802.11i standard to improve the security of 802.11 networks. This new system is called the *Robust Security Network* (RSN) and is designed for both personal and enterprise users. Enterprise use is based on the 802.1X protocol to provide authentication and establish a security context. A “personal” profile uses a *pre-shared key* (PSK) based on a password provided for consumers and SOHO users who do not require the necessary 802.1X backend authentication infrastructure.

33.3.1 Features. The core protocol of RSN is IEEE 802.1X, which forms *RSN Associations* (RSNA) with the wireless network. RSN provides the following features:

- Mutual authentication mechanisms. These mechanisms can authenticate users as well as the network client or machine. The AP and backend authentication server can also be authenticated to the client defeating rogue AP and man-in-the-middle attacks.
- Key-management algorithms
- Cryptographic key establishment (through PMK and Pairwise Transient Key [PTK] establishment)
- Cryptographic message integrity codes to defeat the bit-flipping attacks possible in the original standard (WEP)
- Two data privacy protocols which also implement message integrity:
 1. *Temporal Key Integrity Protocol* (TKIP), which is an optional protocol specifically designed so that existing WEP based hardware can be upgraded to use it.

33 · 10 802.11 WIRELESS LAN SECURITY

2. *Counter Mode with CBC-MAC Protocol (CCMP)*, which is mandatory for RSNA compliance. It uses the Advanced Encryption Standard (AES) in Counter mode for confidentiality and CBC-MAC for authentication and integrity. CCMP is a strong protocol that has been designed for the next generation of wireless equipment.

TKIP was designed as a temporary stopgap that would work on existing WEP-based hardware until new hardware containing the CCMP protocol became commonplace. Whereas TKIP continued to use the existing RC4 encryption algorithm that was at the heart of WEP, CCMP uses the AES algorithm and requires more powerful hardware—no longer a problem at present.

33.3.2 802.1X Overview. 802.1X was originally designed for port-based network-access controls for IEEE 802 LAN infrastructures. These infrastructures include Ethernet, token ring, and wireless networks. 802.1X authenticates and authorizes devices attached to an LAN port, and will not allow a device to access the network if authentication fails.

802.1X defines three roles:

1. **Authenticator.** The device that authenticates a network device before allowing it to access network resources. In an 802.11 BSS network the AP is the authenticator.
2. **Supplicant.** The device that wants to access network resources and needs to be authenticated.
3. **Authentication Server (AS).** The AS performs the actual authentication of the supplicant on behalf of the authenticator. The AS can be located with the authenticator, but is commonly an external system such as a RADIUS server.

The 802.1X standard defines the object *Port Access Entity* (PAE) which operates the authentication algorithms and protocols in the supplicant and authenticator. An overview of the 802.1X architecture is shown in Exhibit 33.2 below.¹⁰

The authenticator has two logical ports; the first is an uncontrolled port that allows access to required functionality such as the authenticator PAE. The second port is the controlled port that allows access to the rest of the network. The status of the controlled port is set by the authenticator PAE and is dependent upon the outcome of the authentication between the supplicant and the authentication server.

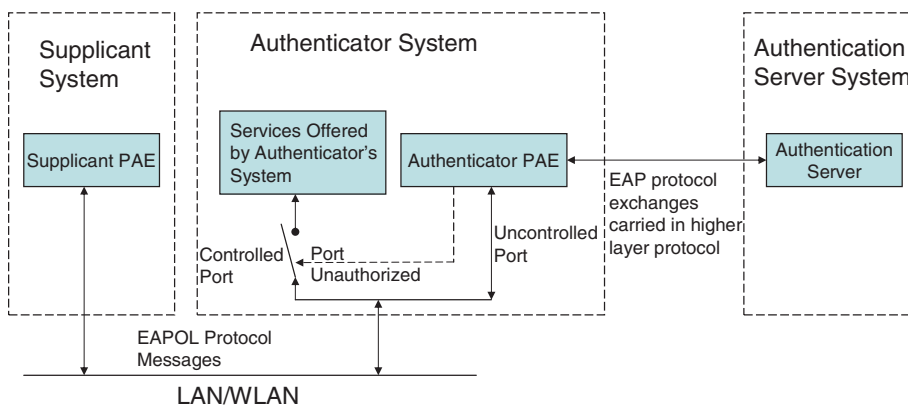

EXHIBIT 33.2 802.1X Architecture

The messages between the supplicant and authenticator use the Extensible Authentication Protocol (EAP) over LAN (EAPoL) framework defined in 802.1X. Communications between the authenticator and the AS leverage the EAP framework carried in a higher-layer protocol such as RADIUS.

33.3.3 EAP, EAPoL, and PEAP. 802.1X relies on EAP¹¹ to perform authentication of the supplicant and authenticator. The EAP protocol is a series of method interfaces that make up the framework known as EAP. EAP was originally designed for use on modem dial-up networks; therefore, the 802.1X specification details the expansion of EAP across Ethernet/Token Ring networks through the EAPoL (EAP Over LAN)¹² extension. In addition to placing EAP methods within an Ethernet payload, EAPoL specifies a number of additional functions to assist in the authentication process during discovery and key exchange. There are currently over 40+ different implementations of the EAP framework. The primary difference in EAP implementations centers on how the supplicant and authenticator are authenticated.

Standard EAP is not a mutual authentication protocol; only the supplicant is authenticated. This makes supplicants vulnerable to rogue AP attacks. Additionally, due to its original design for physical dial-up connections, EAP does not protect its authentication messages from eavesdropping. Therefore, the current EAP/EAPoL implementations establish secure tunnels to provide security prior to exchanging authenticating material. The following are the most common EAP/EAPoL enterprise 802.1X implementations ranked by the level of afforded security:

1. **EAP-TLS¹³:** This EAP implementation only allows mutual certificated-based authentication through *Transport Layer Security* (TLS) X509 certificates. Authentication of both the backend authenticating server and wireless client provides a strong level of wireless security, but requires a full enterprise *Public Key Infrastructure* (PKI) implementation to securely distribute and update client keys on a regular basis. An issue with EAP-TLS is most organizations do not have the necessary PKI to issue the supplicant client TLS certificates.
 - **EAP-TTLS (*Tunneled TLS*)¹⁴:** EAP-TTLS is similar to EAP-TLS and supports mutual certificate authentication but does not require client-side certificates. EAP-TTLS creates a TLS tunnel prior to starting any network authentication process and can therefore tunnel any password authentication mechanism, even insecure legacy mechanisms such as PAP.
2. **EAP-PEAP (*Protected EAP*)¹⁵:** In its native form, EAP-PEAP does not support mutual certificate-based authentication. Native EAP-PEAP uses TLS to authenticate the backend directory server only and leverages a password-based challenge-response process to authenticate the client. Later PEAP extensions help to mitigate this weakness. EAP-PEAP is native to most Microsoft Windows versions and is therefore very prevalent across the wireless industry. There are currently three primary types of EAP-PEAP, which provide varying levels of protection:
 - **EAP-PEAP-MS-CHAP-v2 (*Microsoft Challenge Handshake Authentication Protocol*)¹⁶:** The most common EAP-PEAP inner authentication method uses Microsoft's CHAP-v2 protocol to provide user-identifier (userID) and password challenge-response-based authentication. The MS-CHAP authentication process has historically allowed an attacker with physical access to the AP, to capture the provided challenge and challenge-response hash in plaintext. Due to recent cracking advancements, the time to crack an

33 · 12 802.11 WIRELESS LAN SECURITY

MS-CHAP-v2 challenge-response hash has been reduced to days or less and should be avoided at all costs unless proper client supplicant configurations can be established.¹⁷ This process is described in section 0 of this chapter.

- EAP-PEAP-TLS¹⁸: PEAP-TLS is the second PEAP inner protocol defined by Microsoft. PEAP-TLS tunnels the EAP-TLS protocol within PEAP to provide mutual X509 certificate-based authentication.
- EAP-PEAPv1 (EAP-GTC): The third implementation is defined by Cisco, which allows authentication using generic token cards such as RSA's SecurID token as well as user ID and password.
- 3. **EAP-LEAP¹⁹**: A proprietary protocol developed by Cisco, which performed challenge-response MS-CHAP-v2, based username/password authentication in cleartext. An attacker targeting a network employing EAP-LEAP only needs to monitor traffic to capture challenge-response hashes for offline dictionary attack. This is in contrast to EAP-PEAP-MS-CHAP-v2, which requires a rogue masquerading AP for an attacker to intercept MS-CHAP-v2 challenge-response hashes.
- 4. **EAP-FAST²⁰**: (Flexible Authentication via Secure Tunneling) was developed by Cisco as a replacement to the vulnerable LEAP protocol. EAP-FAST introduced secure pre-authentication tunnels without using certificates. EAP-FAST has secure mutual authentication capabilities, but also has an automatic PAC provisioning option—which is vulnerable to man-in-the-middle attacks.

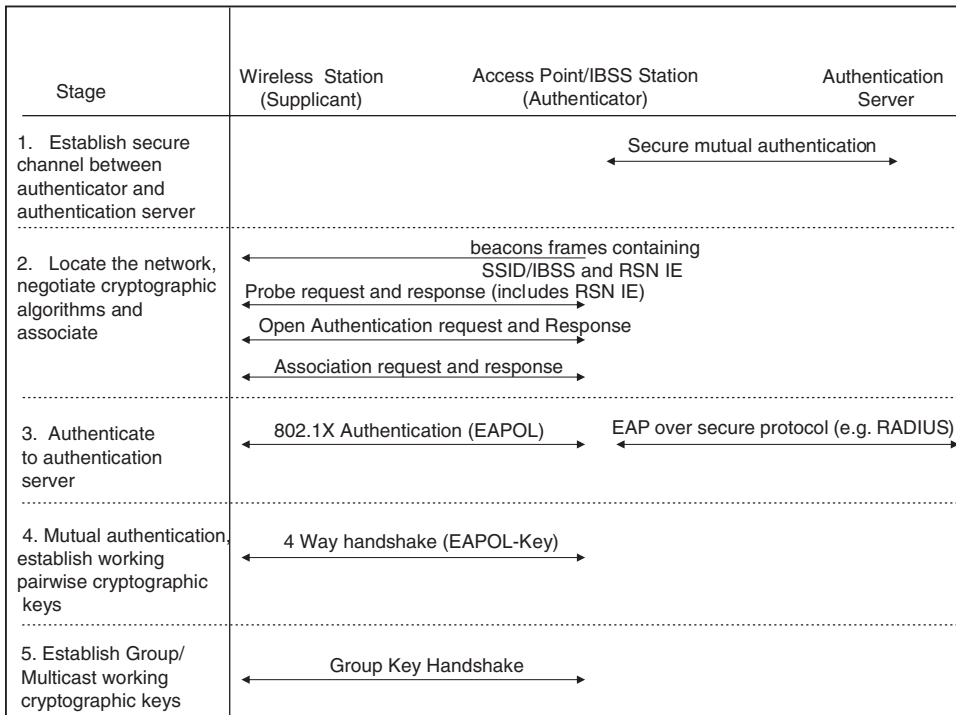

33.3.4 Insecure Legacy EAP protocols. When EAP was first integrated into 802.11, the EAP-MD5 and Cisco's EAP-LEAP protocols were commonly used. Unfortunately, these turned out to be vulnerable to attack, which spurred the development of the secure protocols covered above. EAP-MD5 and EAP-LEAP should not be used for enterprise wireless deployment.

33.3.5 Detailed EAP/EAPoL Procedure. Exhibit 33.3 shows the high-level RSN security association management flow. It consists of five stages that:

1. Establish a secure channel between the authenticator and authentication server
2. Locate the network, negotiate cryptographic algorithms, and associate to it
3. Provide 802.1X authentication to the authentication server
4. Provide Mutual Authentication and establish pairwise cryptographic keys
5. Establish Group/Multicast cryptographic keys

The following sections describe these stages. There are two aspects that vary the security association flow. The first is whether the wireless network contains an Access Point (a *Basic Service Set* or BSS) or whether it is an *independent* BSS (IBSS), also known as an *ad-hoc network*, which is a peer-to-peer network topology.²¹ The second is whether the master cryptographic key is a global PSK or if it is established during the 802.1X authentication protocol. Any variations caused by BSS/IBSS and 802.1X/PSK are described within the sections.

Stage 1—Establish a Secure Channel between Authenticator and Authentication Server

**EXHIBIT 33.3** RSN Security Association Management

In this stage the authenticator and AS mutually authenticate one another and establish a secure channel between them using a protocol such as RADIUS, IP Security (IPSec), or TLS. This channel is used to securely carry the authentication exchanges between the supplicant and the AS. This stage is not required if the network uses a PSK.

Stage 2—Locating the Network and Associating To It

This stage is mostly the original 802.11 functionality for locating, authenticating, and associating to a wireless network. The key difference in RSN is the beacon frames, probe responses, and association requests contain Information Elements that indicate supported and available authentication and privacy protocols. In addition, the fast BSS transition protocol defined in 802.11r²² enhanced these frames again to speed up AP roaming.

Stage 3—802.1X Authentication to the Authentication Server

The purpose of this stage is to mutually authenticate the supplicant and AS to one another and independently generate the PMK for use in stage 4. The EAP described above is used to achieve this. The messages exchanged between the supplicant and the AS are defined by the EAP method. An overview of this stage is given in Exhibit 33.4.

For a BSS network, the wireless client is the 802.1X supplicant and the AP is the authenticator. The AP relays the authentication messages between the supplicant and the authentication server, which can either be a separate service or built in.

33 · 14 802.11 WIRELESS LAN SECURITY

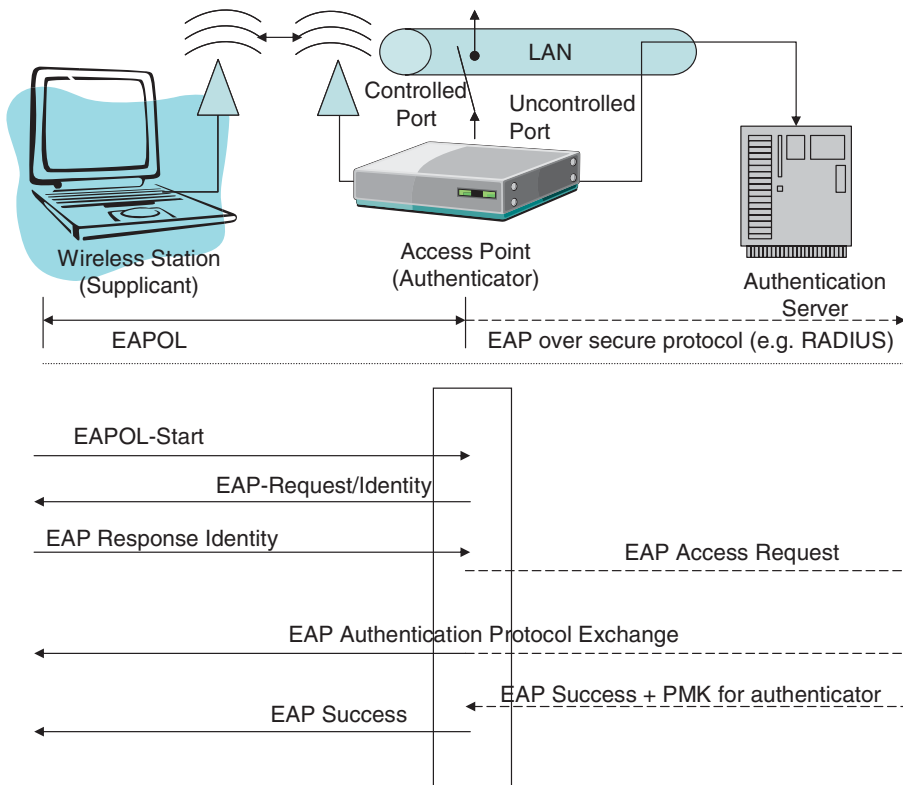

EXHIBIT 33.4 802.1X Authentication to Authentication Server

For an IBSS, the client wanting to associate to another client is the supplicant, and the target client is the authenticator. This means that clients in an IBSS can simultaneously be supplicants and authenticators depending on who initiated the association. Additionally, each IBSS client will need an authentication server unless the network uses PSKs.

As covered in stage 1, a secure channel has to be established between the authenticator and authentication server prior to this exchange; this serves two purposes. The first is to protect the integrity and authenticity of the authentication exchange, the second is to allow the AS to securely send the PMK to the authenticator once authentication is complete.

Stage 4—Mutual Authentication and Establish Pairwise Working Keys

Stage 3 established a PMK in both the supplicant and authenticator. If the network uses a *pre-shared key* (PSK) then the PSK is the PMK. This stage is called the 4-way handshake and has the following purposes:

1. To mutually authenticate the supplicant and authenticator to one another by confirming they both have the same valid PMK.
2. To generate a *Pairwise Transient Key* (PTK) from the PMK and fresh temporal keys bound to their MAC addresses.
3. To synchronize the installation of the keys in both devices.

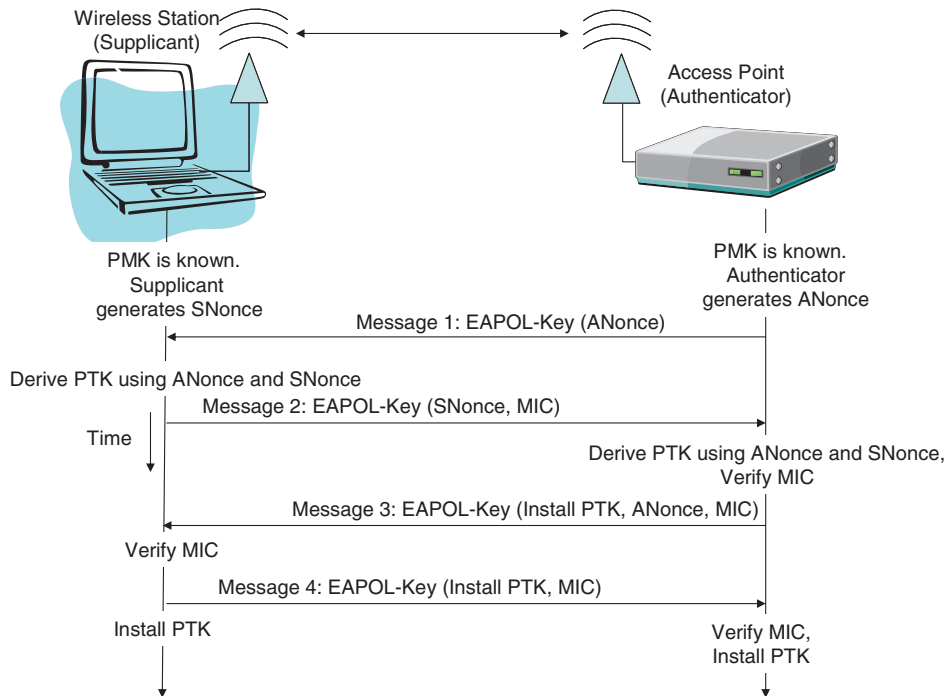

EXHIBIT 33.5 The 4-Way Handshake To Authenticate and Establish PTK

The 4-way handshake is implemented by EAPoL-Key messages exchanged between the supplicant and the authenticator and consists of the following as shown in Exhibit 33.5.

1. The authenticator and the supplicant both generate nonces for use in the authentication protocol. The authenticator's nonce is called ANonce and the supplicant's nonce is called SNonce.
2. The authenticator sends an EAPoL-Key message containing the ANonce (Message 1).
3. The supplicant derives the PTK using the ANonce and SNonce and calculates EAPoL-Key Encrypting Key (KEK) and EAPoL-Key Message Integrity Code (MIC).
4. The supplicant sends an EAPoL-Key message containing the SNonce and an MIC calculated using the EAPoL MIC Key (Message 2).
5. The authenticator can now derive the PTK because it has both the ANonce and SNonce. It then calculates the EAPoL-Key KEK and EAPoL-Key MIC Key and verifies the MIC in Message 2.
6. The authenticator sends a message containing the ANonce, and a flag instructing the supplicant to install the key. The message is also authenticated by an MIC (Message 3).
7. The supplicant verifies the MIC and sends a message to the authenticator confirming the installation of the key. This message is authenticated by an MIC and encrypted using the EAPoL-Key KEK (Message 4).

8. The authenticator installs the new keys and starts the last stage to establish the group keys.

Stage 5—Establish Group/Multicast Cryptographic Keys

In Stage 4, the PTK and temporal keys were established. These keys are used to secure an additional message pair in which the authenticator sends the group temporal key (GTK) in an encrypted form to the client. The group keys are used to secure broadcast messages such as ARP requests and multicast traffic.

In a BSS network, all clients have the same group/multicast key, which is sent to each client by the AP. However, for IBSS networks, there is no AP to set a common key, so each client has its own group transmit key that it sends to all clients in the IBSS. This is achieved by executing the 4-way handshake and group key handshake in both directions.

33.3.6 RSN Key Hierarchy and Management. A key-management system derives working (temporal) keys from a root master key. The exact key hierarchy varies slightly between TKIP and CCMP, but broadly follows the same system. This section describes the key-management system and notes the differences between TKIP and CCMP.

There are two key hierarchies: the first contains the pairwise keys, which are shared between two wireless devices (e.g., between two clients in an IBSS or between a client and an AP in a BSS). The second hierarchy is the group/multicast keys that are used for network broadcasts such as ARP requests or multicast traffic.

33.3.6.1 Pairwise Key Hierarchy. There is a maximum of four levels of cryptographic keys in the pairwise key hierarchy.

1. **The 802.1X Authentication Keys.** These keys only exist if the supplicant and authentication server mutually authenticate one another using preinstalled keys. An example is EAP-TLS, which requires both the supplicant and authentication server to have PKI credentials. The 802.1X keys are used to establish the pairwise master key (PMK).
2. **Pairwise Master Key.** The PMK is 256 bits and is either the key established in level 1 or a PSK installed in the devices. The PMK, device MAC addresses, and nonces are fed into a variable length *pseudorandom function* (PRF) to generate a pairwise transient key (PTK). The nonces are derived from a 256-bit key counter that is initialized at system start-up from a random number, the time, and the MAC address. The nonce is then incremented every time a key is changed.
3. **Pairwise Transient Key.** The PTK varies in length from 128 bits to 512 bits, and is split up into the required temporal keys. The key lengths and number of keys are dependent on the algorithm. For TKIP, the PTK is 512 bits and this is split into 5 temporal keys. For CCMP, the PTK is 384 bits and is split into 3 temporal keys.
4. **Temporal and per-packet keys.** The temporal keys are mixed with variable data such as packet counters, which has the effect of creating a fresh key for every packet. See Exhibits 33.6 and 33.7 for a description of the TKIP and CCMP temporal keys.

EXHIBIT 33.6 TKIP Temporal Keys**TKIP Temporal Keys**

Key Name	Length	Purpose
EAPoL-Key MIC Key	128 bits	This key is the first 128 bits of the PTK and authenticates the EAPoL-Key messages that establish the temporal keys. The key is used to calculate a message integrity code (MIC).
EAPoL-Key Encryption key	128 bits	This key is bits 129–256 of the PTK and is used to encrypt the contents of EAPoL-Key management messages.
Temporal Encryption Key	128 bits	This key is bits 257–384 of the PTK and is used to encrypt a packet using WEP.
Temporal MIC Key 1	64 bits	This key is bits 385–448 of the PTK and is used to authenticate messages in one direction.
Temporal MIC Key 2	64 bits	This key is bits 449–512 of the PTK and is used to authenticate messages in the other direction.

Exhibit 33.8 shows the entire key hierarchy for TKIP.

33.3.6.2 Group Key Hierarchy. The group key hierarchy is similarly structured to the pairwise key hierarchy. The authenticator creates a group master key. This master key, the authenticator's MAC address, and a *group nonce* (GNonce) are processed by the PRF to produce a group transient key (GTK), which is then split up into temporal keys.

33.3.7 Temporal Key Integrity Protocol (TKIP). The Temporal Key Integrity Protocol (TKIP) is a suite of algorithms to resolve the known key management issues in WEP for the existing 802.11 equipment already in the field. A key management mechanism was never specifically identified in the WEP protocol, which TKIP was designed to address.

To ensure compatibility with the existing base of wireless products, TKIP needed to take into account the hardware architecture of the existing wireless products.²³ Wireless products have two CPUs; the first is in the MAC chip that implements the wireless protocol, the second is the host CPU.

EXHIBIT 33.7 CCMP Temporal Keys**CCMP Temporal keys**

Key Name	Length	Purpose
EAPoL-Key MIC key	128 bits	This key is the first 128 bits of the PTK and is used to authenticate the EAPoL-Key management messages by calculating a MIC
EAPoL-Key Encryption key	128 bits	This key is bits 129–256 of the PTK and is used to encrypt the contents of EAPoL-Key management messages
Temporal Key 1	128 bits	This key is bits 257–384 of the PTK and is used for message encryption, authentication, and integrity. The nature of the CCM algorithm does not require a separate MIC key.

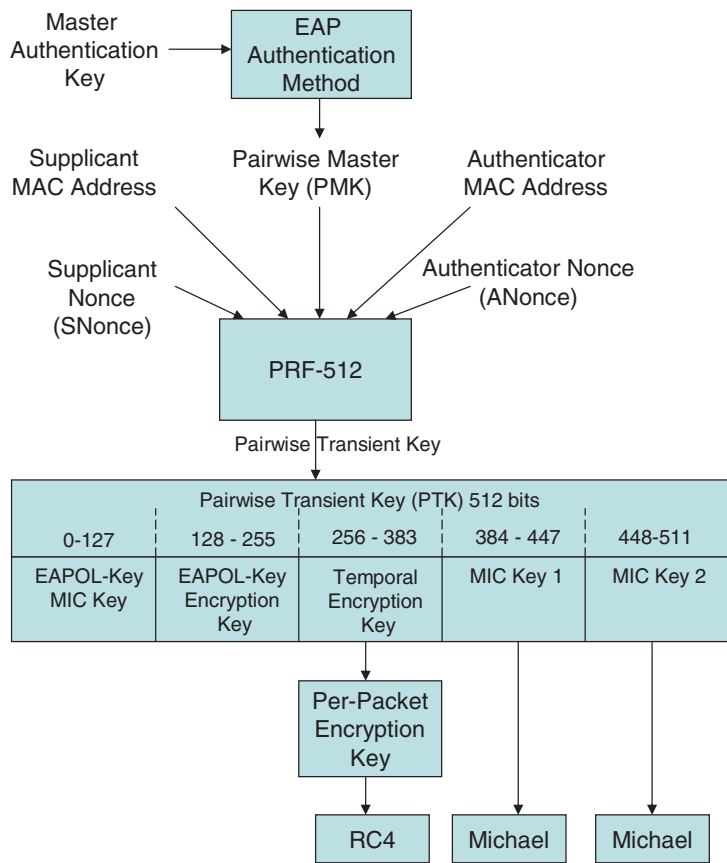

EXHIBIT 33.8 TKIP Key Hierarchy

For APs, the host CPU is a dedicated CPU that runs the AP. For wireless LAN PC cards the host CPU is that of the host PC. For performance reasons most MAC chips have a hardware RC4 encryption engine to perform the encryption. To avoid an unacceptable performance impact by moving encryption to the host CPU, TKIP needed to use this existing MAC encryption engine. This required TKIP to continue to use RC4 and WEP but in a way to overcome the identified problems.

The designers came up with a solution to the issues, and the result was TKIP with the following functionality:

- Each MAC service data unit (MSDU) is authenticated and integrity protected using a keyed cryptographic MIC. An MSDU is a message to be sent to another client. An MSDU may be fragmented into more than one MAC protocol data unit (MPDU), which are packets/frames sent by the physical layer. When all the MPDUs have been received, the recipient reconstructs the MSDU and passes it up the protocol stack. The source and destination addresses as well as the MSDU plaintext are included in the MIC calculation. This prevents forgery and masquerading attacks.
- However, the strength of the MIC is limited and can be compromised by trial and error. To overcome this shortcoming, TKIP provides optional countermeasures that stop communications for a period of time (60 seconds) when an invalid MIC

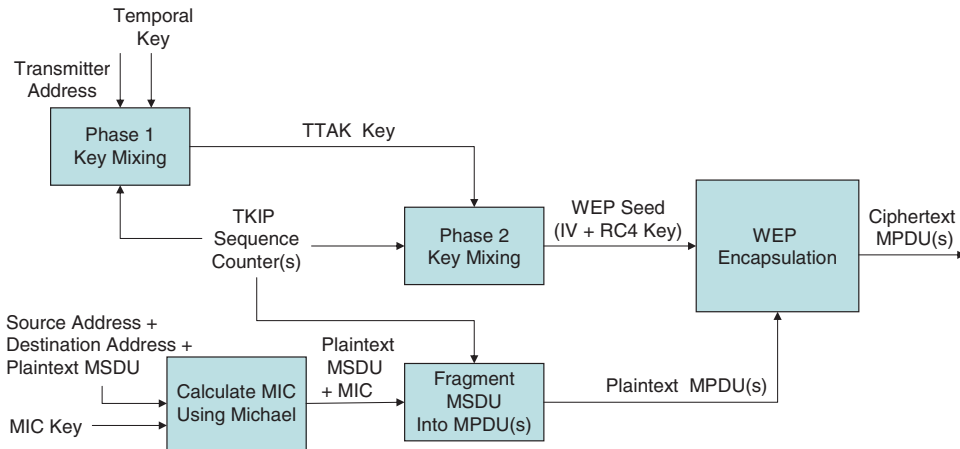

EXHIBIT 33.9 TKIP Algorithm in the Transmitting Client

is received, and then immediately forcing a re-key of all clients. The designers estimated that the MIC with countermeasures would resist attack for about one year before an attacker would correctly guess the MIC.

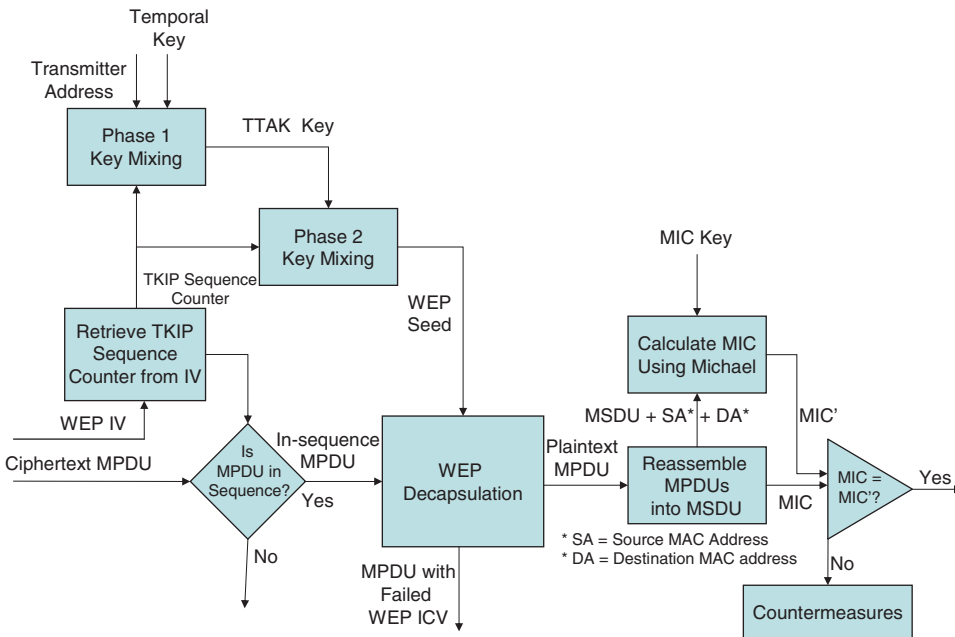

- Each TKIP MPDU (packet) has a sequence number encoded in the WEP Initialization Vector. Any MPDUs that arrive out of order are dropped.
- TKIP mixes a temporal key, the transmitter's address, and a sequence counter in a two-phase protocol to form the RC4 WEP seed. The mixing is done in a way to defeat weak-key attacks.
- RSNA uses 802.1X EAPoL-key message to regularly change the temporal keys so that RC4 key streams are not reused. The key change is triggered automatically when the sequence counter is close to exhaustion.

These controls largely address the issues identified in the legacy system by introducing cryptographic message authentication, preventing key stream reuse, and never using a weak IV. However, TKIP is still not considered a strong solution because of the strength of the MIC. TKIP should only be used as an interim measure until existing equipment can be replaced with CCMP-capable equipment. Exhibits 33.9 and 33.10 show the TKIP process in the transmitting and receiving clients.

33.3.8 Counter-Mode/CBC-MAC Protocol (CCMP). CCMP is the mandatory protocol defined in RSN to provide confidentiality, authentication, integrity, and replay protection for the next generation of wireless equipment. It is not possible to upgrade existing equipment to use this protocol due to resource requirements on hardware, which implements AES.

CCMP uses AES encryption in counter mode to provide confidentiality and CBC-MAC (AES-CCM) for message authentication and integrity. The inputs to the algorithm include:

- A 128-bit block cipher encryption key (the temporal key).
- A nonce based on an incrementing packet number that is used only once with the encryption key to encrypt a message. Reusing a nonce to encrypt more than one message destroys its security properties.

**EXHIBIT 33.10** TKIP Algorithm in the Receiving Client

- The message to be encrypted.
- Additional data to be authenticated but not encrypted, such as the packet header containing the source and destination MAC addresses.

33.3.9 Fast Secure Roaming. After studying the RSN authentication system, the reader is likely to be struck as to the complexity of the system and the number of messages required to establish an association to the network. In an enterprise scenario using the 802.1X/EAP framework, roaming between APs could take up to one second to complete. This creates usability issues for time-sensitive applications such as mobile voice.

RSN contains the PMK caching and preauthentication protocols to try and address this problem; however, both protocols have limitations. PMK caching involves the client and APs remembering the keys they used with each other when the client roams away. But this is only useful when roaming back to APs you have roamed from. Preauthentication addresses this issue by completing the 802.1X authentication and establishing keys with APs as they come across them, even if the client never roams to that AP. This creates significant unnecessary authentication traffic that could overwhelm the authentication server.

The 802.11 committee decided to look at the problem again and developed the 802.11r standard that enhanced RSN PMK caching to establish a cached PMK with a central controller, which then distributes a variant of the PMK to APs as needed. This protocol is called Opportunistic Key Caching (OKC) and means that the lengthy 802.1X authentication is no longer required, reducing roaming times to approximately 100 milliseconds. 802.11r also enhanced the authentication and association messages to include the OKC parameters saving the need for additional message pairs.

33.4 FUNDAMENTAL WIRELESS THREATS. It's important to ensure an enterprise is prepared to manage the many fundamental threats which are enabled by the existence of a wireless medium. As an enterprise examines their infrastructure and needs as a whole, there is an inherent lack of consideration for the increased threat exposure due to the elimination of physical layer controls. These types of controls are typically taken for granted and not considered despite the change to a completely new physical medium. It is important to understand the fundamental differences between a wired and wireless medium and be prepared to take action through implementing necessary controls to secure a wireless network to a level equivalent to a wired LAN.

The implementation of a wireless network expands network availability beyond that of facility walls or even parking lots. It's not uncommon for adversaries to sit within a corporate lot and use special antennas (called *cantennas*) to eavesdrop on wireless communications from a safe distance. Wireless networks rely primarily on logical controls which occur at data link layer and above in the form of authentication and encryption to compensate for the fundamentally public availability of the medium.

Driven by the ease of accessibility of wireless communications, the threat model an organization faces due to the existence and use of a wireless network may change as previous threats are eliminated (such as unauthorized network jack use) and others are created. The increasingly complex threat landscape and security-monitoring responsibilities can affect an enterprise's decision to implement a wireless solution for a particular use or limit its scope to designated functional uses.

Within this section, we will cover the fundamental threats enabled by the use of a wireless network and we will take a deeper dive into a subset of specific technical threats, which should be a priority consideration for an enterprise. It's not necessary for an enterprise to understand every threat they may face, but it is necessary to acknowledge their presence and take actionable steps toward countering these threats.

33.4.1 Unauthorized Network Extensions. When transitioning to a wireless environment from a wired network or a combination of the two, threats which were seemingly easy to identify in the past are now increasingly difficult to manage. Due to the inherent lack of transparency in regulated and unregulated airwaves, it is possible for a nonauthorized access point (AP) to hide amongst authorized APs through SSID spoofing. In a wired environment, it is more difficult to hide an unauthorized device due to physical appearance. An enterprise's ability to identify an unauthorized AP will require additional controls to perform this operation after authorized wireless access has been deployed.

33.4.1.1 Rogue Access Points. A rogue AP is attached to the network without authorization or which impersonates an attached device. Rogue APs come in multiple forms:

- **Nonmalicious Internal Rogue AP:** This type of rogue AP is commonly implemented by an employee or staff without malicious intent, but may be abused by an outside attacker. By connecting a Small Office Home Office (SOHO) grade AP to the internal network, enterprise grade protection mechanisms designed to keep attackers out, such as perimeter firewalls, can be bypassed with direct access to the internal LAN. Endpoint security mechanisms are also invalidated, such as host-based antivirus and firewalls, due to the Network Address Translation (NAT) capability of an SOHO router. Consumer-grade security controls present

on an SOHO AP, combined with the lack of proper security configuration by the installer, can lend themselves to successful compromise, which would result in direct access to the wired internal network. Nonmalicious rogue APs can typically be identified through a nonenterprise standard SSID such as “Linksys” or “netgear.”

- **Attacker Malicious Internal Rogue AP:** An attacker can masquerade an AP as a legitimate enterprise AP by using the same SSID as authorized enterprise APs. In this situation an unsuspecting endpoint client will automatically connect to any AP, which broadcasts the requested SSID (such as “employeeWireless”) and will select the AP with the strongest signal. An attacker can then perform denial of service attacks to force clients onto their malicious AP.

A malicious rogue AP with internal access can be leveraged by an attacker with physical access to the facility to capture credentials or other data from unsuspecting endpoint clients, which leverage the AP to access internal resources such as administrative panels or employee portals. An attacker with an internally connected AP has multiple benefits as they are able to seamlessly allow a user to access all regularly accessible resources. This type of attack would require physical access to the facility and corresponding network jacks.

- **Attacker Malicious External Rogue AP:** An external rogue AP uses similar tactics to an internal rogue AP to force unsuspecting endpoint clients to connect to it. The primary difference is the physical proximity of the AP and the network it provides access to. It is much easier for an attacker to deploy an external rogue AP in a nearby corporate parking lot than gain access to the facility and plant an internally connected AP. The downside of an external rogue AP is the inability to provide requested internal resources to a connected client. If the desired resource is the Internet, this can be provided through a forwarding process allowing the attacker to view all traffic.

Both types of malicious APs allow an attacker to capture sensitive network traffic and attack the endpoint itself by attempting to exploit vulnerabilities in the endpoint’s operating system or network services. Client configurations typically mandate that a client wireless radio connect to the strongest signal strength that matches the desired SSID and Authentication requirements; e.g., WPA/WPA2-PSK, WPA/WPA2-Enterprise (EAP-PEAP, EAP-TLS).

Threats enabled by rogue APs include:

- An attacker’s gaining access to the wired network by compromising weak or absent security controls on a nonmalicious employee-installed rogue AP
- An attacker’s obtaining sensitive data through network captures of clients connected to an attacker-provided rogue AP (such as domain credentials). This threat is usually more effective if used in conjunction with social engineering tactics, such as injecting IFRAMES within HTTP traffic that directs them to a malicious site, which contains browser exploits for various plugins such as ActiveX or Adobe.
- An attacker’s gaining access and penetration testing enterprise endpoint machines connected to an attacker-provided rogue AP at a different physical location.
- Internal users’ bypassing wired 802.1X port security configurations through the use of NAT, which allows multiple users to communicate through the WAN port of an installed SOHO AP.

33.4.2 Layer 1 Attacks. Wireless mediums can be heavily relied upon by staff or business applications to provide connectivity to wired network resources in locations where physical connectivity is difficult to implement. The absence of an enclosed private physical medium allows for tampering of the layer 1 wireless carrier signal regardless of upper layer protective controls. This is a fundamental threat to any form of wireless communication and not necessarily specific to 802.11, although each wireless protocol such as CDMA, 3G, or 802.11 may include a mechanism to detect tampering, they cannot prevent it from occurring.

- The 802.11 protocol functions within 2.4 GHz band. The 2.4 GHz consumer band can be interfered with by using something as simple as a microwave oven
- The 2.4 GHz spectrum only provides three nonoverlapping channels. The 802.11 spectrum runs between the range of 2.412 GHz and 2.462 GHz. Overlapping channels are side-by-side channels, which through propagation and other wireless tendencies, can bleed into the neighboring 20 MHz bandwidth allocation. A nearby AP can cause a minor denial of service condition by using an overlapping channel.
- Management frame spoofing
 - 802.11 management frames are part of the MAC layer of the 802.11 protocol. Management frames are used to bootstrap the authentication and association of clients to an AP. Management frames “manage” the connection between an AP and all connected clients. There are various types of management frames, some of which are received by any client within range of the AP, and others which are targeted at connected/connecting clients.

Most significant management frame types:

- Probe Request/Response
- Authentication
- Association Request
- Association Response
- Dissociation

As with a wired LAN, the unauthenticated nature of initial data link layer protocols, such as 802.11 management frames, can allow an attacker to spoof and interfere with an existing session or the session initiation process. This fundamental issue is comparable to the unauthenticated Ethernet → IP ARP protocol, still vulnerable over 802.11, but easily abused across a wired connection.

The security afforded to wired bootstrap protocols relies on their physical controls, none of which are afforded to wireless. This void prompted IEEE 802.11w family of standards to adopt the 802.11w specification. This specification details the use of MICs to authenticate management frames to their source. This would effectively eliminate the ability for an unauthenticated attacker to force clients off of a legitimate AP to an attacker provided rogue AP. 802.11w sounds great on paper, but in reality, implementation will take years. The process of authenticating material for each management frame increases the load on an AP's already busy processors, which means a software upgrade may not be feasible for all devices. In addition, all client devices must support 802.11w to create outgoing and process incoming MIC data. Client support would require new

driver firmware for wireless radios and potentially more hardware acceleration for potentially all connected clients depending on the AP's implementation of 802.11w.

33.4.3 Endpoint Attacks. A new class of endpoint attacks is enabled by wireless endpoints. Endpoints can include anything from a laptop, wireless printer, or handheld scanners. In a pure wired environment the threat of wireless endpoint compromise is slightly reduced due to the absence of corporate wireless authenticating materials stored within the endpoint's wireless supplicant. Authenticating materials include items such as domain username/password pairs, certificates, or even pre-shared keys. Storing authenticating materials on an endpoint means the "keys to the kingdom" can be obtained and used to access the network without even entering the facility.

While the ability for an attacker to compromise an endpoint with a hotspot style attack, is still a viable threat to the integrity of an endpoint, endpoint security measures such as host-based firewalls, IDS, and regular patching can mitigate this threat to an acceptable level. It is necessary to understand that an endpoint is still susceptible to the same attacks in an enterprise wireless environment, but the outcome of these attacks could result in the capture of authenticating materials used to access the corporate wireless. The capture of authenticating materials avoids the need to compromise the endpoint to gain internal access to a corporate network. If employees do not use wireless enterprise access, they are less likely to succumb to social engineering attacks combined with a hotspot attack. An example of this situation involves an attacker using a hotspot attack to gain connectivity to the endpoint, intercepting their Internet browsing, and prompting the user with a spoofed corporate intranet site, which requests remote VPN credentials through a simple Web form.

Endpoint attacks enabled by enterprise wireless access:

- Employer identification through descriptive SSID probe requests.
- Increased effectiveness of Hotspot + Social Engineering attacks based on the fact that a user regularly accesses the enterprise wireless, in contrast to a user whom has never had wireless access.
- RADIUS impersonation for capturing WPA/WPA2-enterprise EAP credentials.

33.5 SPECIFIC WIRELESS SECURITY ATTACKS

33.5.1 MAC Address and IP Spoofing. MAC address-based access control mechanisms are the lowest hanging fruit of wireless security threats. This form of access control is not enterprise grade and primarily originated in SOHO grade APs and hotspots for tracking authorized connections without issuing unique keying material. Pure MAC address authentication is based solely on the connecting devices MAC address; if the identified MAC address is included in a predefined list of allowed MAC addresses, the device is allowed to associate. This is obviously not a scalable means of authentication, due to constant updates in the event of static mappings, and is commonly used to track valid client connections after initial Web-based authentication.

This type of situation is commonly referred to as a Captive Portal or hotspot-based authentication. The AP operates in open authentication mode, allowing anyone to connect to it, but users who have yet to authenticate cannot access the Internet and are dropped into a restricted penalty box. Users are prompted with a Web interface to enter credentials and, upon successful network-based authentication, gain access to the Internet or other protected resources. Captive Portal authentication takes place at

layer 4 (Application) and relies upon layer 3 (IP address) and layer 2 (MAC address) as reliable mechanisms to track users which have successfully authenticated.

This attack is enabled by the fact that all traffic in a Captive Portal system is transferred unencrypted. No encryption necessary to allow clients to access the Web-based authentication page with no previously established encryption keys or previous knowledge of the AP. An attacker now has the ability to capture plaintext traffic occurring on the AP to and from each client. This is performed through setting a compatible wireless card into monitor mode. Monitor mode allows an attacker to see all traffic on a specific 802.11 channel without needing to associate with an AP. On wireless networks which deploy an encryption mechanism such as WPA/WPA2-Enterprise, an attacker will see no plaintext payloads for 802.11 frames.

An attacker can leverage this to monitor traffic and identify MAC address and IP addresses of connected/authenticated clients. This information can then be spoofed by an attacker to gain access to the portal's restricted content (Internet or other resources) without being directed by the portal to the authentication page. Authenticated clients are maintained by the AP via MAC address, IP address, or a combination of both.

33.5.2 EAP (WEP/WPA/WPA-Enterprise) RADIUS Impersonation Attack. Wireless implementations, which leverage RSN with clients which have not been configured to trust a specific AP type, and do not employ client mutual certificate-based authentication, are inherently vulnerable to a deadly combination of rogue AP and authentication server (e.g., RADIUS) spoofing. This attack relies on the ability for an attacker to force clients to connect to a malicious AP and begin the expected EAP authentication method. In a typical EAP RSN deployment, in response to an authentication request a RADIUS server will send back a RADIUS access challenge, which is forwarded by the AP to the client. In this attack, the malicious AP is configured to use an attacker provided RADIUS server. This RADIUS server carries out the EAP authentication process and forces the client into providing their password hash in response to a fixed, known, challenge. Depending on the EAP implementation in use, the username associated with the client may be provided in plaintext within the EAP-Identity-Response sent prior to authenticating material exchange.

Since the attacking rogue AP uses a fixed challenge we now possess the ability to brute force the password using standard dictionary attacks. This attack only applies to EAP implementations, which do not use client certificates for authentication, but leverage username and password combinations, such as EAP-PEAP with MS-CHAP-v2.

If a client connects to a rogue AP, the spoofed authentication server certificate will likely not validate correctly and the user will either not see anything or be prompted with a small message. See Section 6.2 for additional information pertaining to proper client supplicant configuration for server-side certificate verification.

EAP challenge/response hashes can be captured and cracked using the following tools:

- **FreeRADIUS WPE (Wireless Pwn Edition):** Used to readily deploy a RADIUS server to accept connections from the rogue AP using a spoofed version of the expected EAP type.
- **AsLEAP:** Used to crack EAP (PEAP, LEAP, etc.) challenge/response hashes using the password hash, known challenge, and word dictionary as input.

33.5.3 Management Frames. 802.11 frames carry protocol and data for upper layer protocols. Primarily, two types of 802.11 frames are commonly used, data and management frames. Data frames are used as carriers for upper layer protocols, while management frames carry specific information regarding link operations. Historically, management frames are a fundamental weakness to 802.11 security. Across the majority of wireless implementations management frames are never secured and therefore always accessible despite authentication or encryption mechanisms, which may secure the payload of a data frame's contents. As described previously in section 4.1, 802.11w attempts to address this issue through the use of MICs, but like most wireless improvements, the industry lags behind fully adopting these controls due to costly client upgrades and new AP devices and/or firmware updates. The lack of adoption is likely due to the fact that management frame spoofing is not readily seen as a direct threat, despite its deadly impact when used in combination with other attacks.

Management frame spoofing and manipulation enables the following types of threats:

- **Beacon frame spoofing:** Allows an attacker to masquerade as any AP. Crafting a beacon frame will make you show up in a network client "scan" of available networks. This vulnerability enables hotspot and RADIUS impersonation attacks to take place and is largely unstoppable due to the necessity for unauthenticated beacon frames to be accepted by any unassociated client within range.
- **Authentication/Deauthentication:** These frames are heavily used by 802.11 during the secure authentication process. Used to relay the intention of a client to connect to an AP. Even in situations where an AP is using "open" authentication and requires no keying material an authentication frame procedure is performed. In the event of WEP pre-shared key authentication these frames are used to carry traffic associated with this network-based authentication.
- **Association/Reassociation/Disassociation:** Association response frames are used to synchronize radios between an AP and a client radio. This includes details such as supported data rates. This process allows the AP to allocate memory for the client and begin processing communications. Reassociation frames are used when a client roams to another AP within the same BSSID, this indicates to the original AP that it should forward any remaining buffered frames. A disassociation frame is sent by the client to gracefully remove itself from an AP and allow the AP to garbage collect any necessary memory.
- **Request to Send (RST) and Clear To Send (CTS):** RST frames are optional and provide a way to survive in a condition where one client cannot see another client's traffic due to physical proximity to the AP. This frame is sent to the AP and the AP will response with a CTS frame. The CTS frame includes a narrow time frame for the client to send data where all other connected clients must wait. This procedure reduces collisions from hidden AP clients.²⁴

The manipulation of management frames occurs by injecting them into the airwaves and spoofing the source as if they came from the AP BSSID. These frames are not viewable from a standard packet capture on the host system, as the wireless card driver will not pass this traffic to the underlying operating system. Spoofing management frames does not affect an AP, as it is unaware of their presence.

The following Aircrack²⁵ tools can be used with a compatible wireless card set into monitor mode to manipulate management frames²⁶:

- **Aireplay-ng -0:** Spoof deauthentication to remove a client from the AP by sending dissociate packets to one or more clients, which are currently associated by forging a disassociate packet with the source MAC address of the target.
- **Aireplay-ng -1:** Spoof authentication with an AP using a specified source and destination MAC address by sending association management frames.

33.5.4 Hotspot and Cafe Latte Attacks. Depending on the wireless chipset and driver, wireless clients typically actively probe for all networks they have associated with in the past and when an AP responds they will automatically associate with it. The root of this vulnerability stems from the behavior of wireless clients and their lack of AP authentication during the early stages of authentication. Only the SSID and authentication/encryption type must match the “known” state for the client to begin the association process. Due to thin AP wireless deployments, a wireless client cannot be specific or remember the MAC address of the AP it requests to connect to, even though this would greatly curb this attack.

A wireless client probing for an SSID last used from a public Wi-Fi hotspot can be identified by an attacker and masqueraded as if they were the public Wi-Fi hotspot, even though the victim is nowhere within the location of the previously remembered public hotspot. Since most public hotspots don’t require authentication, it’s safe for an attacker to assume they only need to match the requested SSID and no other traits to facilitate a successful connection by the targeted victim. If the AP a client is probing for requires WEP or WPA, it will not automatically connect to any AP with the same name. The data transfer rates and encryption levels must align correctly, as described within the process of association.

An attacker sniffing the wireless for SSID probe requests will not necessarily know which networks require encryption and which don’t, but trial and error will eventually yield the correct answer.

The following is the process associated with hotspot spoofing where an attacker recognizes a particular wireless client would like to connect to an AP, that may or may not actually be present (this is the nature of Wi-Fi autoconnect), and actively impersonates the requested AP to satisfy the client and gain momentary connectivity (in the event the client disconnects due to an invalid key management process).

33.5.4.1 Hotspot Attack Procedure

1. Victim machine sends SSID probe requests for APs it has communicated with in the past (supplicants keep this history to enable fast connections).
2. Attacking machine monitors airwaves for SSID probes and takes note of requested AP names (e.g., “coffeeshop,” “airportWifi,” etc.).
3. Attacking machine creates an AP with the SSID name requested by the client (e.g., “coffeshop,” “airportWifi,” etc.).
4. Victim machine automatically associates with new AP and encryption/authentication levels are accurate.

At this point it is up to the attacker to correctly guess the encryption the client expects (WPA/WPA2/WEP) or open (none). It is very common for

Microsoft Windows and third-party supplicants to autoconnect to a known AP in the background and show no warning of the connection with the exception of a “connected” symbol in the taskbar.

5. The victim now has a functional connection to the attacker’s AP and the attacker can establish *man-in-the-middle* (MITM) traffic by relaying it to the legitimate AP on a neighboring interface or the Internet, or attack the victim by exploiting vulnerabilities on the connected system.

An older yet valuable extension to this attack revolves around the SSID, which is broadcasted by a “parked” wireless card and is prevalent in older Windows wireless drivers. During Windows Wireless Zero Configuration, a wireless card will attempt to connect to all previously known networks before placing itself in a “parked” state. The “parked” condition consists of the adapter ceasing to attempt connections and using a dynamically generated SSID as a default value. Once this default value is assigned, the wireless card will no longer actively seek networks but will continue its normal beacon behavior, this time with the parked SSID. This behavior introduced a new vulnerability, which allowed an attacker to always have an SSID to rely on, even if the client has no previous networks to seek for. This vulnerability has since been addressed through setting an encryption level (WPA/WPA2) and random key for use by the wireless card during park mode.²⁷

33.5.4.2 The WEP Cafe-Latte Factor. An added twist to hotspot spoofing takes it a step further by actively attacking a client that broadcasts a particular SSID from a network which deploys WEP encryption. This attack leverages a multitude of WEP vulnerabilities to crack a WEP key passed by a client. All clients will store the WEP key within the supplicant or registry of some sort for later use. An attacker can force the client to encrypt certain packets using this key while performing the aforementioned hotspot spoofing attacks to draw the client onto an AP that is masquerading as a requested one employing WEP encryption (albeit with an incorrect matching key). Specific packets are always sent by a client upon associating and during initial authentication as part of “quick reconnect,” which are encrypted using the client’s stored WEP key. These include ARP, DHCP, and specific 802.11 management frames.

Of particular interest are gratuitous ARP packets sent by a client upon associating to an AP it believes is legitimate. Through bit flipping techniques an attacker can forge encrypted ARP requests to a connecting client by reusing previously captured gratuitous ARP packets and turning them into a request. This technique leverages WEP’s absence of integrity checking and reliance on a CRC error-checking mechanism as the sole integrity control. CRC algorithms are not intended to provide anything outside of error-based integrity and prone to abuse across WEP attacks. The compilation of hotspotting and WEP vulnerabilities can yield the WEP key to a corporate network within six minutes, without even needing access to the actual network. An attacker can now take his latte, your corporate WEP key, locate the corporate network, and connect from a parking lot.

33.5.4.3 Caffe-Latte Attack Procedure²⁸

1. Victim machine sends SSID Probe requests for APs it has communicated with in the past (almost all supplicants keep this history to enable fast reconnections).

2. Attacking machine monitors airwaves for SSID probes and takes note of requested AP names (e.g., “coffeeshop,” “airportWifi,” etc.).
3. Attacking machine creates an AP with the SSID name requested by the client (e.g., “coffeeshop,” “airportWifi,” etc.).
4. Victim’s machine attempts to connect but fails, likely due to an encryption mismatch.
5. Attacking machine modifies AP to possess WEP encryption with a false key.
6. Victim machine attempts to connect to the AP again and successfully authenticates due to a properly matching SSID name and encryption grade.
7. Victim machine pauses during further network-based authentication due to a key mismatch and never fully associates.
8. Attacker captures gratuitous ARP, DHCP, and other packets sent by the victim after association, which are encrypted with the victim’s stored WEP key.
9. Attacker provides victim-encrypted gratuitous ARP packet to ./cafe-latte resulting in bit-flipping to produce a CRC-correct encrypted ARP request.
10. Attacker replays encrypted ARP request to solicit responses from victim with new IVs until enough IVs are captured to exhaust 40-bit key space.
11. Attacker executes Aireplay-ng (or comparable WEP cracking utility) providing IVs captured during ARP request replays.
12. Attack receives plaintext hex of WEP key and uses to gain access to target network.

The following tools can be used to perform a hotspot and cafe latte–style attack:

- **Airbase-ng:** Create an AP with specified SSID
- **Cafe-latte:** WEP cracking script, which takes the captured gratuitous ARP packet and bit-flips it into a request that can be repeated to the client thousands of time.

33.5.4.4 What about WPA/WPA2? WPA and WPA2 implement cryptographic integrity checks, which remove any ability to deduce a plaintext key, but still suffer from a hotspot style of attack. A WPA/WPA2 tailored attack involves masquerading as a known AP where a client expects WPA or WPA2 encryption. Upon providing the correct encryption level the client will try to connect and fail due to the AP not possessing the correct key. Failure is expected, as the pre-shared key hashes with a salt of the SSID has already been sent from the client and captured by the attacker. This hash can then be brute forced.

33.5.5 WEP. Despite the public and lengthy exposure of WEP vulnerabilities and little security it actually affords, its widespread use at the enterprise level is shocking yet usually unknown due to its use in many small crevices of the business that it may have wedged itself in years ago.

WEP was conceived during a time when computing power, and in particular embedded computing power, was hard to come by. The computing power required to carry out the WEP RC4 encryption and key management is very minimal, which coincided perfectly with the computing power of many handheld and other embedded devices. This very principal is still the reason why WEP remains in many environments and will for the foreseeable future. Sunk costs in infrastructure devices incapable of performing

resource heavy functions such as AES and CCMP in WPA2. WPA's implementation of TKIP was precisely done to enable backward compatibility with WEP hardware. In today's enterprise environment it is commonplace to see WEP fully expunged from employee WLANs but prevalent in retail or distribution centers on handhelds and other portable devices.

Further compounding WEP's poor implementation of the RC4 stream cipher is the ambiguous definition within the standard for specific encryption function processes, largely leaving the decision to the vendor. This is particularly obvious in the way Initialization Vectors are generated; some vendors use a Pseudo-Random-Number-Generator (PRNG) and others merely start at 000000 and work their way to FFFFFFFF. We will briefly dive into the following tried-and-true core vulnerabilities affecting WEP, and its failure to provide proper key management, integrity, or encryption, and finish with a brief description of WPA/WPA2's advancements in this area.

33.5.5.1 (WEP) Repeating Initialization Vectors (IVs). WEP is home to a number of vulnerabilities including FMS, KoreK, PTW, and ChopChop. We are only going to cover the most famous and original attack, called FMS. WEP has been sunset ages ago in favor of alternative technologies; as such we will dive into the details of this vulnerability only to shed light on the advancements that have been made since its discovery.

WEP's underlying encryption revolves around the RC4 stream cipher. An initialization vector (IV) is used to ensure two identical inputs do not result in the same cipher text output. The IV is leveraged to lengthen the key life by uniquely generating an IV for each frame. WEP keys come in two forms depending on the version, an effective 40 bits (64 including IVs) with some implementations going as high as an effective 104 bits (128 including IVs) WEP uses a 24bit IV which, on a busy network, there is a 50 percent probability that the IV will repeat after 5,000 packets.

A fundamental solution to the WEP IV key scheduling vulnerability is the use of session keys established at the onset of authentication and encryption, which are used for a finite period of time during the encryption session. The process used to derive the temporary or session key is crucial to the success of a key scheduling process. WEP suffered from concatenation of RC4 output with an IV, and was improved upon with TKIP's "mixing" of these values prior to RC4. If a solid key scheduling and management function can be established, the encryption routine itself will deliver as expected. Attacks which target vulnerabilities in WEP's key scheduling process include the famous FMS attack, named after its inventors Fluhrer, Mantin, and Shamir.²⁹

33.5.5.2 (WEP) Key Management. WEP does not provide any form of key management, such as the ability to rotate keys with clients. The result of no key management structure is the reuse of stale keys as input into the key scheduling and underlying encryption process for an extended period of time, further compounding the repeating IV vulnerability mentioned earlier. WPA and WPA2 provide session-based key management through the implementation of TKIP (WPA) and later CCMP/AES (WPA2). It is important to outline that the secret key in a pre-shared key implementation (WPA/WPA2-PSK) is only really leveraged to provided authentication; encryption is derived from the client and AP possessing the same key, but the pre-shared key is not directly involved. This is in contrast to WEP's use of a pre-shared key directly in the encryption process by leveraging it for authentication and including it in the RC4 stream cipher. Through the use of EAP and RADIUS, WPA and WPA2 Enterprise editions fully support key management through directory-based structures. These directories manage authentication keys outside of the WPA/WPA2 implementation and add increased

security through the combination of directory-based authentication key management (LDAP/Active Directory) and TKIP/CCMP encryption key management.

Tools used to exploit WEP vulnerabilities:

- **Airmon-ng**³⁰: Used to place the wireless adapter into monitor mode.
- **Airodump-ng**: Used to capture WEP IVs using monitor mode.
- **Aireplay-ng-1**: Fake authentication to the AP; this will allow you to associate to the AP but not continue the authentication process. This is necessary for the AP to receive data from your wireless adapter.
- **Aireplay-ng-3**: ARP request replay attack mode, this will listen for encrypted gratuitous ARP packets sent by a legitimate connected client. This mode identifies ARP packets by size and other factors despite being encrypted. Once an ARP packet is found, Aireplay will bitflip and turn it into a request which is replied thousands of times. The purpose of this is to generate lots of encrypted packets from the victim and start exhausting IV space.
- **Aircrack-ng-b**: Performs statistical analysis and brute force of captured WEP traffic to recover the key. The process is to use statistical analysis to zone in on potential byte values at each location of the key, then use brute force to complete the process.

33.5.6 WPA/WPA2 Pre-Shared Key. WPA and later WPA2 aimed to address many of the deficiencies in WEP and WEP advancements. The following are attack vectors and mitigating controls implemented in the WPA standard:

- **48-bit Initialization Vectors**: Addresses WEP's 24-bit vulnerability and poor RC4 implementation through the use of TKIP/CCMP to significantly reduce IV reuse and improve the ability to "seed" the encryption function.
- **Key Management**: TKIP and CCMP/AES provide per-frame unique encryption keys in contrast to stale WEP key storage within client supplicants and reliance on the IV as a primary differentiating factor. WPA/WPA2 also natively supports both PSK and enterprise based authentication mechanisms for third-party authentication key management (e.g., LDAP directory).
- **Key Length**: WPA/WPA2 provide a minimum 256-bit pre-shared key length.
- **Message Integrity Code**: WPA correctly provides message integrity through a hashing mechanism known as a MIC or Message Integrity Code. This is contrast to WEP's Integrity Check Value (ICV), which is comprised of an encrypted CRC-32 error-check. WEP's ICV is plagued by bit-flipping attacks due to its incorrect use as an integrity mechanism despite CRC-32's intended use as a transmission error detection mechanism.
- **Mutual Authentication**: WPA/WPA2 provides the ability for an AP to be authenticated by a client through the use of certificates and RSN.

The core vulnerability which plagues WPA/WPA2 is not necessarily a vulnerability in the implementation, but an attribute of the necessary 4-way handshake process (EAPoL) for basic pre-shared key authentication. PSK is not designed for enterprise use (but nonetheless finds itself in the enterprise), which is why solutions exist within WPA/WPA2 to eliminate this vulnerability at the enterprise level but not at the SOHO level.

Pre-shared key authentication is commonly used in absence of a backend directory normally accessed via RADIUS and LDAP protocols. This type of implementation is common for solutions, which are not intended to be used by a wide variety of clients and therefore the cost of implementing such a solution is not effective. Pre-shared key authentication relies on an out-of-band key-management system. WPA-PSK and WPA2-PSK do not provide any key-management or tunneled encryption of the pre-shared key authentication handshake process. The password hash procedure used by WPA/WPA2 combines the stored passphrase with a salt of the destination AP's SSID and sends it over in plaintext.

Reliance on a single attribute for access control means that each client is indiscernible from the next and no amount of accountability can be afforded to each user outside of a DHCP MAC address log.

33.5.6.1 WPA/WPA2 Key Hash Capture and Cracking. The WPA/WPA2 pre-shared key authentication process is a series of handshakes used to eventually transfer a hash of the passphrase to the AP. This process can be captured through monitor mode and used to extract the hashed passphrase. Since this process only occurs when clients are initially authenticated to the AP, an attacker can either wait for a new client or deauthenticate an existing client by spoofing management frames as described earlier in the chapter.

Once a WPA hash is obtained an attacker can attempt to crack it using brute force. Due to the salting of the hash with the SSID of the AP, rainbow tables cannot be used to assist in the cracking process. The use of a salted hash combined with a lengthy hash process makes for slow cracking of WPA hashes on CPU-based systems. An exhaustive dictionary attack on a CPU-based system can typically process between 5,000–15,000 pairwise master keys per second.

GPU-based cracking systems are becoming more popular, as programming interfaces such as Nvidia's CUDA opened the door for developers to access many components of a GPU that would normally require advanced programming experience. GPUs can be leveraged to greatly increase the probability of successfully cracking a captured WPA handshake to the tune of 50,000+ pairwise master keys per second for an average set of CUDA-enabled GPU graphics cards.

Tools used to capture and crack a WPA/WPA2 pre-shared key:

- **Airmon-ng**³¹: Used to place the wireless adapter into monitor mode.
- **Airodump-ng**: Used to capture traffic using monitor mode.
- **Aireplay-ng-0**: Deauthenticates a client from the AP and forces them to re-authenticate and perform the pre-shared key handshake. This tool is necessary to allow Airodump-ng to capture the pre-shared key during the re-authentication process.

33.5.7 WPA/WPA2: Wi-Fi Protected Setup (WPS). Wi-Fi Protected Setup allows users with little understanding of wireless security configurations to easily configure a pre-shared key configuration without necessarily logging into the router. WPS describes the protocol and *personal identification number* (PIN) sequence used to negotiate a WPA/WPA2 pre-shared key without the need to manually configure it on the client and AP. WPS is only provided on SOHO-grade APs and not enterprise-grade hardware. This vulnerability may apply to the enterprise environment through its

existence as a nonmalicious rogue AP, which an internal user has securely configured but is vulnerable to WPS.

Two types of WPS exist:

- Push-Button-Connect (PBC)
- 8-digit PIN

A PIN may be provided by the AP for input into the client WPS agent or the client WPS agent may provide a PIN for input into AP WPS prompt. WPS authentication is based on 802.1X EAP and a vendor-specific implementation of EAP, which uses a Diffie-Hellman Key Exchange to prove possession of the first half of the PIN between the AP and client and eventually the second half.

Because WPS divides the PIN into two separate authentication steps, this process severely limits the number of combinations for each half of the PIN. An attacker can derive the first and the second part of the PIN through abusing an EAP message, “EAP-NACK.” This message is issued by the AP on failing to provide the correct first or second portion of the PIN. Brute forcing each *separate* portion of the PIN requires only 10^4 tries at most, so there are only $10^4 + 10^4 = 20,000$ possible combinations instead of the original keyspace of 10^8 or 1,00,000,000.³²

On average, WPS cracking tools can recover the WPA/WPA2 plaintext password in 4–10 hours.

Tools used to perform a WPS attack:

- **Airmon-ng**: To detect target AP and place adapter into monitor mode.
- **Reaver**³³: Brute forces the WPS EAP process to recover the WPA/WPA2 key.
- **Wpscrack.py**³⁴: Alternative tool to brute force the WPS EAP process to recover the WPA/WPA2 key.

33.5.8 MS-CHAP-v2—Divide and Conquer. EAP implementations that leverage MS-CHAP-v2 have already been discussed as vulnerable to dictionary attacks with the use of EAP-LEAP or EAP-PEAP-MSCHAP with poor supplicant configurations. Traditionally, the challenge-response hash-cracking process where a challenge-response hash is provided to a cracking program along with a dictionary was the only feasible approach to exploiting this vulnerability.

Thanks to research by Moxie Marlinspike (also the author of SSLStrip), this process was recently expedited through a new understanding of the seemingly painfully obvious and much overlooked functionality within the MS-CHAP-v2 protocol. During MS-CHAP-v2, the MD4 hash of a user’s password is bitwise divided to construct three individual DES keys (seven bytes each). A typical penetration-testing tool such as *Asleep* will input the MD4 hash, break it into its three DES keys and use those keys to encrypt a given plaintext dictionary value for comparison to the original ciphertext hash.

The traditional cracking approach would result in a total keyspace of $2^{(56 + 56 + 56)}$ or about 10^{50} —a very large number that’s infeasible for incremental brute-force cracking. This is exactly the reason why dictionaries were traditionally used as a “best guess” approach, because incremental (character-by-character) brute forcing is just not an option for any reasonable amount of time due to dictionaries’ salting through the use of a challenge.

The use of three DES keys is prime for exploitation. An MD4 hash is only 16 bytes, whereas three seven-byte DES keys brings us to a total of 21 bytes. How is the difference made up? Padding, which reduces the effective keylength of the third DES key to two bytes. If each of the two seven-byte and singular two-byte keys are cracked individually, the effective keyspace is reduced to $2^{56} + 2^{56} + 2^{16}$, or about 10^{17} —a decline in keyspace by a factor of 10^{32} . The interesting part about the MS-CHAP-v2 routine is that each DES key is used to encrypt the same plaintext; therefore, during the cracking process we can use the same key input for each of the two DES functions, effectively reducing the amount of DES functions for each iteration to one, leaving the only dual operation as the comparison of the DES output to each of the two previously determined ciphertexts. This is a final effective keyspace of 2^{56} (10^{16}), which in 1998 could be cracked in 4.5 days on average, and on the massively parallel architectures commercially available by the early 2010s, in about half a day on average.³⁵

Tools used to crack MS-CHAP-v2:

- **Airmon-ng:** To capture MS-CHAP-v2 keying material during the challenge-response process.
- **Aireplay-ng-0:** Used to deauthenticate a connected MS-CHAP-v2 client.
- **Chapcrack.py:** Used to parse/extract the keying material from MS-CHAP-v2 handshake.
- **Super Computer:** A hardware-accelerated cracking machine designed to crack a single DES routine (available through cloud services).

33.6 MITIGATING CONTROLS. This section provides enterprise-grade technical mitigating controls that should be evaluated in every wireless solution regardless of the vendor-specific implementation. These controls respond to the fundamental wireless-security issues discussed earlier and provide a layered defense as part of secure enterprise design.

33.6.1 Improvements. Wired access controls have remained relatively steady with the inception of 802.1X port-based authentication, which is now standard in most modern switches. 802.1X port-based authentication is fundamentally the same authentication function baked into the WPA security standard and combined with the *Temporal Key Integrity Protocol* (TKIP). WPA2 builds on WPA by adding even stronger encryption, which requires dedicated hardware for AES encryption. The 802.1X wired standard is fully implemented in WPA and WPA2 but reliant on the configuration as to whether it is leveraged, such as *WPA-Personal*, which uses a pre-shared key, or *WPA-Enterprise*, which uses a central authentication repository.

The use of wireless for endpoint connectivity can provide security, which rivals traditional wired architecture through the ease of administration and management of a thin-client AP environment and network choke-points for monitoring in close proximity to the initiating clients at the outermost edge of the network.

33.6.1.1 RSN. Complete RSN support in WPA2 and 802.11i draft support in the WPA standard is essential to ensure wireless confidentiality and integrity. To deploy RSN, any AP which can perform 802.1X authentication will suffice. Support for 802.1X on an AP is usually just a matter of understanding the EAPoL protocol and accepting a RADIUS server as a configuration parameter. The AP does not need to be configured

for any particular EAP type, as this aspect of the network is completely transparent to the AP.

In a typical wireless environment, there are two fundamental management functions at play: user authentication management and key management for encryption, initial keying material, and key distribution. In a nonenterprise implementation, the user and key-management functions can be combined. The fact that a client possesses a correct pre-shared key authenticates them to the AP, and the bits which make up the pre-shared key may be used in the encryption process to derive a pairwise transient key for the encryption of the 802.11 payload.

33.6.1.2 Authentication and Access-Control Key-Management Considerations

- Solid authentication key management is necessary to deliver secure communication of keys in contrast to a pre-shared key environment where keys must be distributed through an out-of-band mechanism. A key can be in the form of a user/password combination, certificate, or other identifying material such as an RSA SecurID number and PIN.
- Leverage an existing directory-based infrastructure used to authenticate users to computer systems on the wireless LAN or rollout an endpoint PKI infrastructure. The use of EAP and a backend user repository for authentication through the RADIUS protocol is the silver standard method of authentication. A PKI infrastructure, which provides client public/private keys to every wireless endpoint effectively eliminates the possibility for an attacker to capture a password hash challenge response.
- Strong EAP implementations include a TLS tunnel established between the endpoint client and backend authentication server (e.g., RADIUS) before any identifiable information is exchanged.

33.6.1.3 Encryption Key Management Considerations. As described in this chapter, encryption key management is the Achilles' heel of confidentiality. Modern encryption algorithms have matured to the point of perfection, as with AES, and are only as weak as their weakest link—that is, input. The best key-management functions are available only with the latest evolutions of wireless technologies. WPA2-Enterprise's AES/CCMP is the de facto standard and should be the minimum requirement for any new implementation. WEP, WPA, and WPA-2 present multiple methods of key management with improvement in each generation of 802.11 authentication/encryption schemes.

33.6.2 Authentication Server and Client Certificates. Certificate-based authentication between a client and backend authentication server is the *de facto* standard of wireless authentication. X.509 Certificates are used for the authentication of server to the client (RADIUS as a broker), client to the authentication server, or both.

To leverage endpoint-user and computer-based certificates for authentication in place of directory-based password authentication requires the implementation of a full *Public Key Infrastructure* (PKI). PKI is necessary to provide and regularly update/associate certificates with endpoint devices and sign them using an enterprise root Certificate Authority (CA) or outside root CA such as VeriSign.

For details of PKI, see Chapter 37 in this *Handbook*.

The following are three of the most common uses for AP or client certificates within modern enterprise wireless implementations:

- **Authentication Server Certificates Only:**
 - A barebones RSN EAP implementation should require at a minimum a signed authentication server certificate. This ensures to connecting clients that they are performing authentication with a trusted AP and authentication server. In absence of a server certificate, clients are susceptible to MITM attacks, which can be used to capture EAP challenge-response hashes from the client. The RSN protocol ensures that a client must authenticate the authentication server before authenticating itself to the server. This sequence protects against RADIUS-impersonation attacks and rogue APs if configured properly.
 - Wireless implementations which leverage authentication-server certificates but do not enforce them at the supplicant level forgo any security provided by this control. An attacker can masquerade as the legitimate backend authentication server through the use of same-SSID and hijack the authentication process.
- **Client and server mutual certificate-based authentication:** Each endpoint client is provided a certificate signed by the enterprise root authority and installed in the Operating System's certificate store. EAP-TLS is commonly used with this type of PKI infrastructure to authenticate the server's certificate (as with directory-based authentication) and the client's certificate by validating the certificate's signature. This client certificate also contains field information to identify the user and any other applicable information for use by the authentication server.
- **Client- and server-based authentication with external client certificates:** A PKI infrastructure can provide even greater security in the form of "something I have that others don't." A client certificate (private key) can be stored on a smart card, requiring the user to possess the certificate separate from the operating system in the event the laptop is lost or stolen. The smart card must be inserted into the computer prior to attempting authentication.

33.6.3 Endpoint Supplicant Configurations. The endpoint-client supplicant configuration is a crucial and commonly overlooked component of a secure wireless deployment. Deploying a *secure* wireless network within the enterprise protects the internal network, but most deployments neglect to assess the security of the endpoints that connect to the new wireless network.

Enabling wireless connectivity at the enterprise levels means that laptop computers, which are taken out of the office, will almost always have their wireless radios on. A wireless radio is not an inherent risk, but when combined with default operating-system and driver configurations, such unprotected devices can easily provide all kinds of connectivity information to listening parties.

Most default wireless-client supplicants lend themselves to some sort of attack, which can potentially compromise the endpoint at a remote location, such as a coffee shop, and re-establish connectivity when the client goes to work and connects the infected machine to the enterprise wireless network.

Employees may be flying, sitting on a bus, or just grabbing something to eat—and if they sit in a physical location long enough, an attacker could glean a wealth of information from an insecure supplicant configuration. This information can range from a pre-shared key hash for a home network, remembered SSIDs (e.g., the

enterprise wireless SSID), or even password hashes for enterprise directory-based authentication.

The following are recommendations when for securing an endpoint supplicant configuration:

- **Disable SSID Probe Requests:** Many operating systems and third-party supplicants will continuously probe for the last known SSIDs. This process is performed to ensure the client can connect to an AP, which may not be sending beacon frames to identify itself or if the client has missed the AP's beacon interval. A beacon interval is defined on the AP as the period of time between sending beacon frames to identify itself to all nonassociated clients within range. Disabling this feature prevents an attacker from passively monitoring 802.11 traffic and acquiring a list of SSIDs to which a particular client is attempting to connect. This information can then be leveraged to coerce the client into connecting to a rogue AP masquerading as one of the identified APs.³⁶
- **Wireless Profiles:** Wireless profiles should be configured to separate corporate AP profiles from hotspot or home AP profiles. Third-party supplicants commonly provide this capability to prevent the situation where a corporate employee uses their computer at a coffee shop and their wireless driver unknowingly broadcasts the corporate SSID, therefore inviting an attacker to masquerade and potentially capture a WPA/WPA2 pre-shared key hash or challenge response directory-based password hash. The use of different profiles limits the ability for the client to know how to connect to APs on the corporate network when not located at the office.
- **Secure Authentication Server Configuration**
 - **Certificate Authority:** A supplicant should only accept authentication server certificates, which were signed from a designated/single root CA. This situation prevents the ability to connect to an AP and underlying authentication server, which is displaying a valid/matching Common Name signed by a legitimate but different root CA.
 - **Certificate Validation:** Users should not have the ability to overwrite and enable the use of an untrusted server certificate during the authentication process. By default, many supplicants will prompt the user if an invalid certificate is detected and provide the option to ignore. The supplicant should be configured to not prompt the user and remove any possibility for successful authentication attempts to an AP with an invalid or untrusted certificate.
 - **Common Name (CN):** Ensure the backend authentication server's common name or CN is specified in the client. This will prevent a connection to an AP and authentication server which possess a trusted certificate (assuming a nonenterprise-specific root CA) but uses an incorrect hostname/FQDN.

33.6.4 Wireless Intrusion-Detection Systems. The wireless intrusion-detection system (WIDS) has come a long way to become a standard network-security monitoring appliance, becoming an everyday security-monitoring tool, like a traditional wired IDS. A WIDS is capable of monitoring the 802.11 airwaves at the data link and MAC layer regardless of encryption or authentication. Although a WIDS cannot be used in place of a wired IDS, it can provide visibility into a cloudy segment of the network edge. A WIDS is also not exclusive to enterprises that deploy a wireless network. A WIDS can also provide value for enterprises, which don't

deploy wireless networks by ensuring against the unauthorized use of wireless connections by continuously monitoring the airwaves and alerting appropriately for internal rogue APs.

Multiple large breaches have stemmed from poor wireless management and visibility; this is a large problem for organizations with many physical retail or corporate outlets. Due to the widespread use and ease of installation of an SOHO AP obtained from a consumer retail outlet, it is becoming increasingly important to detect unauthorized extensions of the corporate network. In addition, the increased reliance on wireless communications for various business cases (such as corporate access, vendor devices requiring their own AP, or retail devices requiring dedicated APs with low-grade encryption due to low process power) has resulted in increased difficulty inventorying a network's authorized APs and confirming the proper segmentation or absence of internal connectivity for noncorporate access APs. In the event an enterprise can manage and inventory all known APs, there remains no native solution to quickly and accurately audit the implementation of enterprise standard authentication and encryption levels from a remote location.

33.6.4.1 Types of WIDS. Most modern WIDS infrastructures can be configured to leverage existing APs or use dedicated sensors to monitor 802.11 traffic. Dedicated sensors provide much more functionality at the expense of additional cost. A dedicated sensor has the time and CPU to solicit useful data from neighboring APs and clients, whereas an existing enterprise-thin AP may allocate only a fraction of processing toward these functions.

33.6.4.2 Use Cases. Due to the encryption, which takes place at the data link layer and above, a WIDS cannot inspect data-layer traffic. The majority of wireless threats involve the exploitation of a vulnerability, which exists in the data-link layer such as the 802.11 protocol itself or following authentication and encryption processes. The core value of a WIDS lies in the ability to provide assurance for wireless controls by verifying their existence and continuously monitoring for unauthorized changes.

A dedicated WIDS can provide the following services:

- Identify unauthorized APs across all physical locations (rogue APs).
- Detect and block the use of various wireless hacking tools with identifiable layer 1/2 signatures.
- Identify and continuously monitor for below enterprise-grade encryption or authentication mechanisms on authorized APs.
- Detect and block unauthorized connections to internal APs from clients with unauthorized wireless cards.
- Determine client supplicant configuration parameters as they relate to the transmitting of known SSID beacons.

33.6.4.3 Detailed WIDS Benefits

Regulatory Compliance. Regular wireless penetration testing and rogue AP audits are a necessary function of many regulatory certifications (such as the Payment Card Industry [PCI]). Leveraging a remote dedicated WIDS sensor may be a cost-effective alternative to deploying contractors or internal employees to each physical location to survey and assess controls.

Rogue-AP Detection. Rogue APs are the number-one issue threatening wireless-network security.³⁷ Even in the face of 802.1X switchport access controls, Port Address Translation (PAT) can provide access to the wired network for multiple wireless clients by sharing a single authorized MAC address. A single unmanaged AP could provide unlimited access to the internal network for an extended period.

Methods of rogue AP detection:

- Corporate AP white-listing by:
 - Vendor: Rogue APs can be detected based on a nonstandard make/model by performing a lookup on the base clients OUI portion of the MAC address.
 - SSID: Rogue APs can be detected through the identification of transmitted SSID beacons containing a nonstandard enterprise SSID (such as “Linksys” or “Netgear”).
 - MAC Address: A static list of authorized AP MAC addresses can be obtained through SNMP or other means and provided to a WIDS system as “known good” APs.
 - Encryption/Authentication Grade: The WIDS can attempt to connect to potential rogue APs and enumerate available/requested encryption/authentication levels. A nonstandard level or method would be indicative of a rogue AP.
- Associated clients
 - A WIDS can perform analysis on a potential rogue AP’s connected clients to determine if clients are enterprise-provided based on MAC address OUIs.
- Signal strength
 - A WIDS is constantly monitoring the airwaves and can alert on anomaly detection of a new AP in close proximity to the physical sensor/location by determining the signal strength of the potential rogue AP measured in dBm. If the dBm strength falls within a user configured threshold, an alert can be triggered.

Confirming internal LAN connectivity:

- Internal Device Connectivity: The remote WIDS sensor can attempt to connect to the rogue wireless network and ping a known internal device to confirm connectivity to the enterprise network (assumed no authentication).
- Simple Network Management Protocol (SNMP) content-addressable memory (CAM) table³⁸ enumeration: Internal network switch CAM tables possess all MAC addresses a device knows about and which port they reside on. This detection technique is based on the fact that wireless APs possess two network cards. One network card resides on the wired side of the AP, and the other on the wireless side/radio. These cards both possess MAC addresses, which are one or two values apart. A WIDS sensor can identify the MAC address in use by the wireless radio through passive monitoring of the data link layer and search all known switch CAM tables via SNMP for a similar MAC address. The WIDS controller can be provided an SNMP read string to the enterprise-wide switch environment used by the network management team for various monitoring/polling processes.

Counter-Action. If a rogue AP is detected, the WIDS can be configured to disable the switch port it resides on through SNMP write strings or to trap an alert to the central

console. A WIDS sensor can also be placed into a *blocking mode*, which will leverage spoofed 802.11 deauthentication packets to prevent clients from successfully establishing a connection to the rogue AP. Spoofed deauthentication packets were covered previously in Section 33.5.3, Management Frames, and in the correct circumstance can be used to *increase* security. These actions should be carefully analyzed prior to execution to minimize the probability of unknowingly attacking a legitimate neighboring business or household.

Defense in Depth—Rudimentary Controls. The previously described controls are best practice that can make or break the security of an enterprise wireless network. In addition to these controls, there are some controls which by themselves do not afford much protection, but together can reduce an attacker’s success rate.

Security through obscurity may be a bad idea if it’s the only security measure, but combined with solid security controls, one can potentially reduce legitimate attacks against core security control (such as EAP-MS-CHAP-v2). These controls are what we refer to as *script-kiddie* controls; they offer little resistance to an experienced attacker but cause an adversary to take multiple steps before even exposing their target objective.

- **MAC-address based restrictions:** Depending on the capabilities of each vendor-specific AP, it may be possible to restrict association to an AP based on MAC address, even in an enterprise environment. Methods exist to dynamically update MAC address mappings within a backend repository, similar to wired MAC-based VLAN assignment.
- **SSID Cloaking:** SSID cloaking is a perfect example of security through obscurity. The presence of an AP and BSSID can be identified through various penetration testing tools capable of analyzing raw 802.11 traffic, but an everyday operating-system default or third-party client supplicant will not display the presence of an AP with nonbroadcasting SSID.
- **Client Isolation:** Client isolation is an AP-specific control that monitors the destination MAC address of the incoming traffic. If traffic is destined for another client on the same AP, or SSID in thin client environment, it will be denied access. The purpose of this control is to limit the ability of a malicious user to communicate with other devices connected to the AP. This feature is common on public APs where the end user is not necessarily well vetted or authenticated. Depending on the enterprise use for a particular SSID/VLAN, this feature may be enabled to prevent access to other endpoints in an environment where services are provided over wireless by other wireless clients, such as a printer; analysis should be performed to allow only a subset of communication with those devices.

33.7 SECURE ENTERPRISE DESIGN. Earlier we discussed fundamental and specific vulnerabilities in detail to expose the underlying inherent risk of wireless network mediums and provide a background on some of the latest and greatest threats that should be addressed. Understanding an organization’s risks and associated threats as they pertain to their unique network environment is vital to ensuring they are properly managed. The proper management of technical security risk starts with a secure design and ends with the implementation of secure technical controls to further support a secure design. The phrase “crunchy on the outside, soft and chewy on the inside” plays directly into this particular type of governance. Mitigating controls can

provide a crunchy perimeter, but secure design prevents a chewy interior in the event of perimeter-control failure.

In this section, we discuss priority design considerations which foster a secure enterprise wireless network. These design considerations should be accompanied by the technical mitigating controls discussed earlier to provide a wholesome approach. Integrating and allowing for various types of technical mitigating controls such as EAP methods, SSIDs, PKI infrastructures, AP certificates, or supplicant configurations during the initial wireless design phase can increase their effectiveness as they function as a whole in contrast to after-the-fact add-ons.

33.7.1 Benefits of Wireless Controller Architecture. Enterprise wireless network hardware comes in two primary varieties, thin (lightweight) and thick (autonomous) APs. These two types of designs will have a large impact on the way the wireless network is operated and managed, and the extent of available controls to secure it.

- A thick AP possesses a lot of intelligence and features outside of the core 802.11 or RSN functions. These features include helper services such as DHCP, SNMP, QOS, Firewalls, etc. Although these types of services definitely have a place, from a management standpoint it can become difficult to synchronize configurations across thick clients or varying vendors.
- Thin client APs are bare-bone APs, which implement the necessary 802.11/RSN functions only. Enterprises should leverage thin-client APs to lower cost and increase secure management of the wireless network. These APs leverage connected switch hardware or dedicated wireless controllers for intelligence and configuration settings. Upon boot and initialization a thin client will discover, contact, and download the latest configuration settings.

The security afforded by a thin-client environment reaches beyond ease of device management by providing the following additional benefits:

- **Physical safeguard of configuration data:** A thick client's configuration could be compromised through physical theft and analysis. A thin client holds the bare bone configuration to allow 802.11 connectivity, RADIUS shared secrets, and SNMP strings; other stored configuration information is held on the backend switch or wireless controller
- **Mesh Security Functions:** A common form of communication across APs such as the *Lightweight Access Point Protocol (LWAPP)*³⁹ enables widespread communication between APs and controllers across an entire enterprise. This communication mechanism combined with the physical presence of APs across primary and remote locations enables the ability to leverage them for security functions. Leveraging client APs for security monitoring can be beneficial from a cost-saving standpoint in favor of a dedicated WIDS, albeit with a lack of functionality.
- Detect rogue APs using AP infrastructure rogue-discovery techniques. Vendor-specific solutions exist to leverage client-servicing APs to momentarily scan for rogue AP beacons, which are not part of the LWAPP network.
- An AP can be placed into a detection role and connected to a switched port analyzer (SPAN) port to track down potential rogue AP beacons for internal network connectivity.⁴⁰

33.7.2 Network Segmentation. A basic wireless network should be segmented in two ways. First, the wireless network should be segmented from the internal LAN network, and second, wireless networks should be segmented between wireless networks with different business uses. In addition, during the segmentation process consideration should be provided for WIDS sensor placement with the ability to physically span all areas of the wired network.

33.7.2.1 Wired versus Wireless Endpoint Segmentation. Wired networks commonly assign VLANs on a port or MAC address basis. In the case of port-based VLAN assignment, management relies heavily on proper access-layer switch configuration, trunk-port configuration for uplinks, and pruning the propagation of sensitive VLANs for different physical locations. Operational changes may dictate the updating of numerous switches for relatively minor moves. In the event of wired MAC address based VLAN assignment, MAC-authentication-aware switch hardware and backend RADIUS servers for MAC->VLAN mappings must be used. MAC-based VLAN assignment can improve management capability and oversight but poses a significant security risk as they are susceptible to MAC-address spoofing, which may allow an attacker access to sensitive VLANs by spoofing an authenticated device's MAC address.

In a wireless environment, VLANs can be assigned on a per-SSID or per-user-group basis, and administration efforts to provision a user to a VLAN can be greatly reduced or completely removed. A user is no longer confined to particular physical location to gain access to a required VLAN, as the necessary SSID may be available anywhere on campus. In the event of expansion, deploying a new thin AP in close proximity will deliver the necessary VLANs, which a client supplicant profile is configured for. Since VLAN assignment can be controlled through minor client supplicant configurations and backend RADIUS privileges, segmentation can be determined during the asset provisioning process and require relatively minor management thereafter.

33.7.2.2 Segmentation from the Wired LAN. Due to public accessibility of wireless airwave transmission (encrypted or not), segmentation within the existing LAN should be addressed to mitigate the risk of complete internal access due to a lapse of wireless security. A solid network security posture assumes a particularly risky segment may be compromised and is designed to mitigate the damage from such a disaster.

The value in segmenting the wireless LAN from the wired LAN thrives on the ability to hedge against the following events, which could lead to LAN compromise from a remote location, such as the corporate parking lot.

- Malicious use of compromised employee username/password-based authentication credentials through spear phishing emails or other theft.
- Misconfiguration of wireless security controls, such as a weak EAP implementation (EAP-LEAP or absence of AP certificate verification in EAP-PEAP-MS-CHAP-v2) lending itself to dictionary or RADIUS impersonation attacks.
- Rogue AP “hotspotting” of employee laptops to establish connectivity and compromise the endpoint through exploitation of services or HTTP traffic MITM. Once the endpoint is connected to the legitimate enterprise wireless an attacker could gain access to the LAN.

The need for segmentation of wireless traffic is due to the inherent lack of physical controls for 802.11 traffic and range of accessibility. An external attack at a DMZ or other Internet-accessible device could lead to the compromise of DMZ assets, but controls typically exist in the form of multileg or sandwich-style firewall environments which limit the exposure from the DMZ network and prevent direct LAN connectivity. This type of segmentation should be applied to the wireless environment for similar reasons, albeit different attack vectors.

33.7.2.3 VPN over Wireless. Depending on the purpose of the wireless network, users may require the same access on the wireless network that is afforded on the wired LAN. In favor of exposing the wireless network to the complete wired LAN a VPN solution may be used. This architecture would allow wireless network access to the Internet, just the VPN gateway, or other basic internal assets (such as an intranet site), which force the use of a VPN gateway for any other resources.

An additional strength provided by a VPN on top of wireless authentication is defense in depth. To gain internal LAN access from a wireless network, an attacker must compromise and gain access to the VPN in addition to any layer 2 wireless authentication/access control mechanisms. An attacker who gains access to the wireless medium would likely never suspect the use of a VPN and assume the state of limited internal access or mistake the current state for the complete LAN.

An assessment should be performed to understand the business case where wireless assets need complete access to the corporate LAN, and explicitly allow access on an IP/port basis. Fine-grain segmentation can be obtained by leveraging SSID-based VLAN assignments, explained in detail in the following sections, to assign restrictions on a per-VLAN basis with supporting ACLs at higher points within the network.

33.7.2.4 Inter-Wireless Network Segmentation. Inter-wireless segmentation enables different user types to connect to different SSIDs provided by the same physical AP and be afforded different network-based access privileges. The process of segmenting each SSID into its own network usually involves VLAN tagging at the AP level to distinguish layer-2 traffic by forcing inter-VLAN communication to flow over a firewall or upstream router with VLAN/IP-based ACLs. Backend directory systems such as LDAP can be leveraged by modern APs to provide a decision on the VLAN assignment a particular user will receive—regardless of the SSID on which they currently reside. Dynamic backend directory-based systems are not completely secure due to the reliance on MAC addresses as a unique identifying agent.

This type of segmentation can be enforced at the network layer, through aforementioned VLAN firewalling, or through VPN access lists if employee wireless access is forced through a VPN tunnel to communicate with LAN assets.

33.7.2.5 Benefits and Drawbacks of SSID/VLAN-Based Segmentation. Benefits of SSID/VLAN-based segmentation include:

- Differential treatment for wireless users by group or SSID; for example,
 - An SSID of “corporate-sales” and “corporate-hr” may provide varying levels of access. It would be best practice to disguise and cloak the SSID names to obfuscate their purpose to an outsider.
- Ease of network administration by removing the need to assign VLANs on a per-port basis. SSID-based VLAN assignment only requires endpoint configuration

33 · 44 802.11 WIRELESS LAN SECURITY

to ensure the endpoint provides the credentials necessary to authenticate to a particular SSID.

A drawback of SSID-/VLAN-based segmentation is increased wireless-network overhead and reduced performance due to multiple SSID memory requirements.

Summary of Wireless Segmentation Controls

- LAN segmentation: protects internal LAN in the event of wireless compromise through VLAN and wireless IP-based firewall ACLs.
- VPNs can be used over a wireless medium to allow users to access LAN assets.
- Intra-wireless network segmentation:
 - SSID based: The use of separate SSIDs for different business cases can easily be mapped to a VLAN and provide varying levels of segmentation.
 - Group based: RADIUS-based VLAN assignment for wireless user's current group privileges.

33.7.3 User Segmentation. A RADIUS server can make advanced authorization decisions for a valid username/password match. Leveraging designated user groups in the authorization process can provide fine-grained control over which users are able to use a wireless network segmented in large sweeps. If it's known that domain admins, power users, or general service accounts should never be able to authenticate over a wireless connection, they can be implicitly denied through nonmembership in a wireless-users group. Any user group that requires the ability to authenticate over wireless should be a member of this group.

A default RSN implementation that can and will authorize any user within the provided directory can become a victim of attacks on default, inactive, guest, or test accounts within the designated directory. Test accounts may be vulnerable to weak canonical passwords (e.g., "test" or "password") due to their creation during early stages of software or directory development or through other means that bypass corporate password policy. When a username/password authentication mechanism is in play, an attacker may attempt basic brute-force attacks to gain access to the network through standard test or guest accounts. Many organizations don't feel this is a serious problem, but when a directory contains thousands of accounts, and organizations don't audit on a regular basis, it's easy for things to slip through the cracks.

The use of a designated wireless group:

- Decreases the surface area of an attack, even if an adversary is able to obtain a list of user accounts and leverage them to brute force a wireless network through the use of basic passwords.
- Decreases the number of endpoints with saved or remembered network profiles that can be attacked and used to capture username/password challenge hashes in a hotspot or RADIUS impersonation-style attack.

33.8 SECURITY AUDITING TOOLS.⁴¹ This section looks at the open source and commercial tools available to help audit a wireless environment and to understand the tools that war drivers have to attack a network. Exhibit 33.11 lists the main programs available, including older software still mentioned in discussions, and the platforms they run (or ran) under.

EXHIBIT 33.11 802.11 Security-Auditing Software

Tool	Description and Home Page	Operating System
Aircrack	A program that breaks WEP encryption, injects packets (Aireplay), and performs a dictionary attack against WPA PSK. http://www.aircrack-ng.org	Linux Windows
Auditor	An obsolete security collection that had all the required drivers and security tools to audit or hack wireless networks. Replaced by BackTrack (see below).	Linux
AirMagnet	A commercial wireless LAN analyzer that runs on laptop PCs and pocket PCs. http://www.flukenetworks.com/enterprise-network/wlan-security-and-analysis	Windows Pocket PC
Airsnort	Outdated tool. Broke WEP encryption using the RC4 Key Scheduling Vulnerability and Korek optimizations. Last update was 2005. http://sourceforge.net/projects/airsnort/	Linux
Airopeek NX	A commercial wireless LAN analyzer that ran on laptop and tablet PCs. Replaced by OmniPeek (see below).	Windows
BackTrack	A Linux security distribution and is the result of the merging of the Whax and Auditor security collections. http://www.backtrack-linux.org/ http://www.remote-exploit.org/articles/backtrack/index.html	Linux
CoWPAtty	A WPA PSK cracker last updated in 2008. http://www.willhackforsushi.com/Cowpatty.html	Linux
Ethereal	A program that understood the format of packets and dumps out their contents. Could capture packets as well as process a log file created by other programs. Replaced by Wireshark (see below) in 2006 when original programmer hired by a new company.	Linux Windows
Kismet	Wireless auditing tool still being actively developed and improved. Latest updates at time of writing were on 2012-12-06. http://www.kismetwireless.net/	Linux, FreeBSD, NetBSD, OpenBSD, Mac OS X
Linux-wlan	The Linux drivers for Intersil Prism 2, 2.5, and 3-based cards used by open source software such as Kismet and Wellenreiter. Last updated 2004. http://www.linux-wlan.com/linux-wlan/	GNU/Linux
Sniffer Global Analyzer	High-end software for use with portable (hardware) analyzer tools. http://www.netscout.com/products/enterprise/Pages/default.aspx	Hardware modules & client software
Netstumbler	Detects broadcasting 802.11 networks. Netstumbler is not suitable as a network auditing tool because access points can be configured to avoid detection. Last update (v0.4.0) was in 2004. http://stumbler.net/	Windows

(continued)

EXHIBIT 33.11 (Continued)

Tool	Description and Home Page	Operating System
OmniPeek	Commercial, sophisticated network-analysis tool from WildPackets with wireless capabilities. Replaced AiropEEK. http://www.wildpackets.com/products/omnipeek_network_analyzer/wireless_network_analysis	Mac, Windows, hardware unit
Wellenreiter	Provides similar functionality to Netstumbler in that it detects access points. However, Wellenreiter has a major advantage over Netstumbler in that it detects access points that Netstumbler cannot see. At time of writing, the last update was 2012-07-17. http://sourceforge.net/projects/wellenreiter/	Linux
Windows wireless client	A built-in wireless subsystem that displays a list of available networks.	Windows
Wireshark	Highly regarded network protocol analyzer. Version 1.8.4 released 2012-11-28. http://www.wireshark.org/download.html	Windows, Mac

33.9 CONCLUDING REMARKS. The convenience and increasing bandwidth of wireless networks will inevitably result in continued growth of both technological improvements and implementation. Network and security managers must continue to monitor these developments and take appropriate action to secure all of their systems against constantly evolving threats to information security.

33.10 ABBREVIATIONS AND DEFINITIONS. Most of these abbreviations and definitions originate from the ANSI/IEEE 802.11-2012 standard.

Abbreviation/ Term	Meaning/Definition
802.11	The ANSI/IEEE standard 802.11, 1999 edition. Wireless LAN Medium Access Control (MAC) and Physical Layer (PHY) Specifications.
802.1X	IEEE Std 802.1X-2001 defines port-based network access controls. It provides the means to authenticate and authorize a network device before granting access to network resources. ⁴²
Access Controller	The CAPWAP term for a wireless switch that controls and manages Lightweight Access Points (LWAP).
Access point (AP)	A specialized wireless client that bridges other wireless clients to the physical wired network or distribution system.
Authenticator	An 802.1X component that authenticates a network device before allowing it to access network resources.
Authentication Server (AS)	An authentication server is an 802.1X component that performs the actual authentication of the supplicant on behalf of the authenticator.

Abbreviation/ Term	Meaning/Definition
BSS	Basic Service Set. A set of clients controlled by a single coordination function (an AP).
BSSID	Basic Service Set Identification. Due to the ability for a physical AP to provide multiple SSIDs on one interface, a BSSID reference to the MAC address associated with that interface to uniquely identify it as the provider of the SSIDs.
CAPWAP	Control and Provisioning of Wireless Access Points. An IETF initiative to establish standards enabling interoperability between different vendors APs and wireless switches.
CBC-MAC	Cipher Block Chain–Message Authentication Code. A message authentication algorithm based on a symmetric block cipher, where each block chains into the next data block.
CCMP	Counter mode with CBC-MAC protocol. A symmetric block cipher mode providing data privacy using counter mode, and data origin authentication using CBC-MAC. This is the protocol required for compliance with the WPA2 standard.
CRC	Cyclic redundancy check.
CRC-32	A 32 bit CRC that is used in the 802.11 standard.
Distribution System (DS)	A system used to interconnect a set of basic service sets (BSS) to create an extended service set (ESS).
DMZ	Demilitarized zone. This refers to a network segment that separates and protects a trusted network from an untrusted one.
DSSS	Direct sequence spread spectrum. DSSS is an 802.11 modulation technique that spreads signal power over a wide band of frequencies.
DTLS	Datagram Transport Layer Security. Essentially TLS over UDP.
EAP	Extensible authentication protocol defined in RFC 5247. ⁴³
EAP-PEAP	Protected EAP. A draft IETF standard by RSA, Microsoft, and CISCO for doing EAP authentication protected by TLS. ⁴⁴
EAP-TLS	EAP–Transport Layer Security defined in RFC 2716. ¹³
EAP-TTLS	EAP—Tunneled TLS authentication protocol. A draft IETF standard that tunnels EAP authentication through TLS. ⁴⁵
EAPoL	EAP over LANs. The protocol defined in 802.1X for encapsulating EAP messages exchanged between a wireless client and the AP.
ESS	Extended Service Set. A set of one or more interconnected basic service sets (BSSs) and integrated LANs that appears as a single BSS to wireless clients.
Exclusive-Or (XOR)	An add-without-carry logical operation. XOR is used in cryptographic algorithms partly because it is reversible by repeating an operation. A XOR B XOR A will result in B; A XOR B XOR B will result in A.
FHSS	Frequency hopping spread spectrum. A transmission method that sends bursts of data over a number of frequencies, with the system hopping between frequencies in a defined way.

Abbreviation/ Term	Meaning/Definition
IBSS	Independent Basic Service Set. An ad hoc wireless network where clients communicate directly with one another rather than via an AP.
ICV	Integrity check value. A CRC-32 value used by the WEP algorithm to detect changes in the ciphertext and to ensure that the packet has decrypted correctly.
IV	Initialization vector. A 24-bit value prepended to the WEP key, which is used as the seed for the RC4 stream cipher as part of the WEP algorithm.
KSA	The key scheduling algorithm of the RC4 stream cipher.
LAN	An IEEE 802 local area network.
LWAP	Lightweight Access Point. A type of AP that is essentially an 802.11 wireless radio that passes the received packets to a wireless switch for processing.
LWAPP	Lightweight Access Point Protocol. The base protocol chosen for the CAPWAP protocol and used by wireless switches to manage and communicate with access points.
MAC	Media access control. This is the data link layer in a wireless LAN that enables clients to share a common transmission medium.
Mb/s	Megabits per second.
MIC	Message integrity code. A cryptographic integrity code to detect changes in a message.
Michael	The message integrity code (MIC) for TKIP.
MITM	Man-in-the-middle. An MITM attack is one where an attacker can sit between two communicating parties and monitor what is being exchanged, without being noticed.
MPDU	MAC protocol data unit. The packets/frames exchanged between clients via the physical layer.
MSDU	MAC service data unit. Information that is to be delivered as a unit between MAC service APs (SAP). If an MSDU is too large to fit into one MPDU then it will be fragmented into multiple MPDUs and reassembled into one MSDU by the receiver.
OFDM	Orthogonal frequency division multiplexing. A modulation technique used in the 802.11a and 802.11g standards that works by dividing data into several pieces and simultaneously sending the pieces on many different subchannels. This mechanism enables throughput of up to 54Mb/s.
PAE	Port Access Entity. An 802.1X object that operates the authentication mechanism in the participants.
PKI	Public Key Infrastructure.
PMK	Pairwise master key. The PMK is a master session key derived from the overall master key. For 802.1X authentication mechanisms (e.g., EAP-TLS), the key is generated during authentication. For Pre-Shared Key authentication, the PMK is the pre-shared key (PSK).

Abbreviation/ Term	Meaning/Definition
Port	Network access port.
PRF	Pseudorandom function. An RSNA-defined algorithm that is part of the key-generation function.
PSK	Pre-shared key. A static cryptographic key that is distributed out-of-band to all clients in the wireless network.
PTK	Pairwise Transient Key. An RSNA cryptographic key that is the source of working temporal keys that protect wireless messages.
RADIUS	Remote authentication dial-in user service, defined in RFC 2865. ⁴⁶
RSN	Robust Security Network. The name for the new security system implemented in the RSN draft standard. An RSN is one that only allows the creation of RSN Associations.
RSNA	A Robust Security Network Association is where two clients have authenticated each other and associated using the 4-way handshake protocol.
RSN IE	Robust Security Network Information Element. The RSN IE is contained in Beacon and probe frames, and lists the supported authentication mechanisms and cipher suites.
Supplicant	The supplicant is the 802.1X term for the network device that wants to connect to the network.
“The Standard”	In this chapter, the term refers to the ANSI/IEEE standard 802.11-1999 edition.
TKIP	Temporal Key Integrity Protocol. TKIP is a suite of algorithms enhancing the WEP protocol to provide secure operations for legacy 802.11 equipment.
TLS	Transport Layer Security defined in RFC 2246.
TSN	Transient security network. A TSN can form associations with both RSNA capable and pre-RSNA clients.
UDP	User Datagram Protocol. An Internet protocol used to send short messages to other systems. UDP does not provide any reliability or ordering guarantees.
WEP	Wired Equivalent Privacy. The protocol defined in the 802.11-1999 standard to encrypt data on a wireless LAN.
Wireless LAN	In this chapter, the term “wireless LAN” refers to 802.11 wireless local area networks using a radio physical layer.
WLAN	Wireless local area network.
WTP	Wireless termination point. The CAPWAP term for an access point
WPA	Wi-Fi Protected Access. WPA was the first 802.11 wireless security standard from the Wi-Fi Alliance, using the TKIP security mechanism in the RSN standard.
WPA2	Wi-Fi Protected Access v2. WPA2 is the Wi-Fi Alliance’s name for the AES-based CCMP wireless security mechanisms in the RSN standard.
XOR	Exclusive-OR.

34.1 INTRODUCTION. Whether it is referred to as Voice over Internet Protocol (VoIP) or Internet Protocol Telephony (IPT), the digitization of voice messaging has had and will continue to have an impact on society. Voice messaging is part of a shift that some are calling the Unified Messaging System (UMS).¹ Instant messaging, Short Message System (SMS) text messaging to mobile phones, voice communications, video conferencing, email, file sharing, and network presence are already available in applications that are shared by both the home user and large corporations. Users are empowered by freeing our communications from geographically stationary limits. For example, users can decide to work from home and have their office telephones ring into their laptops. Colleagues can view each other's computer screens from anywhere in the world with Internet access.

34 · 2 SECURING VoIP

Skype, for example, reported about 50 million concurrent online users at the time of writing in mid-January 2013—a phenomenal growth in participation in a UMS created in 2003 (about 590 percent per year over a decade).²

Aside from convenience and capability, there are also great financial justifications for VoIP/UMS systems. They replace formerly expensive equipment with common microcomputers, resulting in substantial savings. Some individuals and small offices are finding that they no longer need to buy landline phones: mobile phones and VoIP software with excellent wireless headsets or earpieces are even better than traditional landline units. An August 2012 report indicated that “New York state has seen a 55% drop in landline phones over the past decade. Some estimate that landlines will be completely obsolete by 2025” and argued that VoIP was “probably the most widely used landline alternative, especially among businesses.”³ By December 2012, U.S. Government reports indicated that more than half of U.S. residents did not have or use landlines in their homes.⁴ Offices are turning to VoIP in the form of Hosted Private Branch Exchanges (PBX) to replace conventional landline PBXs.⁵

Just as there are security issues with our current operating systems and applications, the popularity of VoIP has already drawn the attention of criminals. Most disturbing of all is that many current exploits can be used against VoIP.

34.2 REGULATORY COMPLIANCE. Since VoIP affects key areas of an organization, such as systems, applications, privacy, networks, transmissions, and end users, VoIP must be included in all systematic risk analysis and compliance verification.

Among other U.S. laws, the Gramm-Leach-Bliley (GLB), Sarbanes-Oxley (SOX), and Health Insurance Portability and Accountability Act (HIPAA) are particularly significant in any evaluation of VoIP implementation.

For more information on GLB and SOX, see Chapter 64 in this *Handbook*. For more information about HIPAA, see Chapter 71.

34.2.1 Enhanced 911. Enhanced 911 (E911) mandates a location technology advanced by the Federal Communications Commission (FCC) that enables mobile or cellular phones to process 911 emergency calls and enable emergency services to locate the geographic position of the caller. According to the FCC’s Website:

The FCC has divided its wireless E9-1-1 program into two parts—Phase I and Phase II. Under Phase I, the FCC requires carriers, within six months of a valid request by a local Public Safety Answering Point (PSAP), to provide the PSAP with the telephone number of the originator of a wireless 9-1-1 call and the location of the cell site or base station transmitting the call.

Under Phase II, the FCC requires wireless carriers, within six months of a valid request by a PSAP, to begin providing information that is more precise to PSAPs, specifically, the latitude and longitude of the caller. This information must meet FCC accuracy standards, generally to within 50 to 300 meters, depending on the type of technology used. The deployment of E9-1-1 requires the development of new technologies and upgrades to local 9-1-1 PSAPs, as well as coordination among public safety agencies, wireless carriers, technology vendors, equipment manufacturers, and local wireline carriers.

In a simple solution, a VoIP provider takes the stored location information, passes that through its own call center, and routes it to the local 911. In a more sophisticated solution, some gateways can map MAC addresses to locations, and the 911 calls then can be passed to a PSAP.

Currently, E911 is not required for companies that are using VoIP for internal purposes only. This law is empowered by the FCC, but the Department of Homeland

Security (DHS) and the Federal Bureau of Investigation (FBI) appear to want it for surveillance and location tracking.

34.2.2 Communications Assistance for Law Enforcement Act (CALEA).

Electronic surveillance consists of either the interception of call content (commonly referred to as wiretaps) or the interception of call-identifying information (commonly referred to as dialed-number extraction) through the use of pen registers and trap and trace devices.⁶

The standards for surveillance of VoIP networks have been a joint effort of industry and law enforcement for some time.

In 2007, the Packet Technologies and Systems Committee (PTSC) published the *Lawfully Authorized Electronic Surveillance (LAES) for Voice over Packet Technologies in Wireline Telecommunications Networks*, Version 2 (Revision of T1.678-2004), which is a surveillance standard for basic VoIP.⁷

A key part of the U.S. Federal Communications Assistance for Law Enforcement Act (CALEA) enforcement and debate is determining who is responsible for compliance. According to the law, “all entities engaged in the transmission or switching of wire or electronic communications as a common carrier for hire.”⁸ However, a question arises when an organization builds its own VoIP solution; that is, does the organization then become a *telecommunications carrier* subject to the law? It would seem so, according to CALEA:

[A] person or entity engaged in providing wire or electronic communication switching or transmission service to the extent that the Commission finds that such service is a replacement for a substantial portion of the local telephone exchange service and that it is in the public interest to deem such a person or entity to be a telecommunications carrier for purposes of this title.⁹

However, the law specifically excludes “(i) persons or entities insofar as they are engaged in providing information services; and (ii) any class or category of telecommunications carriers that the Commission exempts by rule after consultation with the Attorney General.” Given the ambiguity of this exclusionary language, an organization should seek advice from appropriate legal counsel prior to creating its own VoIP network.

34.2.3 State Laws and Regulations. All states have laws concerning surveillance; 31 states specifically address computers and 14 refer to cell phones. Because a detailed discussion of this diverse environment is beyond the scope of this text, an organization should seek appropriate legal counsel not only concerning the state it is domiciled in, but also the states of any branches, divisions, subsidiaries, or affiliates. The National Conference of State Legislators provides links to the applicable laws of each state and a summary of the coverage (e.g., cell phones, computers, video, photos, etc.).¹⁰

34.2.4 International Laws and Considerations. Similar to the diversity in the United States, many countries have laws concerning surveillance and intercepts. As such, appropriate legal guidance and advice should be sought before installing or using VoIP networks in international locations. In particular, standards such as ISO/IEC 27002:2005 and privacy laws may be applicable, and may affect VoIP implementation and usage.¹¹

34.3 TECHNICAL ASPECTS OF VoIP SECURITY. The next section is designed to provide a technical overview of VoIP and related security issues. It starts with an

34 · 4 SECURING VoIP

introduction to the protocols used and then progresses to associated threats. Following that is a discussion of best practices and then encryption.

34.3.1 Protocol Basics

34.3.1.1 Audio Stream Protocols: RTP and UDP. Real-time Transport Protocol (RTP) is the packet-based communication protocol that provides the base for virtually all VoIP architectures. Part of RTP is timing and packet sequence information that can be used to reconstruct audio streams. Like TCP, User Datagram Protocol (UDP) is a layer 4 network communication protocol. Both of these protocols provide the basic packet addressing needed to get from one network address to another. When dealing with VoIP, packet delivery time is of the essence. Both TCP and UDP add overhead to the organization's network communication. This overhead results in greater time delays to the communication. UDP adds less overhead as it provides comparatively little packet error checking. The compromise is that UDP will help deliver packets quicker but will also result in more lost packets. It has been observed that a packet loss of 10 percent spread over a VoIP call may be virtually undetectable to most users. However, all of the features that can make VoIP secure also add latency. Added latency means more lost or discarded packets, which then results in an unpleasant or unacceptable user experience. In the end, a slow packet is a lost packet.

34.3.1.2 Signaling Protocols: SIP and H.323. Session Initiation Protocol (SIP) is a protocol that is used to establish interactive multimedia sessions between users. In addition to VoIP, it is also used for video conferencing and online gaming. SIP appears to be the most commonly accepted form of establishing VoIP calls. Secure SIP (SSIP) is discussed in Section 34.5.1. Like SIP, H.323 can be used for video conferencing or VoIP call setup. While SIP appears to be the standard for new installations. One may find H.323 in use at enterprise scale installations that have large investments in older, analog communication equipment.

Briefly, the basics of a VoIP call include these details. A VoIP client application, whether on a personal computer or a dedicated handset, uses SIP or H.323 to set up the call. This call setup is an exchange of control parameters that may include encryption and compression algorithms to be used. This is called "signaling." Once the call is set up, the VoIP client uses RTP to start packetizing the voice data. The RTP packets are incorporated into a UDP packet that adds addressing and sequencing information. The UDP packets are collected and sorted by sequence number at the receiving station. Some systems use a "jitter buffer" to assemble and store the packets. The endpoint VoIP client then reads the jitter buffer and turns the RTP packets back into voice.

34.3.2 VoIP Threats. Although not an exhaustive list, these hacks represent some of the vulnerabilities likely to be encountered when using VoIP:

- SPam over Internet Telephony (SPIT)
- Eavesdropping
- Theft of service
- Man-in-the-middle attacks

34.3.2.1 SPIT. Most users have become accustomed to finding 10 or 20 (or 100 or 200) spam email messages in an inbox on daily basis. The thought of receiving an equal number of voicemails on a daily basis leads to the unappetizing acronym

SPam over Internet Telephony (SPIT). Would-be SPIT spammers may have been both encouraged and then disheartened when, in 2004, Qovia,

a company that sells enterprise tools for VoIP monitoring and management, ... applied for a patent on technology to broadcast messages via VoIP—and another one for a method of blocking such broadcasts. The broadcast methodology only works on a pure VoIP network, while most of today's services are hybrids of IP and traditional telephone lines.

The author explains that Qovia realized that broadcasting VoIP messages could be useful for agencies such as Homeland Security but could also be abused by spammers. Therefore, Qovia pledged to “incorporate its SPIT-blocking technology in future releases of its security products, while enforcement of its patent on broadcasting, if granted, could be used to shut down VoIP spammers.”¹²

Sam Rozenfeld, writing in March 2012, summarized some of the measures being used to interfere with SPIT.¹³

- VoIP providers can collaborate with business clients to use network firewalls to block inbound SPIT using blacklisting of sources known to the provider as large-scale SPIT senders.
- It may be possible for the VoIP provider to identify robocalls—automated large-scale SPIT floods—and block them.
- Authenticating the presence of a human being before allowing the caller to complete a call can block SPIT.
- Blacklisting specific individual numbers can help individual users suffering repeated messages from the same sources.
- Since some SPIT sources use area codes from which no legitimate traffic would normally occur, blocking entire area codes may work.
- Whitelisting might work for individuals who know exactly who should be using their phone number, but it is unlikely to be acceptable for businesses who must accept calls from potential customers.

34.3.2.2 Eavesdropping. In an unsecured VoIP environment, eavesdropping is reduced to a task that is quite straightforward. Earlier, it was mentioned that RTP is the de facto protocol for VoIP communication. RTP adds unique sequencing information to its packets. Because of this, one could collect a number of RTP packets and then assemble them in a consecutive order, as a receiving station would collect these packets in a jitter buffer.

Knowing this, the first step in eavesdropping is to obtain a packet-sniffing tool, such as Ethereal from www.wireshark.org. One may then use Ethereal to perform a packet capture, or one may obtain sample capture files from the Ethereal Website. If the user chooses to perform packet capture, care must be exercised not to violate any privacy laws applicable to the user's network. Once obtained, Ethereal is used to sort out any RTP packets. Exhibit 34.1 depicts a packet capture filtered to show RTP packets. Notice that the first column at the left contains a list of sequential numbers. These numbers indicate the packet placement within the capture. However, farther to the right is the actual conversation sequence number. Once the RTP packets are assembled by sequence number, they can be saved as an “.au” file, which can be played on most computers. As shown with this example, eavesdropping on unencrypted VoIP traffic is not a complicated or expensive process.

EXHIBIT 34.1 Packet Capture Showing RTP Packets

34.3.2.3 Theft of Service. One of the classic theft-of-service attacks that has occurred was reported in June 2006. In this case, a brute-force attack yielded special access codes allowing attackers entry into the provider network. Once in, the attackers obtained router passwords and login credentials; they then programmed the network transport devices to implicitly accept and route VoIP messages from the attackers' server. The attackers then sold VoIP access to public providers, who then sold it to the public. In the end, 15 exploited companies were left to pay the bill for the calls that were routed out of their network.¹⁴

An organization's own employees could exploit its VoIP infrastructure as these attackers did.

34.3.2.4 Man-in-the-Middle Attacks. As with any technology that digitizes communications, VoIP that sends data without encryption is inherently open to manipulation if an attacker can intercept traffic, alter its content, and send it on its way to the recipient in a classic man-in-the-middle (MITM) attack.¹⁵ Once an attacker has control of VoIP traffic, the attacker can not only eavesdrop but can also:

- Initiate calls to a third party and impersonate a caller by sending data that appear to come from a legitimate phone belonging to someone else
- Deflect calls to the wrong destination
- Intercept traffic in real time and generate simulated voice content to create misleading impressions or cause operational errors

This last point warrants expansion. An eavesdropper could collect the digital patterns corresponding to words or phonemes generated by a particular user during normal conversation. Using simple programs, it would be possible to generate data streams corresponding to any spoken sequence including those words or phonemes in real time, allowing the MITM to feed the recipient (or even both sides of a conversation) with distorted or invented information and responses. The potential for mayhem is enormous, especially if the conversation involved, say, emergency response.

34.4 PROTECTING THE INFRASTRUCTURE. This section focuses entirely on VoIP networks. For general information on infrastructure protection, see Chapters 22 and 23 in this *Handbook*.

34.4.1 Real-Time Antivirus Scanning. Protecting the VoIP infrastructure would appear to be a routine decision. Remember that as with VoIP, a slow packet is a lost packet. Many of the routine measures used to protect a typical server will introduce latency into the voice system, leading to jitter and sporadic communication. One of the first routine measures to be sacrificed is real-time antivirus protection of the VoIP server. Some vendors will suggest that real-time scanning of the organization's entire VoIP server is next to impossible, and unsupportable. This is an unacceptable myth. The VoIP server must be scanned in a fashion that is at least consistent with other production servers. Requests from system administrators asking to disable real-time scanning is a common first step in creating issues with the VoIP system.

34.4.2 Application Layer Gateways and Firewalls. An organization's VoIP infrastructure is much more than a series of systems that are digitizing voice and forwarding packets. Its servers will have real-time contact with email servers and central authentication systems using Remote Authentication Dial-in User Service (RADIUS) or perhaps Active Directory. It may also have database systems devoted to logging call information or even recording the calls themselves. An attacker who gains access to part of the organization's VoIP infrastructure may be able to access the most sensitive parts of its network. Consider the use of application layer gateways (ALGs) or SIP/VoIP-aware firewalls to segregate the VoIP systems.

34.4.3 Logical Separation of Voice and Data. It would be ideal to have a separate network for the organization's VoIP system. Bandwidth issues would be minimized and troubleshooting simplified. In most instances, it may not be possible to make a business case justifying the installation of a separate set of cables and network gear. The VoIP handset on the user's desk or the VoIP softphone in the user's PC will share the same wire as the workstation. The logical separation of voice and data begins with assigning the organization's VoIP devices to a network subnet separate from the data devices. This is initiated by a Dynamic Host Configuration Protocol (DHCP) request from the user's handset. Part of this request allows the DHCP servers to distribute addresses based on hardware identification parameters. For example, connecting a laptop to the organization's network will result in the assignment of an address that is on a subnet different from the Cisco handset that is plugged into the same connection. This logical separation of voice and data allows the organization's firewalls to protect its VoIP infrastructure by screening out protocols and requests that are not voice related.

34.4.4 Quality of Service. The term "quality of service" (QOS) refers to a set of configurable parameters that can be used to control and/or prioritize communication through the network. Again, with respect to VoIP, a slow packet is a lost packet. QOS can be used to prioritize the VoIP packets so they can be delivered in a timely fashion. Most vendors will provide a choice of default QOS configurations to be used according to the organization's needs. Some even provide VoIP firewalls that are capable of buffering VoIP messages and retransmitting packets. Regarding QOS, it is not just one parameter that can be turned on to make the VoIP installation work properly; it is a series of parameters that may need to be tuned to fit the organization's exact needs. For more technical detail, see IEEE standards 802.1p and 802.1q.

34.4.5 Network Monitoring Tools. Best practices require a dedicated security operation center (SOC) watching the organization's networks for attacks. Whether

34 · 8 SECURING VoIP

it is a 7 × 24 SOC or just one network administrator who does everything, it is absolutely critical to provide the tools and training necessary to detect attacks and to troubleshoot performance issues. With VoIP, the staff will be facing attacks using a new set of attack vectors and protocols. If the network administration is outsourced, review of existing service-level agreements to guarantee that the provider is capable of supporting VoIP is strongly recommended.

34.4.6 Device Authentication. Device authentication can be accomplished in a variety of ways. The simplest is to store a list of device MAC addresses on the organization's VoIP server and to authenticate all SIP requests through that list of addresses. The standard is to deploy devices to desktops without configuration. Upon connection, a technician enters a setup utility that connects to the VoIP server and then downloads a preconfigured image.

34.4.7 User Authentication. The organization's finance people likely will demand some type of call tracking and usage so departments can be charged or reviewed appropriately. Users can also be placed into different groups that the organization can configure. This group-level access can be used to limit services, such as long distance or international calling. It is common for a VoIP infrastructure to have ties to a central authentication server, such as Lightweight Directory Access Protocol (LDAP) or Active Directory. This central authentication will ease functions such as forwarding voicemail to a personal computer or cell phone. There are two common problems to watch for:

1. The *authentication interval* will be set by user. The organization can configure a demand for authentication to be hours, days, or months; 24 hours is suggested. Some users complain, and demand that their central credentials be stored in the handset for months so they only need to log in infrequently; this practice is generally undesirable.
2. Most handsets will come with *default accounts and passwords*. These accounts must be disabled or, at the least, strong password discipline must be maintained over them.

34.4.8 Network Address Translation and NAT-Traversal. Network address translation (NAT) is a technique commonly used by firewalls and routers to allow multiple devices on an internal network to share one IP address on the Internet. A user's internal address should be known only to systems on that user's own network. When connecting to an external network, the organization's router or firewall forwards the user's communication to an external address but replaces the user's private address with its public address. When the communication is returned, the firewall routes the message back to the correct private address. Similarly, consider the broadband router in a home. The user may connect a series of systems to this device, each with a unique internal address distributed by the router, but the ISP sees it as only one address. These internal or private addresses are stored in what is commonly called a "translation table." At a higher level, the process of getting a packet through a NAT device is called NAT-Traversal (NAT-T). Understanding how NAT-T issues affect VoIP is vital to understanding the danger of sending a voice call to the Internet.

Section 34.3.1.2 outlined how SIP is commonly used to set up a call. Once the call is set up, the actual audio stream typically is relayed via RTP/UDP. This is where

the issues start. The firewall does not have a problem with passing SIP traffic back and forth to the Internet, as the internal address of the VoIP device is stored in the translation table. However, the SIP signaling has passed on the private address of the user's VoIP device. This means that a device outside of the local network is trying to send the RTP/UDP audio stream to a fictional IP address. Essentially, NAT prevents VoIP from functioning.

Several work-arounds are commonly used. Sometimes the NAT device can be configured to provide VoIP support. Sometimes VoIP devices can be configured to work over otherwise open ports, overloading a common protocol such as HTTP, unfortunately, often with unintended side effects. Or VoIP proxy servers can be used on either side of the NAT in order to facilitate the traversal. Each of these solutions opens up its own security concerns, which should be carefully addressed; these concerns include the consequences of external proxy servers or creating anomalous traffic over other protocols, as in the overloading example.

34.5 ENCRYPTION. Encryption plays a critical role in communications security. For a general introduction to encryption, see Chapter 7 in this *Handbook*; for more details of public key encryption, see Chapter 37.

34.5.1 Secure SIP. Transport Layer Security (TLS) was sponsored by the Internet Engineering Task Force (IETF) to secure and encrypt data communications crossing public networks. It is intended to replace Secure Sockets Layer (SSL) as a widely accepted form of securing data communication. This protocol consists of a “handshake” and a “record.” TLS was designed to be application independent so developers could choose their own way of initiating a TLS session.

Secure SIP is a mechanism designed to send SIP signaling messages over an encrypted TLS channel. A SSIP session is initiated by a SIP client contacting a SIP proxy and requesting a TLS session. The proxy returns a certificate that the SIP client then authenticates. The client and proxy then exchange encryption keys for the session. If the call is destined for another network segment, the SIP proxy will contact that segment and negotiate a sequential TLS session, so the SIP message is protected by TLS the entire time.

34.5.2 Secure Real-Time Protocol. Secure Real-Time Protocol (SRTP) is an enhancement of RTP that provides encryption, authentication, and integrity to the VoIP audio stream. The Advanced Encryption Standard (AES) originally was a block cipher; SRTP incorporates AES into the data stream with an implementation that utilizes it as a stream cipher.

Encryption is good but it does not protect the user or organization against replay attacks. SRTP uses a Hashed Message Authentication Code (HMAC-SHA1) algorithm to provide authentication and integrity checks. The MAC is calculated using a cryptographic hashing function in conjunction with a private key. SRTP uses one of the five Secure Hash Algorithms (SHA) designed by the National Security Agency. All five of these algorithms are compliant with requirements set in the Federal Information Processing Standards (FIPS).

34.5.3 Session Border Control. To this point, a number of issues affecting a VoIP deployment have been identified. Session border control (SBC) is a set of services that address VoIP issues related to security, QOS, NAT traversal, and network

interoperability. SBC collects real-time bandwidth statistics that can be used to allocate the network resources necessary to maintain the QOS desired. SBC will also support a number of NAT-T algorithms that will allow calls to be routed to public networks while maintaining the anonymity of internal resources. At the same time, SBC can accommodate both SIP and H.323. This allows the signaling protocol translation necessary to connect both types of networks.

34.6 CONCLUDING REMARKS. VoIP provides expanded functionality and lower costs for corporate users, but managers must integrate security considerations into the architecture and implementation of all such systems to prevent interception, deception, and denial-of-service attacks. In addition, technologists must monitor developments in this rapidly changing field to keep abreast of new attack methodologies and countermeasures.

35.1 INTRODUCTION. Peer-to-peer (P2P) communications, instant messaging (IM), short message service (SMS), and collaboration tools must be directly addressed in any comprehensive security plan. The dangers are real, as is the probability that at least one of these technologies is in use in almost every organization.

35.2 GENERAL CONCEPTS AND DEFINITIONS. This chapter is designed to present enough information and resources to aid in integrating the defense of each function into the organization's security plan. A list of resources is provided at the end of the chapter to aid in further research.

35 · 2 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

35.2.1 Peer to Peer. Peer-to-peer networking, also referred to as P2P, is not a new concept or technology. The term was contained in some of the original designs and proposals for the Internet as an efficient and logical way to exchange information from one resource, or peer, to another, on a large interconnected network. Today, the term is most associated with applications that transfer multimedia files across the Internet.

Peer-to-peer networks generally consist of different computers, or nodes, that communicate directly with each other, often with little, if any, need for a central computer to control the activity. Often utilizing an application with a client-server appearance, the two computers set up a direct connection between each other for file transfer. A central indexing computer may or may not be needed to help these computers “find” each other, to index and publish their contents, or to facilitate the connection. However, what is most important, the two computers must have a direct, logical connection to transfer the file or files. File transport may take place over a local network (LAN), a wide area network (WAN), a value-added network (VAN), or via the Internet.

Peer-to-peer technologies and applications were much more common in the early days of networking when it was not financially possible for many organizations to have expensive servers and complicated network topologies. This is especially true of personal computer networks that performed simple file sharing from computer to computer in a one-to-one model instead of today’s much more common one-to-many server-to-client setup. However, there are legitimate uses for peer-to-peer technologies. One common example is the sharing of Linux distribution software images. Peer-to-peer sharing of these often large ISO disk images requires much fewer resources for the distributor, because there may be thousands of computers distributing the software among themselves, instead of every user trying to download the file from a single server.

35.2.2 Instant Messaging. Instant messaging, or IM, has become one of the most widely used communication mediums and is on pace to overtake email as the preferred technology to communicate with others. This tool allows users to communicate with each other in a real-time, synchronous, instantaneous fashion via computer, tablet, or mobile device. Today’s IM applications are nowhere near the first generation of IM. The concept of communicating, or chatting, in real time made its appearance on multiuser computer systems, when users could initiate a text-based conversation with each other. The most common example of this type of communication was a host-based system such as a mainframe environment or UNIX system using programs like *talk* or *ytalk*. Initially, users may have been restricted to messaging each other when logged into the same machine; eventually users were able to communicate with each other, either via Internet Relay Chat (IRC) or via an early online service like America Online. The first widespread uses of IM were made possible with the popularity of the PC with a modem and were used mainly for brief, informal, personal conversations.

With time, IM has become a business tool and, in some organizations, a necessity, especially with telecommuters. The need to communicate with colleagues, salespeople, clients, customers, and the like has transformed a gimmick technology into ubiquity. With this change, it is necessary for security management to change and adapt accordingly. Users are able to send messages, files, real-time streaming video and audio, utilize collaborative online whiteboards, and share desktops, almost instantly. Essential to the organization or not, IM can become a dangerous medium for security breaches.

35.2.3 Short Message Service. Short message service, or more commonly SMS, is another previously minor technology that has become ubiquitous and a large part of everyday life for many people. Although some mobile phone standards and companies had different ideas for the uses of SMS, a common early use was to notify customers of information one way, from the mobile phone provider to the user. A popular example was alerting the user of a missed call or voicemail message. Many carriers never dreamed customers would actually be able to send text messages from one mobile phone to another, nor did the carriers think users would ever *want* to do such a thing. The name, short message service, also implied a limited amount of text a message could contain. Originally, users were limited to 160 characters or less.

SMS has morphed into something much larger. The commonality of mobile phones has pushed the original concept far beyond its original meaning and function. Today, two-way communication between mobile phone customers, often on different mobile phone carrier networks, between customers and mobile phone providers, and between customers and other information systems has become a way of life. Customers expect instant, always-on, reliable SMS services. Most mobile phones are capable of SMS text messages, taking and sending pictures, instant alerts, and a number of other services that utilize or expand on the original concept of short message service.

35.2.4 Collaboration Tools. People working together have created a need for even more technology to aid them in completing their tasks. There are many products in today's market to facilitate sharing, collaboration, and organization of data. As some information security professionals joke, "Computers and technology are generally safe and secure, until you let a human near them." Humans are inevitable when it comes to collaboration tools and systems. Many collaboration tools and systems are designed to aid workgroups that are physically far apart. Once a system has requirements that contain the words "open," "via the Internet," or "access from anywhere," information security professionals cringe. Securing collaboration tools can be difficult, especially when it comes to balancing functionality versus security. A handbook would not be complete if the cloud were omitted, which is precisely where most of the current collaboration tools reside, including their data. These tools are also creating a tug-of-war between users and security professionals—users want to use these tools; security pros worry about the consequences.

File-sharing services such as Dropbox and Google Docs have put effort into securing the data stored and shared by individuals and groups. For example, Dropbox answers the question "How secure is Dropbox?" as follows:

We have a dedicated security team using the best tools and engineering practices available to build and maintain Dropbox, and you can rest assured that we've implemented multiple levels of security to protect and back up your files. You can also take advantage of two-step verification, a login authentication feature which you can enable to add another layer of security to your account.

Other Dropbox users can't see your files in Dropbox unless you deliberately share links to files or share folders. Dropbox employees are prohibited from viewing the content of files you store in your account. Employees may access file metadata (e.g., file names and locations) when they have a legitimate reason, like providing technical support. Like most online services, we have a small number of employees who must be able to access user data for the reasons stated in our privacy policy (e.g., when legally required to do so). But that's the rare exception, not the rule. We have strict policy and technical access controls that prohibit employee access except in these rare circumstances. In addition, we employ a number of physical, technical, and heuristic security measures to protect user information from unauthorized access.¹

35 · 4 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

Nonetheless, there are serious security concerns about cloud-based file-sharing tools and Dropbox in particular. At a Black Hat EU conference in 2013, the paper “DropSmack: How cloud synchronization services render your corporate firewall worthless” caught the eye of writer Michael Kassner. The paper summary included the following points:

- “... [C]loud-based synchronization solutions in general, and Dropbox in particular, can be used as a vector for delivering malware to an internal network.”
- “... Dropbox synchronization service can be used as a Command and Control (C2) channel.”
- “... [F]unctioning malware is able to use Dropbox to smuggle out data from exploited remote computers.”

The paper’s author, experienced penetration-tester Jacob Williams, warned that if a bad actor has any access to a secured Dropbox folder, it is possible to synchronize a remote-access Trojan he wrote called DropSmack with all the shared Dropbox folders. The tool would allow the infiltration of the entire corporate network. Williams also warned that access to a Dropbox folder by employees using their personal computers raises legal issues:

Many general counsels are more than a little worried about the appearance of authorizing us to pen test what could end up being be home machines. That’s becoming a sticky issue with pen-testers these days as people open spear phishing emails delivered to the corporate email addresses on machines that may be privately owned.²

Integrated collaboration tools have another danger, especially for inexperienced users who don’t take daily backups: deleting one or more files (or all of them) in a shared Dropbox folder will propagate the deletion to all users of the shared folder. If any one of the users keeps a daily backup, the entire group of users can be protected against disaster; if none of them do, they may be in serious difficulty. In a related issue, any user who moves the files out of the Dropbox folder into a local folder will wipe the data from all the other users’ Dropbox folders too.³

In a 2012 article, Matthew J. Schwartz urged corporate users to pay attention to Dropbox use among their employees. His five recommendations (with more details in the original article) are:

1. Monitor Dropbox use
2. Compare cloud service security
3. Beware lackluster security cloud practices
4. Treat Dropbox as a public repository
5. Beware insider data exfiltration⁴

A free tool, Cloudfogger, automatically encrypts data on the client side when it is uploaded to any external collaboration tool using 256-bit AES encryption. The tool then automatically decrypts the data when it is downloaded by an authorized user.⁵

35.3 PEER-TO-PEER NETWORKS. One of the earliest mass applications of P2P was for free file-sharing of music through Napster, LLC. Despite difficulties over copyrights and a subsequent bankruptcy, Napster’s technology, in substantially the same form, is still in widespread use. Practical applications have expanded beyond music

downloads into the business world, such as allowing small groups of users to share files without the interaction of a systems administrator and distribution of open source software. Likewise, it may be possible that employees are utilizing the organization's high-speed Internet connection to supplement their at-home movie collection via P2P downloads.

35.3.1 Dangers to the Business. Using P2P technology without proper care and controls, an organization may face serious consequences. There are many threats to an organization that does not properly control P2P networking, as for any other network configuration or protocol. Many problems are discussed in Chapters 21, 25, and 26 in this *Handbook*. However, this section contains several important issues that information security management should consider while performing risk analysis and policy implementation for P2P networking.

35.3.1.1 Abusing Company Resources and Illegal Content. Organizations must have an acceptable usage policy in place, one that limits what employees can do with the technology resources provided to them. The policy should clearly state the kinds of technology and applications that are prohibited or restricted in specific ways. In most cases, P2P technology used to download music or videos for personal use will violate the policy.

P2P technology is a specific danger to company technology resources because the inherent nature of P2P technology is to use every resource to the maximum extent possible. For example, a single P2P application, configured properly, will use every bit of bandwidth that is made available to it. This would include LAN bandwidth, WAN bandwidth, and Internet bandwidth. One of the most popular uses for P2P technology still remains the sharing of extremely large files, especially multimedia files, including full-length movies. These large files can take hours to download in full. This fact can have an extremely negative impact on an organization's network infrastructure—including expensive Internet bandwidth.

In practice, a single P2P application has been demonstrated to completely saturate a 12-megabit Internet connection, virtually denying, or severely limiting, access to all other computers.⁶ In this case, these dangers to the business are common to many areas of information security management:

- Threat to **availability**. If an organization's resources, including network resources, are not available, the business cannot properly function.
- Threat to **integrity**. If the organization's resources are crippled or misused by employees utilizing P2P technology, data may suffer from a breakdown of integrity and usability.
- Threat to the **organization's image**. If the organization's information systems and infrastructure cannot be relied on because of interruptions from P2P abuses, there is a risk of financial or public image degradation. Some organizations are not able to overcome a substantial loss of image, credibility, or both.
- Threat from **litigation**. It is common to see illegal content being shared via P2P technology; illegal music and video sharing is often credited with having made P2P technology popular. An organization may suffer legal troubles, including copyright and intellectual property suits, if its resources are involved with the sharing of illegal materials. Some anti-piracy groups have become extremely aggressive in combating illegal sharing of copyrighted content.

35 · 6 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

35.3.1.2 Loss of Confidentiality. There are many ways an organization may suffer a loss of confidentiality from P2P technology. One common mistake is a misconfigured P2P application. The case study in Section 35.3.4 describes one situation. However, the dangers of a misconfigured P2P application are real—it is quite easy for data to be shared inadvertently. When users are in a hurry or do not understand what they are doing, a P2P application may allow for unauthorized access to information because its restrictions are too lax or missing altogether. A common mistake in a Microsoft Windows environment may be to share the entire “My Documents” folder when a user intended to share only photos. A misconfigured or maliciously altered P2P application may also become a conduit or access point for an attacker to enter an otherwise secure network environment.

Another, less well-known and often overlooked threat involves the amount of data a P2P application can reveal to unauthorized persons. For example, a P2P application may offer detailed information about its host, including:

- Operating system, version, and configuration
- Corporate network address scheme, host naming convention, DNS information
- Detail about the P2P application version or build (useful for attackers to exploit known vulnerabilities in a “buggy” release or version)
- Network routes, privileged access from a certain PC to sensitive networks within the organization (behind a firewall, etc.)
- Open network ports in the organization’s firewall

Although many of these examples may seem rather benign by themselves, the P2P application may be revealing information that an attacker can use as part of a bigger attack. Chapter 19 of this *Handbook* details how small pieces of information can be gathered and used together in an information security breach. The nature and functionality of P2P applications leaks sensitive information that otherwise would not be revealed.

All P2P applications are not created equal; a P2P application may be different from the user’s expectations. Can the P2P application actually be a reliable, malware-free, secure application—especially when the application is a free download from the Internet? It is possible that a backdoor exploit, malware, spyware, or the like may be built into the P2P application, or introduced later. This was especially true in the days of Napster; many applications included unwanted malware that ranged from innocent to downright dangerous.⁷ Similar exploits are still possible.

Many users still do not completely understand the application’s functionality. What may start out as a user trying to download a single movie can turn into an application that never gets uninstalled and is always running, uploading, or “seeding” that single movie for weeks or months on end. Since many of these applications are built to silently operate in the background, the user may think that the movie is downloaded, and the application isn’t used any longer, when in reality, it is still running until it is removed. This is not only a waste of resources, but a likely way to expose the organization to a DMCA (Digital Millennium Copyright Act) complaint from the organization that owns the intellectual property.

35.3.1.3 Consequences. Any organization that does not protect against data loss via P2P networking is at great risk of public disclosure and scrutiny, financial

penalties, regulatory penalties, and so on. The functionality and nature of P2P applications may provide an investigator or, worse yet, the press with definitive evidence of the use of P2P technology within an organization. (It is easy to discover an organization that has users utilizing P2P applications because there are several online databases of IP addresses recorded while participating in a P2P “hive.”) A majority of the public may only understand P2P technologies to be used in conjunction with illegal music sharing; even this simple, negative perception can greatly influence public opinion on the organization. It would be difficult to refute packet analysis or screen shots containing an organization’s IP address in which the computer was compromised, used for illegal software or media sharing, or the computer was used by an unauthorized entity to extract data. In the age of P2P applications commonly used to illegally share and distribute the intellectual property of unwilling participants, organizations are taking aggressive steps to find and prosecute offenders. See Chapter 55 in this *Handbook* for a discussion of cyber investigations; see Chapter 61 for guidance on working with law enforcement.

35.3.2 Prevention and Mitigation. Protecting the organization from information security breaches via P2P technologies is one of many important parts to an overall security plan. Depending on an organization’s structure, leadership, function, and similar factors, methods for preventing and mitigating P2P threats can range from simple to complicated. Obviously, each organization must perform a risk analysis and determine its threat threshold when it comes to P2P technology. Chapter 62 provides means for risk assessment. The guidelines that follow can help an organization defend against the threat of P2P technology causing security breaches.

35.3.2.1 Policy. It is important for every organization to address the use of P2P technology in a policy, such as an acceptable use policy, HR policies, or security policies. The relevant policy, along with all other security-related policies, should be clearly stated, clearly communicated to the entire organization, uniformly and equally enforced, and updated as necessary.

35.3.2.2 Complete Ban on Peer-to-Peer Technology. In *most* cases, the organization can ban the use of P2P completely, especially through enforceable policy. Care should be taken to ensure all employees and computers are in compliance with the ban. It should be forbidden or, even better, impossible to install P2P applications on personal computers, servers, and all other information systems that could be used to send and receive P2P-related traffic. Most computer users should be running as a standard user of their computer, not as an administrator. If employees are allowed to install software, or are allowed administrative access to their desktop, regular, automated inventories and audits of the computers should take place. Removal should be immediate and appropriate corrective actions taken.

Several technologies may also aid in disallowing P2P traffic, although no technological solution is completely foolproof. These measures are additional safeguards, not complete solutions. Firewalls should be configured with a default deny policy and should only allow TCP/IP ports to pass that are necessary for normal business operations. While many P2P applications are able to tunnel through TCP/IP ports such as those used by HTTP or other common protocols, this is a necessary first defense. Packet-shaping technologies can also be useful to identify P2P-related traffic and block its communications. Packet-shaping and traffic management devices are often able to detect the signature of P2P traffic, no matter what TCP/IP port the application may

35 · 8 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

be using. Some intrusion-detection and intrusion-prevention systems may also be able to identify and block P2P traffic, as would many Internet filtering devices. Logs and reports should be examined daily and infractions should be quickly remedied. This is also a case where a managed desktop environment is important—automated software install/removal, uniform desktop imaging, and automated software inventory/reporting aids the desktop administrators in the effort of combating P2P software installed against policies.

35.3.2.3 Information Security and Information System Audits. All information systems and components should be audited (both on a schedule and via random audits) to ensure that they are not configured, intentionally or unintentionally, to participate in P2P file sharing. This task should be part of every organization's regular information system and information security audit processes. If possible, external and neutral resources are most useful to ensure all systems are audited in a uniform, exact, repeatable, and objective fashion.

35.3.2.4 Legitimate Business Use Must Be Managed. There are times when an organization does not wish to completely ban or block the use of P2P technologies. One increasingly common and legitimate example for P2P involves open source software distribution or updates via BitTorrent. BitTorrent is a P2P-based protocol for the distribution of data—often large amounts of data. A widespread use includes the distribution of several distributions of the Linux operating system. Installation of Linux often involves obtaining CD-ROM or DVD images to create install discs. By utilizing BitTorrent technology, software vendors and distributors are able to provide large amounts of data to their clients without carrying the entire burden of distribution, bandwidth, and computing resources. However, the organization must manage how this technology is used to ensure resources are not abused and that the P2P applications are used for only allowed, legal ends.

This can be accomplished through policy, auditing, and various network access and control technologies. Each organization must define its own level of acceptable risk for legitimate P2P technology usage and must find solutions that will match the acceptable level. Some examples include:

- Use of encryption
- “Anonymous” P2P routing technologies such as onion routing (see Chapter 31 in this *Handbook*)
- Network isolation for computers used to obtain software with P2P applications
- Company-acquired DSL or cable modem connections to the Internet, avoiding the use of corporate network resources

35.3.3 Response. It is necessary for all organizations to define exactly how to respond to security breaches and policy violations, including situations where P2P technology is involved. Not only should the process be included in the overall security plan, but also incident response processes should be in place to remove offending systems from the network. In some cases, the rebuilding of a compromised resource may be necessary, but some organizations may choose to remove the compromised machine from production and/or preserve a forensic copy of the machine for legal, forensic, or investigative processes.

35.3.4 Case Study. Misconfiguration, unintentional use, curiosity, and experimentation with P2P in the workplace do happen, with consequences. Although this case is only one type of specific security incident involving P2P technology, it should serve as an example of how such a situation can occur.

An employee of one organization reported a slow-running computer to the helpdesk. All of the usual helpdesk suggestions and tricks were exhausted with little effect on the performance of the computer. The usual symptoms of a slow computer were present—massive wait times to accomplish simple tasks, random errors and shutdowns, lockups, and other operational problems. However, there was one difference: After a reboot, it would take several minutes for the computer to slow down and become unresponsive. After some time, an employee commented, “I did try installing a music sharing program last week, but I didn’t like it and uninstalled it.” This led the engineer to examine each and every process that was running on the computer.

Although it appeared that the P2P application had been uninstalled, it actually had not been; it was still installed and running in a stealth mode. The uninstaller only masked the P2P application. Not only was the P2P application still running, but it was misconfigured to share the entire contents of the C: drive. There were literally thousands of other P2P users attached to the machine actively searching, uploading, downloading, and altering the contents of the computer’s hard drive. The computer was not only giving away all of its data, it was being used for a server to host thousands of media files. Since the computer was on a network segment that had full TCP/IP 1-to-1 network address translation, it was effectively completely open to the outside world—and the outside world was taking full advantage of the opportunity. The hard drive was virtually full, and files were being added and deleted at will by remote users. The host’s firewall was even modified by the P2P application’s install to open all necessary ports to the world.

It is unknown if the user’s personal data was actually accessed, downloaded, or used for any malicious activity, but the capability was certainly there. Because of a user’s unauthorized download, inadequate network security, and other policy violations, the organization could not be sure of the confidentiality or integrity of the computer or its data. Necessary steps were taken to prevent this incident from occurring again, but this scenario has played out at other organizations, and will continue to do so as long as the P2P risk exists.

35.4 SECURING INSTANT MESSAGING. Instant messaging has become an integral part of communications—both business and personal—for many people. It was fairly easy in the recent past to simply create a policy that banned IM for personal use and only allow internal, business-related IM within the company. However, IM has become an integral part of life. IM is pervasive in most organizations—for personal and business use. As a result from executives to interns, IM may be found on many desktops, but it must be managed and secured on all.

35.4.1 Dangers to the Business. With any technology, especially those that make connections to the Internet, there is a risk to the organization. Instant messaging is not a petty annoyance that should be taken lightly; if the technology is not controlled by the organization, a serious breach of security could occur. Remember, IM applications today go well beyond just txt; they are capable of transmitting much more than just interpersonal casual banter.

35 · 10 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

35.4.1.1 Loss of Information. Information loss and loss of confidentiality, intentionally or unintentionally, is most likely the biggest threat of IM to the business. There are several ways information can be harmfully conveyed via IM⁸:

- Revealing secrets via text chat, especially when a company has taken extensive effort to filter and block such communication via email with gateways, intellectual property data management, and other technologies
- Copy-and-paste functions (including screen captures) used to transmit confidential or secret information from other secured applications or environments
- File transfers
- Screen sharing and real-time collaboration functions such as shared whiteboards or desktop sharing functions
- Forgetting to turn off a voice or video session and unintentionally relaying sound or images to the original correspondent—especially dangerous when leaving voice mail through the IM client
- Relaying voice, video, or both to another party (unintentional or intentional)
- Use of Webcam technology to relay visual information within a secure facility
- Downloading malware to collect and steal data
- Impersonation (This tactic usually involves stealing a known IM account or creating a fake account to impersonate someone the victim knows.)
- Subpoenas or search warrants executed to collect IM logs, conversations, and so on

Although this is not a complete list, it should serve to aid in security planning and policy development. There are many good resources on the Internet to further explain similar threats and consequences, but the preceding list should encourage thoughtful brainstorming about the ways in which an organization may lose data. Some of the listed methods would be extremely difficult to detect and remedy. With high-speed networks and high-speed Internet links at most organizations, a massive amount of data can be conveyed within a small amount of time.

35.4.1.2 Consequences. Like other security threats, the consequences of not securing IM technology can be serious. Many organizations today have experienced a security breach that involved IM, and there are probably more to come. Instant messaging security breaches can be deadly to an organization by themselves or as part of a much larger attack on the business. Stealing or transmitting information through IM is no less risky than any other form of information theft. One single file, whether sent through an IM file transfer or meticulously cut and pasted, bit by bit over a great period of time, can destroy a company's reputation and standing in the public eye or even benefit a competitor. A breach from a single IM conversation has the potential to depress a corporation's stock price in a matter of hours or days. There have even been cases where a chief executive officer's confidential information was captured and posted on the Internet for all to see.⁹

35.4.1.3 Denial of Service. IM cannot be written off as a tiny application with no real footprint on network resources. Instant messaging can be a tool used to create a denial of service attack on an organization, resulting in a loss of availability. IM

technology can be a powerful and useful tool for an attacker, including the use of IM clients with a direct connection to the Internet. With the right combination of malware and access, an attacker may be able to exploit one of many vulnerabilities discovered in IM applications, including the ever-popular buffer overflow. The National Vulnerability Database listed 38 current vulnerabilities in instant messaging software as of March 2012.¹⁰

35.4.2 Prevention and Mitigation. Every organization must guard against the threats caused by IM technology. Proper review and analysis of the risks associated with IM must be carried out within the organization, and the organization must determine the amount of risk it is willing to take. It is also necessary to evaluate the costs and efforts associated with the prevention and mitigation of this threat. Organizations will judge the risks and rewards of using IM differently. There is no set standard for every organization or business; there is no universal set of rules that can be applied in all situations. (For a discussion of risk assessment and management, see Chapter 62 in this *Handbook*.) The next sections provide strategies, tactics, and considerations for securing IM.

35.4.2.1 Policy. Policy must come first, especially with the popularity and widespread use of IM. Without adequate policies, the organization has no chance of actually protecting itself. Policy must be the foundation that all other considerations rest on. Clearly defined, well-communicated, and equally enforced policy is one of the most important fundamentals information security relies on. No matter what the organization decides when it comes to IM rules, it must be stated in a policy.

Instant messaging, while risky, is one of the most visible policy decisions a business will make for employees. While it might be best, and preferred for best security, to completely disallow IM, which could lead to frustrated employees, unable to use the facility for personal use, business use, or both. Every management team should be conscious of the potential ramifications of an overly strict policy. Conversely, allowing unfettered IM is certainly not the best solution.

Some organizations, depending on their software platform, may be able to provide employees with a managed IM environment where the employee can connect to the organization's official IM platform, as well as some of the popular IM services used for personal communications. At the same time, the organization can centrally deploy settings such as which services are allowed, how they connect (encrypted or not), and what logging options are in use—including if conversations can be recorded or archived.

Compliance and governmental regulations must be taken into consideration. If IM communications are to be allowed, they may become part of the organization's business communications, and therefore may be subject to subpoena, open records requests, and archiving and document retention requirements. This can be especially dangerous if the chosen IM platform is integrated into the organization's voice over IP system. New regulations and legal rules may greatly affect policy decisions. It is important to remember that instant messaging logs and conversations *may* be subject to legal discovery, search, and seizure. Consult counsel for proper legal advice.

35.4.2.2 Effects of a Complete Ban. A ban on all IM technology would be the best way to ensure better enterprise security. However, this will only produce dissatisfied users, without being effective. Users can become technology-savvy in a hurry if they are determined to circumvent a policy. A block on IM communications often

35 · 12 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

causes users to do just about anything they can to accomplish their goal of unobstructed IM. Some clients are designed with this in mind and will happily tunnel out of commonly allowed TCP/IP ports such as 80, usually open for HTTP communications. The software may be configured to bypass firewall rules, detect and avert packet-shaping technology, and tunnel its way to the Internet via encrypted connections. Many IM services also provide Web-only interfaces that do not require software to be installed while communicating via HTTP. Unfortunately, this technology can be a difficult and frustrating one to ban within the organization; a complete ban is probably not a practical solution.

35.4.2.3 Prevent Installation of Instant Messaging Software. Although a complete ban may not be possible, or even desirable, one step that a more secure organization can take is to prevent users from installing IM software. This tactic is not going to solve the whole problem, but it certainly will help. Controlling the installation of IM software should be part of the organization's overall software installation policy. In general, installing software without permission should be denied. If it is feasible, local workstation administrator rights should be denied for most employees. In many user or system management solutions, it is also possible to block software installation through individual, group, or workstation policy templates and procedures. Universal software installation prevention is much easier than trying to define policies or templates for every possible IM peer, application, group, or tool.

35.4.2.4 Fight Technology with Technology. Technology on its own will not provide the organization with an all-in-one solution for securing IM. However, there are a number of network devices, appliances, traffic monitoring software, and other technologies to help an organization minimize IM use. Do not believe marketing claims that any device or technology can guarantee IM blocking; few can deliver on this promise. The only *true* way to guarantee an IM-free company is to block access to the Internet completely—which is not realistic. An organization can also leverage existing security infrastructure such as IDS or IPS.

35.4.2.5 Limit Risk and Exposure. For most organizations, *limiting* IM through policy and technology is the solution to the threats that IM introduces. Combining those two approaches will help to reduce the possibility of data loss. Security managers and administrators should agree on what can and what cannot be allowed within the organization. An organization may choose to block file transfers, Webcam functions, or screen-sharing functions for IM communications. These types of actions will not prevent IM security breaches, but they could limit data loss. As with any policy and risk management, proper audit, reporting, and compliance controls must be in place.

35.4.2.6 Providing Secure Instant Messaging. In environments where IM is needed to run the business, the best strategy is to provide secure, managed IM services to the employees. Of course, the needs will vary among different organizations for different levels of IM connectivity, functions, and software. Many of today's popular corporate email and collaboration systems have built-in or optional IM services. When properly deployed, these IM systems can meet many of these secure IM best practices:

- Encrypt IM communications wherever possible: client to server, server to Internet, and so on.

- Encrypt logs and chat conversations at the workstation and server.
- Ensure that all logs, chat conversations, file transfers, and archives meet data transmission, retention, and destruction policies.
- Ensure that “presence awareness” features (software features that allow the user to communicate his or her presence or availability, such as “online,” “away,” or “out to lunch” to all users) comply with corporate personnel policies.
- Administratively disable features that cannot be encrypted or properly managed (screen sharing, file transfer, whiteboard, etc.).
- Where possible, lock or force configuration settings to ensure policy compliance.
- Establish procedures for periodic monitoring and auditing of IM systems; do not ignore logs.
- Enforce prudent password policies for IM systems.
- Properly secure IM communication systems with Internet connectivity; consider using proxies or intermediary gateways that protect internal corporate IM systems; ensure appropriate server lock-down policies and procedures.

Corporate-owned and -managed IM systems may not be possible in all situations. In those cases, the organization must form policies and procedures to limit risk and exposure with commercial IM systems. Some systems do provide “secure” IM, but one must be skeptical of exactly how much protection they provide. Consider limiting commercial IM needs to nonessential computers with limited network access, limiting or restricting users to specific IM applications or services, and monitoring instant message network traffic and usage. Some commercial IM services also provide “corporate” or “business” IM services, often for a fee. These premium offerings may provide the organization with the necessary or acceptable level of functionality and security. Access to public IM services should also *always* be blocked from machines with privileged access to critical data assets.

35.4.3 Response. Instant messaging breaches and compromised systems generally do not require special handling after a security incident. In general, normal policies and procedures can be followed to properly investigate, document, and respond to security breaches. There are many commercial tools, including forensic software, to aid in incident response. Infected or compromised systems, if no longer needed for investigation should be reimaged before redeployment to an employee; never allow a machine to be “cleaned” from an incident and returned to production.

35.4.4 Safe Messaging. Although most users at the organization are generally satisfied with mainstream IM systems, clients, and services, there are dangers to be considered. There seems to be almost an unlimited number of open source IM clients, Web-based IM and chat providers, social networking Websites providing IM, and the like. When considering policy and management of IM within the organization, it is important to analyze the source and intentions of all of the possible services. All IM software and services are not created equal; some may originate from untrusted sources and may contain malware and other security risks such as password stealers or keyloggers. Instant messaging software or providers may also be remotely logging information without the user’s knowledge or consent.

Also, if the organization will utilize commercial IM software and services, it is critical to carefully examine the provider’s terms of use and license agreements. The

35 · 14 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

responsibilities and liabilities of both parties should be carefully weighed by information security managers, company executives, and legal counsel before allowing use of the software and associated services.

35.5 SECURING SMS. Few technologies are more ubiquitous than SMS. Virtually all mobile phones are capable of sending and receiving SMS communications. Since mobile phones are virtually everywhere, security considerations must be in place to guard against the threats that they present. A technology with a relatively minor footprint can cause a world of destruction when used as a weapon. Today, SMS technology, and its associated complementary services, has grown exponentially. Securing and defending against SMS must be included in every organization's comprehensive security plan.

To understand SMS security, it is also important to look beyond the cell phone. SMS does not require a cell phone to utilize the technology. Many phone carriers allow SMS messages to be generated and sent from an unsecured, public Website. SMS messages may also originate from email messages, instant messaging services, and the like. SMS messages can even come from subscription services such as a daily horoscope or critical systems like emergency notification services. Beyond this, today's mobile phones, including smart phones, are more powerful and contain many more features and show no sign of slowing down. Phones are increasingly gaining processing power, memory, complex operating systems, and other features that essentially could redefine the device as a personal computer. Phones are able to access the Internet, install applications, communicate from phone to phone, and even access corporate data networks. Information security managers and professionals should never underestimate the power or versatility of a mobile phone. They are a threat to all of an organization's information security.

35.5.1 Dangers to the Business. SMS can introduce many types of security threats into an organization. SMS can cause a data breach by innocent mistakes or by deliberate attacks. This technology can be used as a criminal tool to deliberately steal information, to extract data, to extort information, and to deceive. It may also be a conduit for inadvertent data loss. The consequences of data lost via SMS are relatively the same as any other data breach: loss of confidence in the organization, loss of image, bad public relations, financial penalties, and so on. A serious or even minor data breach may appear to communicate to the world that the organization does not have a comprehensive security plan in effect, or the company does not abide by such a plan—whether true or not. Some investors, customers, or people in the general community may look at a breach of such a simple technology and ask, “How could the company not have proper security for something as simple as a cell phone?” A missing laptop with confidential data is a serious security breach, but a mobile phone, with all its capabilities, must be treated as nearly the same type of critical infraction.

35.5.1.1 SMS as a Tool for Deliberate Data Loss. One danger an organization may face involves an individual or group of people utilizing SMS technology to ferry critical data to unauthorized persons, usually outside the organization. This action would replicate an age-old tactic of stealing information piece by piece from within the organization to someone who should not possess the information. Consider classic tricks of criminals, such as copying information in tiny pieces over great amounts of time to avoid causing suspicion. Any number of technologies can be used to move data, including flash or thumb drives, iPods, scraps of paper, photographs, screen printouts,

embedded code, or even memorization. Disgruntled employees may use SMS to send confidential information to an accomplice or even to themselves for later use, such as selling the data, extortion, and the like. It would be virtually impossible to know that an employee is slowly leaking data outside the business from a mobile phone, especially when that phone is not owned or controlled by the organization. What may appear to coworkers as a serious text-messaging addiction may actually be a serious data breach.

Another fact information security management must consider is that SMS service, whether exactly true to the original definition or not, has expanded well beyond messages of only 160 characters. Mobile phone users are able to send real-time video streams, recorded video, photographs, substantially longer text messages beyond 160 characters, Web page links, and just about anything else the phone carriers can implement. If the mobile phone industry considers all of these features to be synonymous with SMS, the organization's security plan should as well. Business risk has increased greatly with every new technology addition.

35.5.1.2 Inadvertent Data Loss via SMS. Data loss can occur by mistake, bad luck, stupidity, misinformed user, or misunderstanding of features as well as by theft of the data device itself. Both deliberate data theft and inadvertent data losses are extremely dangerous, with potentially serious consequences. Search engines reveal many different tactics and war stories of data loss from a mobile phone as well as other SMS-specific security issues. These are scenarios and techniques to consider:

- SMS via email or the Internet
- SMS snooping or sniffing
- Recovery of improperly deleted data
- Stolen, mixed up, or lost phones
- Misdialed numbers
- Wi-Fi connectivity
- Unattended phone with no password
- Malware installed on phone (keyloggers)
- Recipient's phone is lost, stolen, or borrowed
- Impersonation

35.5.2 Prevention and Mitigation. SMS technology is not going to disappear anytime soon, so every organization must come up with a plan to prevent data loss and protect itself from this risk. Once again, the organization's leadership, security management, and security professionals must evaluate the risk of SMS versus the need to operate the business and maintain an amiable group of employees. Every organization must decide for itself exactly what kind of practices to put into place for SMS security and the cost/benefit of each practice. Everything must be considered, from policy and procedures, to deployment of security technologies and mobile phone company-provided services. With today's varying needs, newly emerging technologies and an array of mobile phones, it is difficult for any two organizations to adopt the same prevention and mitigation strategies. However, the next suggestions can be used to begin, update, or enhance the organization's security plan when addressing SMS technology.

35 · 16 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

35.5.2.1 Policy. An SMS policy should be developed for all cell phones that are company owned or company sponsored. The policy, when written on a solid foundation, is key for enforcement by human resources, especially when something may end up in litigation. Vague acceptable use policy will not be enough. A clearly stated position must be written, adopted, and communicated to all employees. The policy should apply to every employee, executive or trainee, with no exceptions. The policy should regularly be reviewed, updated, and redistributed, with recurrent training as necessary, especially in a rapidly changing world such as mobile technology.

A good policy must also address an important distinction common to mobile phone use in the organization: personal phones versus company-provided/sponsored phones. The policy must address: what is acceptable for employee conduct on the job; whether personal phones are allowed on the premises; what type of phone is allowed (usually refers to whether employees are allowed to have smartphones); where, when, and for what purposes can they use personal mobile phones; what is allowed on business-provided phones; and the like.

35.5.2.2 Mobile Phone Ban. In some cases, security needs may necessitate prohibiting the use or even possession of mobile phones on company grounds or in certain areas. This type of action should be included in company policy and should be clearly communicated. It may be necessary to remind employees with signs and repeated communication as well. This is a common practice to prevent data loss from any mobile phone function, including SMS. The organization should be sure to make distinctions for employee-owned phones and emergencies. If an area requires a high amount of security, err on the side of caution, and forbid mobile phones completely. The policy must extend to visitors, vendors, contractors, and other outside entities as well as to every employee—regardless of rank.

35.5.2.3 Providing Secure SMS. Providing “secure” SMS can prove to be difficult, and it can be easy to fall into a false sense of security. Information security managers must know exactly how their mobile phone infrastructure works before declaring the system secure. Although one component of a phone’s connection may be secure—for example, from the phone to its messaging infrastructure—the entire path of an SMS message may not be secure. Some devices, such as the BlackBerry from Research in Motion, provide encrypted transport for messaging. However, email or messages to users on different phone networks or other messaging servers may not be encrypted. Information security professionals must clearly understand the technology they are deploying, and they must test for proper installation and configuration as well as working with the vendor to verify marketing claims. However, it is important to remember that if a solution is not as secure as the organization’s policies and needs require, SMS, mobile phones, or both should be banned. Some phones or smart phone solutions allow administrators to “block out” services such as SMS or to install secure communications software. Carefully consider and evaluate all options and solutions.

35.5.2.4 Bring Your Own Device. There was a time when the corporate standard was the BlackBerry, provided by Research in Motion. While still popular and the most manageable platform for smartphones, a much more recent problem has emerged in today’s organization. Tax law changes have increasingly made company-provided cell phones a thing of the past. Today, the rule is bring-your-own device; more

and more often, that device is an unmanaged Apple iPhone or Google Android variant smartphone.

Employees will want to connect their smartphone to the organization's email and calendaring system, as well as utilize the Wi-Fi infrastructure. They will want to stay connected for professional reasons (corporate email keeps them connected to the office and more productive), connected for personal reasons (personal email, social networking), and utilize battery-saving Wi-Fi instead of the cellular data networks. On the flipside, they may want to use their phone to tether another wireless device via Wi-Fi where they cannot or are not allowed to connect to corporate Wi-Fi.

This, combined with the knowledge these devices are unmanaged, have almost unlimited unknown applications, or "apps," and basically are small mobile computers, is enough to make most security pros wince. It is increasingly difficult to tell employees "no" when it comes to them utilizing these devices in the workplace, especially when they are sometimes required to do so for their job. This new challenge must be addressed in the organization's policy for mobile phones/mobile computing. It should be strictly laid out what is allowed, what is not, and how the rules will be enforced. Device management features should be utilized when allowed by the organization's platform to control things like encryption, email sync, data retention, device passwords, and device lock-out.

35.5.2.5 Other Considerations. The next list provides points to consider when planning for SMS security, many of which are from NIST Special Publication 800-48, "Wireless Network Security."¹¹

1. Create policies and procedures to deal with lost mobile phones. The phone may contain sensitive data, including stored and deleted SMS messages.
2. If cell phones are banned from the organization's premises, ensure that physical security has procedures and rules for checking visitors and employees for mobile phones.
3. Many mobile phones have the capability to back up and synchronize their contents to the desktop. Ensure proper procedures to secure data and data leakage.
4. Policies and procedures should be in place to limit and manage the acquisition of mobile phones by employees—information security may not be aware of the existence of new phones in the environment.
5. Mobile phones are not easily audited, nor is there much software to aid in the auditing process.
6. Despite proper labeling of a company-owned device, if lost it will rarely be returned to the organization. Plan to mitigate damage caused by a lost mobile phone; utilize security features such as remote wiping the device after loss via "poison pill" features or "auto-destruct" features after several invalid password attempts.
7. If a mobile device supports screen-lock and power-on passwords, use these simple protections wherever possible.
8. Through policy and education, prevent as much sensitive and private information on the organization's mobile phones as possible, including SMS messages.
9. Utilize Public Key Infrastructure (PKI) technology where possible.
10. Install antivirus software where possible.

35 · 18 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

11. Utilize VPN and firewall technology for safer data communications.
12. If a phone is to be carried on international travel, SMS messaging should be prohibited if it all possible. The risks associated with taking a mobile phone to international destinations increase exponentially.

35.5.3 Reaction and Response. When a security incident involving a mobile phone and SMS does happen, unless the organization has in-house staff trained in mobile incident response or forensics, it may be best to work with the mobile phone provider, possibly also the manufacturer. Procedures and correct processes associated with data retrieval, preservation, investigation, and so on are best handled by those most qualified. If necessary, involve law enforcement. This is an area where a long-standing good relationship with local, state, or federal law enforcement is extremely beneficial—even if the investigation would not necessarily require law enforcement investigation. For more information on this subject, see Chapter 61 of this *Handbook*.

Investigating SMS issues, including tracking messages, tracking phone location, and tracking the path an SMS message took, can often be accomplished with the help of the mobile phone carrier. Law enforcement and court-ordered subpoenas may be necessary, depending on the situation.

Compromised devices should be carefully reviewed before returning them to regular use. Mobile phone providers can assist in “wiping” the device clean of all software, including malware if the device doesn’t have such capability built-in. Specific practices and procedures vary by phone and provider, but some organizations may also choose to archive or destroy devices involved with a security breach of any kind.

35.6 SECURING COLLABORATION TOOLS. Information systems that provide online facilities for collaboration are increasingly valuable business tools. Although these tools provide excellent conduits for increased information sharing, they also have the potential to increase security threats. Even the Internet itself, with many Websites dedicated to information sharing, groupware, shared tools, and data storage, has become a collaboration workspace. New features and movements such as Google Apps, “Web 2.0,” “The Cloud,” and even free or online conference calling services must be taken into account in any organization’s security plan. The nature of collaboration and the need to get critical business done efficiently is critical to most of today’s organizations. Many companies and organizations are trying to get more work done with less people. Technology has become an important partner to allow employees to work together and to accomplish more in less time. Collaboration tools have become even more critical as businesses expand to include people working together from different geographical locations.

35.6.1 Security versus Openness. One of the longtime battles for security managers is security versus openness or functionality. The nature of collaboration requires uninhibited data and information sharing, which can be difficult to secure. Organizations have to find the right balance between allowing users free and open information exchange and providing the required level of security. Finding this balance takes cooperation and respect between the two groups: those who use the tools and those charged with securing the organization. The two groups must fully understand each other’s position; without this understanding, finding a middle ground and negotiating compromise cannot take place. The goal of the organization surely must be efficient, uninterrupted business, but not at the expense of good security. The only way to work

through this complication is with good-natured, open, goal-oriented communication. This is *not* an information technology-only problem or process. Finding that optimum balance of security and functionality will require all types of management and staff to work together. Although this may be true of all information security domains, it is especially true of collaboration tools security. Without this important balance, the tools are essentially worthless: too secure and they will not be used, too open and the business could suffer catastrophic data and integrity loss. Some businesses are not able to recover from such a loss.

35.6.2 Dangers of Collaboration Tools. Collaboration tools are becoming powerful, and they must be given full security considerations. These tools should not be installed, accessed online, or integrated into the business without the proper planning, risk analysis, security configurations, and testing; ad hoc, unmanaged systems, installed without the knowledge of security personnel, must be prohibited, and violations corrected. Collaboration tools can easily become a nightmare for security management, especially if securing these tools is not a primary consideration from the beginning. Designing and implementing security measures on an already-deployed production system is invariably a frustrating exercise in futility for both the users and the information security personnel. Likewise, finding out after-the-fact that a cloud-based collaboration tool has become mission critical to the organization is a terrifying thought for most security professionals.

Some of the features and general dangers associated with many of these systems include loss of confidentiality, integrity, or availability. These dangers can occur due to any of these problems:

- **Lack of authentication requirements, rules, or procedures.** A wide-open system or one with poor authentication would allow for unauthorized persons to gain access.
- **Data snooping or capture.** Transmission of data to and from the system could be intercepted by unknown persons.
- **Impersonation.** Proving exactly who the user is may be difficult if not well managed, especially with weak authentication and authorization methods.
- **Unauthorized posting** of confidential information into insecure or public areas.
- **Misconfiguration.** A simple mistake in configuration could reveal private information.
- **Search engines.** Documents or other information may be subject to search engine crawlers/agents/spiders if proper security is not established.
- **Rogue collaboration systems.** If a department or group deploys its own tools, privately or publicly, without the knowledge of the security group, proper security cannot be guaranteed.
- **Internal threats.** One cannot be concerned only with external threats. One department's collaboration system may be another department's limitless temptation.
- **Users.** Users may not always have security in mind. Small mistakes or shortcuts could lead to major security breaches.

When deploying or evaluating collaboration tools, risk analysis must be performed to determine if the organization is able and willing to accept the associated risks. Security groups should thoroughly brainstorm and research as many possible security

35 · 20 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

threats to the collaboration system as possible. It may be beneficial to work with the solution provider's support group to minimize or eliminate as many security risks as possible.

Workgroups utilizing collaboration tools place a great amount of trust in the application and the tools. Many of the applications available today are light on security and heavy on marketable features. Although many online companies have become much more serious about data security, they are not the owners or protectors of the organization's data; that is still up to the organization.

35.6.3 Prevention and Mitigation. Collaboration tools and systems should receive the same security care as any other information system. Although the nature of collaboration may be somewhat open, the same policies, procedures, and careful controls should apply. The goal must still be the confidentiality, integrity, and availability of the data and the information system. Collaboration tools must still benefit the business while ensuring the business will not be harmed by a security incident. By taking the necessary steps to prevent and mitigate security issues, collaboration tools can be invaluable to the organization.

The next suggestions can be utilized to aid an organization in securing collaboration tools and systems.

35.6.3.1 Policy. It is debatable whether collaboration tools necessitate specific, separate policies. What is more important is that a complete, well-written, and well-communicated policy exists, one that includes provisions for collaboration tools, systems, and associated technology. Clear understanding and communication of collaboration tool security must be well researched, well written, concise, well communicated, and updated regularly. It is critical that the policy remain valid as new and more complex collaboration tools are developed and deployed.

Policies should also include security options that may otherwise be out of the control of the organization. For example, if a company forbids using public file-sharing services, the policy should cover users attempting to use the service from outside the organization as well as within it. Employees should not be able to use services or systems that do not comply with the policy, no matter where or how the service is to be used.

A good policy should be inclusive, especially when defining exactly what the organization considers a collaboration tool. It would be easy to forget applications such as email, IM, online meetings, blogs, social networking, shared network resources, remote access software, peer-to-peer file sharing, and the like. Many technologies have collaboration components that must be considered to ensure security.

35.6.3.2 Prevent Access or Use. Another option, in conjunction with policy, is to block the use of collaboration tools, depending on the organization's needs. This may involve deploying technology to accomplish this goal, including content blocking, firewalls, or both. This should disallow installation or use of rogue collaboration tools. Periodic review of networked systems and network traffic should be conducted to ensure compliance with prevention or limitation of collaboration tools.

35.6.3.3 Limit Access. Many collaboration tools can be deployed as an internal-only system, a cloud-based system, or both. Organizations will want to choose how users will access these systems. For example, disallowing unsecured communications from the Internet may help increase security. Likewise, it may be necessary to block

access to public services from within the organization's network. Or technical solutions, such as VPN connections from outside the organization's network, may be used to meet communication needs.

35.6.3.4 Deploy or Enhance Security Frameworks and Technologies.

Wherever possible, install solutions that will increase collaboration tool security and that can be integrated into existing security frameworks. If the organization has a high-security, single sign-on solution, integrate the collaboration systems into it. Another example would be to integrate the collaboration systems into a new or existing PKI infrastructure. Utilize well-known and reliable solutions such as Secure Sockets Layer (SSL) and encryption for the host and all participants. This greatly reduces the risk of security breaches during data transmission.

35.6.3.5 Audit. No matter what level of policy, procedures, or preventions are put into place, every organization *must* audit for compliance. Procedures for auditing collaboration tools and their use should be included in the organization's regular, structured, information security auditing functions. Any deviations from the policies and procedures mandated for collaboration tools must be acted on in a timely manner.

35.6.3.6 Monitoring. Any organization that deploys collaboration tools must monitor and report on the system's usage, audit results, and data contents. (The organization must examine the actual data contents to ensure compliance with protections such as protected health information [PHI] or Social Security number [SSN]. Many new products have rules written for this reason.) Monitoring and reporting work to ensure that collaboration tools and systems are being used for their intended purposes. Monitoring and reporting of active projects should look for unusual patterns of use, policy violations, inactive users, inactive or outdated systems, and the like. Proper system management should already be in place, but it is important to check the systems periodically. For example, if a group is utilizing a collaboration system for a project, once the project has been completed, all project materials and users should be removed from the system. Reports from system monitoring and auditing should be acted on at once.

35.6.3.7 Consider Outsourcing and the Cloud Carefully. Some organizations are tempted to use commercial online-only collaboration systems or hosted solutions. This decision should not be made lightly; consider the risks versus the returns. The organization should carefully review all terms of service, license agreements, service-level agreements, and legal responsibilities carefully. Legal counsel must be involved to ensure the organization is protected, especially in the area of data ownership, possession, legal discovery, and subpoena power.¹²

The cloud has gotten a *lot* of attention lately. While cloud security is far beyond the scope of this chapter, the cloud should be treated no differently than any other outsourced application. The cloud often contains the same risks as any other service where the data is stored outside of the control of the organization. Security should be a primary concern when evaluating solutions in the cloud, with consideration given to:

- Service level agreements
- Data ownership

35 · 22 SECURING P2P, IM, SMS, AND COLLABORATION TOOLS

- Data security technology in use while data is at rest (encryption, backup, replication, etc)
- Data recovery if the provider is sold, closes, or goes bankrupt
- Physical location of the data and what national, state or local laws apply to that location and data
- Administrator access (for the customer and which administrators at the service provider also have access)
- Liability of data breeches at the service provider
- Key escrow for encrypted data

While this is not an exhaustive list, this should help an organization in brainstorming and researching the risks of cloud-based collaboration tools. There are a lot of online resources from reputable organizations that have already provided guidance for organizations wading into the cloud. As usual, consult legal counsel.

35.6.3.8 Audits and Penetration Testing. As with most information systems, providing necessary security should involve regular, external, third-party penetration testing and audits. Collaboration tools and associated systems should be tested and evaluated for their security fitness. Any problems discovered should be documented and swiftly remedied. Allowing a neutral, external entity to test the system independently is superior to internal testing, so that bias can be ruled out.

35.6.3.9 Keep Collaboration Tools Current. Keeping collaboration tools and their associated information systems up to date is critically important. Applying patches for vulnerabilities is good information technology and information security best practice. After thoroughly testing patches in a test environment, they should be applied to production environments as soon as possible. Do not ignore software vendor patches, especially those for known vulnerabilities.

35.6.4 Reaction and Response. Once a security breach has been discovered involving collaboration tools, the organization's usual policies and procedures should be followed. Procedures for compromised information systems should be well-formed, repeatable processes to preserve evidence, provide for rapid discovery and investigation, and meet necessary regulatory guidelines. When necessary, law enforcement, legal advisors, or both should be utilized to ensure proper evidence collection and documentation. Policies should also dictate the procedures for post-investigation tasks as well, such as requiring compromised systems to be copied, archived, destroyed, reimaged, or reinstalled. It is generally not advisable to try simply to "clean up" a compromised system. It can be difficult to guarantee that a compromised system once again has integrity.

35.7 CONCLUSIONS. This chapter introduces security managers and professionals to securing peer-to-peer technologies, instant messaging, short messaging services, and collaboration tools. The suggestions and information in this chapter are meant to aid in making decisions regarding these tools within the organization's overall security plan. Many of the examples and concepts are meant to aid in the planning, policy development, and review of the organization's exposure to these technologies and their dangers. This chapter should serve as only a starting point for the

organization's research on each topic and to ensure that information security managers at least have a brief understanding of each concept, its risks, prevention and mitigation strategies, and suggestions for response. It is difficult to recommend solutions for every type of business, so each organization must make its own judgment for securing these technologies. The popularity and ubiquity of P2P, IM, SMS, and collaboration tools ensures that they will be part of every security plan for many years to come.

36.1 INTRODUCTION TO SECURING STORED DATA. This chapter reviews methods of securing data stored on nonvolatile media. Nonvolatile media include magnetic disks and their (hard) drives, compact discs (CDs), and digital video disks (DVDs), with their optical drives), and flash drives (also known as *USB drives*, *flash*

36 · 2 SECURING STORED DATA

disks, and *memory keys*). Volatile storage devices, which are not covered in this chapter, include random access memory (RAM) and other storage that loses its contents with a power loss.

One of the most important issues for security management is the frequent loss or theft of laptop computers and other mobile computing devices. For example,

- A 2008 report suggested that in the United States alone, over 600,000 laptop computers were left behind at U.S. airports every year, with about two-thirds of them left unclaimed.¹
- In 2010, "... 275 businesses in Europe... lost a combined 72,000 laptops, costing those organizations a total of \$1.8 billion. Of the 265 laptops lost by the average organization per year, a company will typically only recover 12."²
- In 2012, the rate of loss was still 12,000 laptops lost per week at U.S. airports; another detail of reports at that time was that the unclaimed laptop computers were being auctioned to anyone able to pay for them.³

Unencrypted files on these stolen or repurchased laptop computers are an invitation to violations of confidentiality and control. For example, an audit of discarded computers from the New Jersey state government revealed that "Taxpayers' Social Security numbers, confidential child abuse reports, and personnel reviews of New Jersey workers nearly went to the highest bidder after the state sent surplus computers out for auction." In addition, "Nearly 80 percent of discarded computers in a comptroller's office sample had not been scrubbed of data before being shipped to a warehouse. ..."⁴

Since the last edition of this *Handbook* was published in 2008, cloud-based storage solutions are increasingly being used by individuals and by organizations, so this chapter includes a short discussion of security for such repositories.

36.1.1 Security Basics for Storage Administrators. Storage systems have developed outside the security umbrella of other organizational assets. Because the storage arena is one of the most strategic parts of the infrastructure, professionals should take the same care in developing comprehensive security controls as those that are addressed for the remainder of the network. A number of vendors have focused on the development of secure storage environments that are scalable yet flexible; most address both the logical and physical aspects of security. However, any appropriate strategy for data storage protection includes a balance between protecting the confidentiality and integrity of the information while also ensuring its availability and utility to the system and to authorized users. Ultimately, those with a responsibility for data storage will also be tasked with maintaining this balance at a reasonable cost.

Knowing how and where data will be stored on a network and addressing the known risks to the data is the best option, as it is often more efficient in terms of resource usage (time and money). An organization need not be a high-profile entity to suffer from a compromised pool of data. A single backup can contain enough concentrated personal or sensitive corporate information to experience a loss of credibility, to lose revenue, and possibly to bring the organization to its knees. Worse, a backup that is copied illicitly may show no signs of having led to loss of control over confidential data.

36.1.2 Best Practices. Every organization must keep its applications, servers, and end-user systems up and running to make use of information and to maintain the highest degree of information availability and integrity. A tiered data protection model

works best; it includes a layered defense, due diligence, and restricted management. Implemented correctly, security should be transparent. Best practices for providing a secure data storage environment include the following:

- Performing an audit and risk assessment on the storage infrastructure, looking for risks and vulnerabilities.
- Implementing authentication across the storage network that could coordinate authorization, password maintenance, and encryption.
- Implementing strong role-based access controls and assigning access rights to parties on a need-to-know basis.
- Adopting and enforcing data-encryption and data-classification policies. Based on the classification level assigned to the data, the organization's policy may require the encryption of the data at rest throughout the lifecycle of the data. There may also be requirements to encrypt the data in flight (across the network) as well.
- Requiring strong security features and practices from storage-system vendors and offsite-storage providers.
- Remembering to secure the Storage Area Network (SAN) at the switch (or fabric) level. Carving up the fabric by zones is one technique that limits access to various parts of the SAN.
- Including any data-replication or storage-replication technologies in the overall storage security plan, where such replication traffic may include transaction journals and other temporary locations with partial or full copies of sensitive data.
- Evaluating and implementing data-loss prevention (DLP) technologies to maintain the security of stored data outside the enterprise. Data tagging, or labeling, along with pattern matching (e.g. 999-99-9999 for a Social Security number) are key for assisting with DLP.
- Creating a policy for discarding old devices and media and data-storage services, to include routinely performing tasks such as secure wiping or physically destroying all data-storage devices and media.
- Evaluating and implementing retention and data-destruction policies, ensuring compliance with any applicable organizational or government regulatory issues.
- Isolating the storage management network from the organization's primary network. By not isolating the network, every employee potentially has access to the stored data.
- Establishing access-log monitoring.
- Performing employee and contractor background checks as part of the Human Resources (HR) hiring procedures.
- Establishing facilities controls in the organization to restrict physical access to data centers, locking storage cabinets and server racks, using locks built into some servers, and ensuring the reliability of the perimeter and building(s) and verifying that such controls are in place for remote storage locations.
- Treating the security of backups as warranting monitoring and alarms at a high level of importance. Adopting secure media management tracking and handling policies that include backup requirements for financial information, employee data, and intellectual property.⁵ Chapter 57 in this *Handbook* contains much information about data backup.

36 · 4 SECURING STORED DATA

36.1.3 DAS, NAS, and SAN. There are three primary methods for storing data: Direct Attached Storage (DAS), Network Attached Storage (NAS), and Storage Area Networks (SANs). In addition, remote data storage using cloud computing services are growing in popularity, especially with individual users but even with organizations.

Direct Attached Storage drives are those that are connected directly to the computer. DAS can either be internal, contained within the computer's case, or external and attached via a peripheral component interconnect, PCI, eSATA, or other bus channel. The risks to DAS devices are either their physical theft or access through the computer system that they service.

Network Attached Storage devices are specialized servers that run minimized operating systems and file systems designed specifically to support input/output (I/O) from other servers. The servers that attach to the NAS devices have DAS that contains their operating systems, applications, and other components but, normally, write all data to the NAS device via TCP/IP over Ethernet connections. NAS is utilized via file sharing protocol such as Network File System (NFS) for UNIX systems and Server Message Block (SMB) or Common Internet File System (CIFS) for Microsoft systems. (As CIFS grew out of SMB, the two are often noted as SMB/CIFS or CIFS/SMB.) As with any Ethernet connection, connections between a system and the NAS server that it uses are subject to being sniffed, to eavesdropping, and to packet capture. NFS and CIFS threats are discussed later in this chapter.

Storage Area Networks are collections of centralized disks that can be accessed by numerous servers. Using SANs can facilitate company growth, as most SANs options allow additional disks to be added to the pool as data storage needs increase, without having to take the attached systems offline, as would need to occur if new DAS were being added to individual systems. Data backups can also be easier to control, as a single storage resource could potentially be backed-up instead of each individual system. With the implementation of RAID or other disk redundancy implementations, writing data to multiple disks can be accomplished without impacting the application servers' performance. Systems can be attached to the SAN by various methods including TCP/IP and fibre channels. Fibre channels are discussed later in this chapter. Using IP for SANs connections enables servers to connect over the Internet—but this option must be used with caution, due to the security concerns of transferring data over the Internet.

Cloud backups use Internet connectivity to store backup data on remote systems out of the control of the data owners.

36.1.4 Out-of-Band and In-Band Storage Management. Managers may have to control storage locations remotely, that is, from a location other than a directly attached console. There are two approaches to such control communications, each with its own particular security issues.

In-band management uses the same network as the data transfers; *out-of-band management* uses a separate network.⁶

While in-band storage management uses the same channels as the data itself traverses for storage, out-of-band management uses alternative methods. For example, an out-of-band solution might have a storage administrator working from a desk and connecting to the storage system over the primary network used by all employees, while the data traverses a dedicated channel between the application server and the storage system.

With out-of-band management, consideration must be given to how to ensure that only authorized systems, such as the administrator's, are connecting to the storage system. This is especially necessary if the storage system does not require authenticated

connections being established before a command is accepted. Without authentication, any system able to communicate with the storage system could issue commands that would negatively impact the storage system. Another risk is due to the interface used by management communications and the commands being sent across the wire without being encrypted. For storage systems that are managed by HTTP interfaces by default, it may be possible to use HTTPS instead, in order to mitigate the risk of commands and logins from network packet capture.

In-band management also has concerns. Commands sent in-band are normally sent in clear text. Other threats of in-band storage management include⁷:

- Management interfaces being subjected to denial-of-service (DoS) attacks,
- Commands providing information on other devices and controllers, and
- Set and reset commands being issued inappropriately.

36.1.5 File System Access Controls. File systems provide access control to data. UNIX file systems provide controls based on the user owner, the group owner, and “other,” or those that are not the user or a member of the group that owns the data. Microsoft® Windows systems allow for data owners to be specified and access granted by either individual usernames or group accounts. Access control lists (ACLs) can also be used to provide access exceptions to the normal access permissions of the data files.

When correctly applied, these access controls can be effective in preventing unauthorized access to data through normal usage. However, the file system trusts the computer’s operating-system access controls to have correctly authenticated and authorized the user. If the access controls for the operating system are circumvented, then file system access controls lose their effectiveness.

For more details of operating system and local area network access controls see Chapters 24 and 25 in this *Handbook*.

36.1.6 Backup and Restore System Controls. Systems used for the backup and restoration of data need extra security consideration because the data contained on them are often critical to disaster recovery and business continuity. There are several threats to backup data that are not faced by attacks against other data stores. While most systems only have their data stored on disk (DAS, NAS, or SAN), backup systems often write data to tape cartridges or other removable media specifically intended for off-site storage. Another option is to backup data electronically to a remote system, either at another of the organization’s data centers or with an off-site backup vendor. As with any transmission of data to remote facilities, the data must be protected during transit and at the destination facility.

Regardless of the media used, all data backups need to be stored at a secure, environmentally protected facility sufficiently distant from the originating location to mitigate the risk of losing both primary and backup data from a single major event, such as an earthquake, flood, or volcanic eruption. Additionally, the backup media storage needs to be secured by restricting access to authorized personnel only. Media used for backups needs to be evaluated to ensure that it meets or exceeds the longevity needs of the data, as defined by the organization’s backup policies and standards.

Additional risk from system imitation also needs to be considered. If an attacker is able to insert a system that impersonates a backup system, all of the data intended to be backed-up may instead be written directly to the attacker’s system. Conversely, if an attacker is able to insert a system that can masquerade as one or more data storage

36 · 6 SECURING STORED DATA

systems, then the attacker could request a restoration of data from existing backups, gaining unauthorized access to the information.

To mitigate such risks, interactions between data storage systems and backup systems should be authenticated. For manually controlled backups, systems could have backup accounts created that require an interactive login to authenticate the backup request. For automated backups, other options may be available, including the use of client and server certificates to authenticate both systems involved in the backup connection.

In recent years, developments in cloud computing technology and cloud-based storage have enabled organizations to leverage hybrid data-backup solutions. Instead of backing up data at regularly scheduled intervals, changes to systems replicate to a cloud-based service in near real-time, effectively acting as a replicated copy. The addition of de-duplication technology, sending only those blocks of data with changes, further improves the efficiency of the solution. However, as with all remote backup solutions, continual due diligence with the service provider is necessary to ensure that appropriate security controls exist for the transmission, storage, access, and retrieval of the data. This is especially important given the “on demand” nature of a cloud or hybrid-based solution for data or system recovery. Any use of cloud services should be done only after:

- A thorough assessment of the cloud service provider’s (CSP) security practices,
- Validation that storage of the data in the solution is in compliance with all legal, regulatory, and company requirements, and
- Employing data encryption that maintains in-house management of the data encryption keys.

Off-site storage of data, whether written directly to a storage vendor’s server or on removable media such as tape, deserves its own security considerations. For example, how does the vendor secure physical access to its site? How do they vet their employees? Most risks such as these can be mitigated by performing due diligence of the vendor prior to entering a contract, and by eliminating prospective vendors that do not meet the organization’s security needs.

Another mitigation strategy is to encrypt data backups before they are sent offsite. Many backup applications offer encryption methods. The use of encryption for files and other data storage systems is discussed later in this chapter. Similar techniques can be applied to backup data by encrypting it as it is written to the backup media.

For more details of backup strategies and security, including cloud backups, see Chapter 57 in this *Handbook*.

36.1.7 Protecting Management Interfaces. Management interfaces pose one of the greatest threats to the security of stored data. These interfaces provide administrative access to the data stores, allowing individuals with appropriate access the ability to manipulate data elements, update account security, and perform other house-keeping activities. Therefore, care is required when implementing a storage solution to ensure that a well-defined defense in depth exists. While two-factor authentication is more secure, it is not always practical. At a bare minimum, each administrative user should have a set of credentials, and complex password requirements, with a regular password change frequency. For situations where the data storage occurs via an Internet-based source, certificate or token-based authentication can provide an extra

layer of authentication security. In addition, the individuals responsible for administering security should not be the same individuals responsible for managing the storage environment. This separation of duties limits the ability of any one individual to circumvent security controls, without some type of conspiracy between the storage and security administrators.

Another important component of the defense in depth strategy involves the use of audit logs. Logging should be enabled to detect violations of policy and of prescribed procedures. However, logs are valueless unless subjected to regular and random review, with follow-up if anomalies are detected. It is unrealistic to expect an individual to pore over voluminous log files on a daily basis. However, log aggregation and correlation technology can be employed to provide an additional layer of confidence. Regardless of the final implementation, the use of audit logs, and restrictions on the ability to access and modify those logs, plays an important part in guaranteeing that no data corruption occurred.

Mitigating these risks to the management interface requires careful monitoring and control of who can access and install these interfaces. With the movement to Web-based interfaces, this discussion comes down to strict user access control and authentication. In any case, it is imperative that only trusted users with a need-to-know be allowed access to the management interface. Once inside, individuals can manipulate the environment as needed to support their goals, whether to further organizational objectives or to perform malicious actions.

36.2 FIBRE CHANNEL WEAKNESS AND EXPLOITS. Fibre channels, while very economical, present unique challenges to the storage environment. The term *Fibre channel* refers not just to an optical-fiber-based communication pathway, but rather to a complex communication protocol. There are a number of inherent weaknesses in the technology, some of which are fairly straightforward and manageable, but others introduce questions of the viability of the technology in larger storage environments.

One of the most serious security weaknesses with Fibre channel is that all communications occur in cleartext. Fortunately, when Fibre channel implementations occur completely within a data center or other secured area, this is not a major concern, as the ability of unauthorized individuals to intercept traffic *on the wire* is limited unless they have physical access to the cabling and can avoid detection as they attempt to intercept traffic or to install interception devices. In early Fibre-channel implementation, native authentication and encryption was not available. However, newer fabric switches and SAN devices provide built-in capabilities for authentication and encryption to significantly reduce the risk posed by cleartext data transmission.

From a vulnerability perspective, attackers can use the Internet Protocol (IP) to craft exploits against Fibre channel, since both protocols use a frame-based communication scheme. Unfortunately, based on the cleartext issue discussed above, an attacker could sniff frames from the Fibre channel connection, and gain information needed to craft an attack. This section focuses on three types of common attacks: *man in the middle*, *session hijacking*, and *name-server corruption*. Most attacks on a storage network require physical access to that environment, or access to the appropriate sniffing hardware, increasing the difficulty of successful, undetected attacks.

36.2.1 Man-in-the-Middle Attacks. Man-in-the-middle attacks (MIMAs) take advantage of weaknesses in the frame-based communications through Fibre channel. Like IP-based attacks, MIMAs involve an attacker intercepting communications, stealing or changing data, and passing that frame on to the intended destination. Fibre

36 · 8 SECURING STORED DATA

channel includes a *Sequence ID* and *Sequence Count*, both intended to ensure consistent communication from sender to receiver. Much like IP, the Sequence Count is an easily predictable sequential number, allowing an attacker to anticipate the next sequence number and forward a packet ahead of the sending system. The introduced packet allows the attacker to intercept the stream without the authorization of either party. Mitigating this issue requires data-integrity checking to guarantee reception of the correct information and rejection of the fraudulent packets.

36.2.2 Session Hijacking. Session hijacking presents the same type of problem as MIMAs, and occurs in much the same way. However, this type of attack focuses on the lack of authentication in Fibre-channel environments. Instead manipulating data in each frame and passing it on, the hacker uses knowledge of the Sequence ID and Sequence Count to intercept and control the session, making the recipient believe that the attacker is really the original sender. The newly controlled session can then be used to extract whatever data or other information the attacker wishes. Mitigating this issue requires strong authentication to provide a guarantee that the original sender is still the same system throughout the length of the connection.

36.2.3 Name-Server Corruption. The last type of attack in this section involves address spoofing, similar to DNS spoofing in the IP world. Each Fibre-channel connection registers its name with World Wide Name (WWN) service, through two processes, a *Fabric Login* (FLOGI) and a *Port Login* (PLOGI). Typically, name-server corruption occurs during the PLOGI process by allowing an incorrect host to register itself with the Fibre channel switch (which contains the WWN service) using a spoofed address. The switch registers the host under that address as if it were valid because of the lack of any host authentication. When the real host tries to connect, the switch denies that connection because the incorrect host is already connected. This type of attack requires some timing on the attacker's part, but can be easy to accomplish because of the weaknesses previously discussed. Modern fabric switches provide additional authentication mechanisms to defend against these attacks through validation of the device with the switch at regular intervals.

36.2.4 Fibre-Channel Security. This short examination of Fibre channels has pointed out that many weaknesses exist. However, this does not mean that Fibre channel should be dismissed as a suitable technology. When implementing Fibre channel into an environment, care must be taken to address these vulnerabilities, taking into consideration location, distance, and availability of the implementation to individuals, systems, and other devices on the network. The physical placement of the devices and wiring must also be optimized to mitigate the risks associated with using Fibre channels. Vendors are also answering the call by offering technology to help secure Fibre channel through built-in authentication and encryption capabilities.

36.3 NFS WEAKNESSES AND EXPLOITS. Network File Systems (NFS) provide a service allowing a user on a client machine to access network-based resources as if they were local to that user. This service is built upon the Remote Procedure Call (RPC) service, and although very useful in a networked computing environment, NFS presents a number of security issues that must be addressed prior to implementation. NFS is typically geared toward high-bandwidth environments, such as an LAN, or networks sharing nonsensitive information. Since NFS does not provide encryption

between hosts, using this technology for other networks, especially those exposed to the Internet, introduces additional risk.

This section describes three of the most common weaknesses and exploits for NFS: user and file permissions, trusted hosts, and buffer overflows.

36.3.1 User and File Permissions. Aside from the lack of encryption, NFS allows user access based on the particular host connected to the NFS share. This means that any user connected to that host can access the network resources. Restricting users to read-only access eliminates the potential to use NFS as a collaborative technology, because users can no longer create or update information on the shares.

When mounting shares with read-write access under NFS, any user connected to the host can access another user's files, as the only protection the file has is its permissions. Administrators attempt to mitigate this risk by forcing all users to access the share under a group or common set of read-only credentials, but this approach eliminates some of the benefits that a network share provides. The read-only share then requires administrators to update or edit files, providing a library-style approach rather than a collaborative file management environment.

36.3.2 Trusted Hosts. Problems with NFS specifically concern the authentication of hosts to the NFS environment. Because NFS controls mount requests based on the host connecting, and not on the particular user, a rogue host could request an NFS mount and make changes to resources. An attacker could also compromise a DNS server used by the system exporting the NFS to point that system to an unauthorized machine. Because there are no login credentials shared prior to mounting NFS shares, if the hosts are not trusted, there are no additional checks to validate the integrity of the new host.

36.3.3 Buffer Overflows. In many implementations of NFS, data input checking does not occur before processing a request. This flaw presents an opportunity for a buffer-overflow attack. When a directory-removal request comes to an NFS server from a user with read-write privileges, the server does not check the length of the path name, and the user can include additional instructions beyond what the server should receive. Those instructions, presumably malicious, could then be executed by the server as an administrative account, such as *root* or *administrator*. As a result, unintended or unauthorized data manipulation can occur.

Recent implementations of NFS have included Kerberos authentication to help validate the users and what they are able to do. In addition, the same validation can be used to validate hosts before they connect to the NFS server. However, these improvements are only partial solutions. Criminal hackers continue to develop and apply new buffer overflows, and it would be unwise to assume that NFS, or any other network technology, can be completely secured.

For more detailed discussions of secure programming techniques and software quality assurance to preclude buffer overflows and identify and prevent other software vulnerabilities, see Chapter 38 and 39 in this *Handbook*.

36.4 CIFS EXPLOITS. The Common Internet File System (CIFS), an Internet-enabled Server Message Block (SMB) protocol, builds upon that protocol by including encryption and secure authentication to the existing resource sharing capabilities of SMB. Unfortunately, from a security perspective CIFS blends some of the new with some of the old, and the result includes a number of security issues.

36 · 10 SECURING STORED DATA

36.4.1 Authentication. CIFS implementations provide either a straight password-based authentication scheme or a challenge-response scheme. Both of these approaches occur in cleartext, allowing anyone with wire access to intercept and capture authentication credentials to the network share. Even with the challenge-response approach, attackers could spoof a transaction and gain access to the share. Recent implementations of CIFS rely on Kerberos for authentication, and much like NFS, while providing additional security, introduces Kerberos-based vulnerabilities, which are outside the scope of this section. Some CIFS implementations also provide a “share-level” security model, rather than a “user-level” security model. In essence, rather than each user maintaining individual credentials, the share has only one set of credentials, which all users share. The weaknesses inherent to a share-level model are similar to those found with the use of group or shared accounts on any other system.

In addition to the authentication issues, CIFS is also vulnerable to dictionary and brute-force attacks against a user’s credentials. These generally involve a chosen plaintext attack, helped by intercepting challenge-response pairs during the authentication process. However, both online and offline dictionary attacks are available to the attacker based upon the amount of time available to watch the connection attempts.

36.4.2 Rogue or Counterfeit Hosts. It is important to identify the differences between the attack surface of CIFS and that of NFS. Man-in-the-middle and the trusted host issue both apply to CIFS, with some different concerns. Improperly configured CIFS clients can be fooled into thinking that they should supply a password instead of interacting with a challenge-response scenario, thus supporting man-in-the-middle attacks. Additionally, if a CIFS environment that does not enable session or message authentication, it removes security controls designed specifically to protect against these types of attacks.

CIFS shares many of the same security issues with NFS. However, most of the issues can be avoided by enabling security features included with the protocol. Man-in-the-middle and session hijacking attacks, in addition to replay and spoofing attacks, can be avoided by message and session authentication. This does not suggest that CIFS can be completely secured, but that care must be taken during the configuration step of implementation to make use of all available security controls.

36.5 ENCRYPTION. Many individuals and organizations focus on encrypting data while it is in motion, transiting networks and the Internet. The use of encryption for data while at rest, or stored, is equally important. As previously mentioned, stored data are compromised by security breaches more often than data in transit. With the use of a sufficiently strong algorithm and sufficiently sized key, data that are stored encrypted can be made unusable for those without the ability to decrypt the data. Even if an attack is successful at gaining full control of copy of the data for brute force attempts at decryption, a proper algorithm and key can prevent the data from being decrypted for a reasonably sufficient period—long enough that any personally identifiable information (PII) or other sensitive, confidential, or proprietary information would be of no value except to historians.

When a system is lost or stolen, an attacker has, essentially, an unlimited amount of time to gain access to the data. If the data are not encrypted, they can simply be read once the userID and password have been determined. If cracking the operating-system access controls is not successful, an unencrypted disk drive can simply be read on a different computer using the file system or, if that’s not possible, using

forensic utilities. With encrypted file systems or volume encryption, only a portion of the data is stored encrypted. Data that are not in one of these encrypted locations are vulnerable—including swap spaces and temporary file locations used by the operating system.

See Chapter 7 in this *Handbook* for more details of cryptography; see Chapter 37 for details of the public key cryptosystem.

36.5.1 Recoverability. Key principles of information assurance (IA) include protecting the availability and utility of data. By its nature, encryption can take away these protections in exchange for protecting the authenticity, confidentiality, and integrity of the data while it mitigates the risk of losing possession of the data. When using data encryption it is important to consider the possible need to recover the data in the event that the user or primary key is unable to be located. There are several ways to accomplish this.

Key escrow is one method to facilitate the recovery of encrypted data. By storing the key with a trusted party, a lost key can be removed from escrow and used to decrypt the data. With public key encryption, additional decryption keys (ADKs) can be used with some encryption tools. Corporate ADKs are keys that can be used during the encryption process to automatically encrypt the data with a key that is tightly controlled and only used by designated individuals for the recovery of encrypted data.

36.5.2 File Encryption. The use of encryption on a file-by-file basis is a good method for securing data. With file encryption, a user can pick and choose which files to encrypt. Files containing sensitive data can be encrypted, while nonsensitive files are stored without encryption. This has the least impact on a system, but it puts most responsibility on a user who must determine which files should be encrypted.

Operating system files cannot be encrypted, so configuration files that may contain information on the organization's systems are left as risk—as are application code files. These code files may be for the organization's proprietary application that provides a significant competitive advantage. However, such files are rarely encrypted, as doing so can provide a hindrance for the user who must remember to decrypt each and every file when required.

36.5.3 Volume Encryption and Encrypting File Systems. Both volume encryption and encrypting file systems offer protection to data and can be easier for users than per-file encryption. The ease of use comes from the single operation required to access multiple files. Depending on its configuration, a location can remain decrypted and accessible for a few minutes or several hours.

A critical difference between file encryption and volume encryption is that decryption is carried out at the driver level as data are moved from disk into RAM. The entire volume is *not* decrypted. However, input/output (I/O) to and from the mounted volume can be significantly slower than from an unencrypted disk drive.⁸

In addition, dynamic decryption ensures that there is no extensive plaintext version of the original materials stored on the hard disk or in virtual memory for cryptanalysis in case of an aborted shutdown.

With partial encryption using file encryption or encrypted volumes, only a portion of the data stored on the disk and specifically written to the encrypted partition is protected. Usually, operating-system and application files are not encrypted, so a stolen or otherwise compromised disk is vulnerable to attackers who would gain access to any file not saved into the encrypted volume or file system. If a user forgets to encrypt

36 · 12 SECURING STORED DATA

a file or folder containing sensitive data, then those unprotected data are accessible to anyone who can access the operating system or read the disk drive using forensic or other disk utilities.

36.5.4 Full Disk Encryption. Author Ryan Groom lists cogent reasons for using full disk encryption on laptops.⁹ These can be restated for any system. The primary reasons to use full disk encryption are that it

- Protects data if a drive is lost or stolen,
- Is safer and more effective than volume encryption or encrypting file systems,
- Can be transparent to users, and
- Helps comply with legal and regulatory issues.

Full disk encryption secures the file system and operating-system files but leaves a small boot portion of the drive unencrypted. The unencrypted region allows the encryption software to load, to request the password, passphrase, or token needed to initiate dynamic decryption of the drive contents on demand, and to continue loading the operating system.

Depending on the solution chosen, users can see little difference in functionality or performance between a system using full disk encryption and a system that does not do so. The primary visibility to users is that on a system boot, the user has to identify and authenticate to enable decryption and continue to system boot. System performance is almost undetectably reduced, with only minor delays during the boot of the system while significant amounts of operating-system programs and data from the disk are decrypted, and again on shutdown as unencrypted data are cleaned up to prevent readability without authorization. Although I/O may be slower than on unencrypted systems, most file accesses do not require large volumes of I/O, so overall, these minimal effects on users are greatly outweighed by the protection afforded by full disk encryption.

As with volume encryption, full disk encryption involves dynamic decryption of ciphertext as it flows from disk to memory buffers. With modern data-transfer speeds and processor capabilities, any performance delay due to on-the-fly decryption once the operating system has been loaded is negligible in practice.

With full disk encryption, the entire contents of the drive are protected. Even with full physical access to the disk (e.g., by installing it into another computer under the attacker's control) or with a bit-for-bit copy of the encrypted disk, an attacker must break the encryption in order to gain any information—an almost impossible task with the key sizes currently in use, except perhaps by government cryptanalysis labs using massively parallel architectures for brute-force cracking. With strong encryption, management may be able to satisfy the concerns of clients if an organization has to disclose the loss of equipment and must provide an assurance that, even though the disk was lost, the client and organization's data cannot be accessed.

36.5.5 Vulnerability of Volume, File System, and Full Disk Encryption. As strong as the protection provided by volume, file system, and full disk encryption, there is one significant weakness. Once a user is authorized to access the data, and the operating system dynamically decrypts data as required, the system is vulnerable to attacks by any interloper who has physical access to the unlocked, unprotected session. For example, if a system contains sensitive data and is connected to

a network, any attack over the network can potentially compromise the data when the authorized user's session allows access to the decrypted data.

This vulnerability must be stressed to users who may misunderstand the implications of encryption, especially those who insist on storing sensitive data on their laptops. While full disk encryption protects the data when the system is not booted, once the user decrypts the disk at boot the data are available not just to them but to anyone else who gains access to the system. Systems must use defense-in-depth strategies with personal firewalls to prevent unauthorized network access to the system; users must maintain physical possession of the system, especially once they have entered their decryption key. If a user with a Windows operating system on a laptop locks the screen and then walks away, the data are protected only by the strength of the system password.

Especially sensitive data should be encrypted at the file level. Alternatively, volume and file system encryption can be used with reasonable timeouts applied. Both of these options provide increased protection of data while a system is booted. Combined with full disk encryption, the risks to data are greatly reduced. Some application programs offer options for data encryption (e.g., MS-OUTLOOK includes options for encryption of the PST files containing all the user's data). And what could be worse for an attacker who breaks the full disk encryption only to find that the information is super-encrypted one or more levels, if file encryption, volume encryption, and full disk encryption are all in use?

An important point with the discussion of multilevel encryption is that it requires a strong commitment from the organization to support security at that level. Full disk encryption can be enabled at a global level through group policies or other technology-driven solutions. However, as mentioned above, a user must selectively choose to encrypt sensitive data, placing the responsibility and accountability on them. However, with a multi-layered encryption approach, there is still a layer of protection against a user forgetting or deliberately avoiding encrypting a sensitive piece of data.

Many data privacy laws have arisen over the last several years, including differing laws for the majority of U.S. states and the European Union. Many of these laws require notification of impacted users when data is lost. However, many of these laws include "safe harbor" from notification if the data was encrypted on the lost or stolen device or media. (The authors strongly recommend that you consult with your legal counsel for proper interpretation of the laws for your jurisdiction and/or the jurisdiction of any data subjects potentially impacted by a breach or data loss.)

36.5.6 Database Encryption. For many organizations, the databases that are the primary location for storing data are also an excellent target for attackers. By employing database encryption, the time an attacker needs to gain access can be greatly increased.

Databases can be protected by placing them on a system that can only be accessed via a secured connection and one that employs volume or full disk encryption. In addition, there are database encryption functions or external tools designed to protect the data held within these stores even without disk encryption. These tools employ encryption at the field (individual data element), row (a collection of fields that align in a row when seen in a tabular view), and full database encryption. One of the advantages of database-specific encryption is that it can support strict compliance with legal requirements for data protection. For example, PII such as names, Social Security numbers, medical information, and so on can be protected at the highest level of security available in case unauthorized personnel or intruders gain access to the database.

James C. Foster, in an article for *SearchSecurity.com*, stated that organizations “often jump into database encryption as a quick fix for compliance without considering several key factors. The greatest among these factors is the speed or performance of the application, because poorly implemented database encryption could impact production applications.”¹⁰ Foster recommends four “simple guidelines that will help you secure your database without impeding the business you’re trying to protect,” which are expanded on below:

- Do not encrypt foreign or super keys. These keys are used for indexing, and encrypting them can negatively impact the utility of the database. Since these keys are not encrypted, the keys should never contain information that should be protected—such as using a customer’s Social Security number or credit card number as a key to link tables.
- As with any use of encryption, symmetric algorithms are faster than asymmetric keys. However, if all data are encrypted with a single key, this key must be well protected or else an attacker finding the key could, quite literally, have the key to the kingdom of an organization’s primary data store.
- “Full database encryption is rarely advised or a feasible option. Security best practices would teach you to encrypt everything with multiple keys and differing algorithms.” However, technical staff should evaluate the effects on performance.
- “Encrypt only sensitive data [columns]. This is typically all that is required or recommended by regulations and, after all, is what needs protection.”

36.5.6.1 Improving Vendor Provided Options. Database vendors such as Oracle Corporation and Microsoft have encryption options that are specifically designed to protect the information in their databases. These options have improved over time and are becoming more robust and mature.

Microsoft SQL Server 2005 offers enhancements to column encryption. Also introduced was “an integrated and hierarchical infrastructure for managing encryption keys.” The product documentation continues, “Built-in encryption functions and application programming interfaces (APIs) make it easier for an organization to create an encryption security framework.”¹¹

Oracle Database 10g Release 2 improves on existing encryption options within Oracle databases by introducing Transparent Data Encryption (TDE). When using TDE, a database administrator is able to specify that a column needs to be encrypted, and the database automatically encrypts data during insert operations and decrypts the data during selects. This can be achieved “without writing a single line of code.”¹² Arup Nanda provides a good overview of this feature in the September/October 2005 issue of *Oracle Magazine*.¹³

36.5.6.2 Implementation Considerations. As with any implementation of encryption, careful consideration must be given to determining the method and process for implementing the solution, as well as to the data that are being encrypted. Encrypting a key field needs to be avoided. If sensitive data are in the key field, there may be significant work required to create new key fields and recreate table linkages, or the organization may decide to accept the performance degradation that could occur with encrypting the key field. That is, assuming that encrypting the key field does not cause the database to become unusable.

The costs associated with implementing an encrypted database solution must also be weighed against the business risk. For companies that have little data needing encryption, database encryption may be inappropriate. Legal and regulatory requirements also need to be considered as database encryption may be mandated in order to protect data and to avoid criminal or civil liabilities. The attendant loss of public and customer confidence, in the event of a data breach, is also a powerful incentive.

36.5.7 Smart Phone Encryption. Users may store confidential information on mobile phones and tablets; typical entries include contact entries with phone numbers and sometimes with ancillary sensitive data such as passwords, personally identifiable information (e.g., government-issued identification numbers), and call records. Such devices may also be used as if they were flash drives, with potentially gigabytes of sensitive data downloaded from other sources and carried in a pocket, briefcase, or handbag—and therefore easy to steal or to lose.

Another factor that can be significant for some users is that under U.S. law at the time of writing (in June 2013), a suspect who is questioned, interrogated, or arrested cannot normally be forced to divulge the decryption code.¹⁴

Phones using Android 2.3.4 or later usually come with integrated total encryption; the process typically takes about an hour, ideally starts with a fully charged battery and connection to a power supply, and must not be interrupted. Interruption of this encryption process can damage or delete the data stored on the phone and requires a factory reset that wipes all current data and personal settings from the device.¹⁵

Apple iOS and Microsoft Windows Phone 7 also include encryption functions with varying coverage. Third-party software is available for all the operating systems discussed above.¹⁶

In March 2013, researchers at the Friedrich-Alexander University discovered how to access data encrypted on a version of the Android operating system:

The team froze phones for an hour as a way to get around the encryption system that protects the data on a phone by scrambling it. ... The attack allowed the researchers to get at contact lists, browsing histories, and photos. ... [They] put Android phones in a freezer for an hour until the device had cooled to below -10 C. ... [Q]uickly connecting and disconnecting the battery of a frozen phone forced the handset into a vulnerable mode. This loophole let them start it up with some custom-built software rather than its onboard Android operating system. The researchers dubbed their custom code *Frost—Forensic Recovery of Scrambled Telephones*.¹⁷

36.6 DATA DISPOSAL. A final consideration for securing stored data is the disposal of the media that contains the data.

For sanitizing electronic media, United States Department of Defense standard 5220.22-M can provide guidance.¹⁸ Essentially, the media should be sanitized so that the data originally written to it cannot be recovered. One method for achieving this goal can include the following steps:

1. Erase the data
2. Write random or meaningless data to the media
3. Erase the data
4. Repeat until the desired level of sanitization is met

For information stored on paper, the paper should, at a minimum, be shredded before being discarded. Use of a cross-cut shredder is necessary as it increases the difficulty

of piecing the documents back together. In one notorious incident, confetti examined after it was thrown during a Thanksgiving Day parade in New York City in 2012 proved to be easily read horizontal shreds of confidential files from the Nassau County Police Department. “There were whole sentences, license plate numbers, and police reports.”¹⁹

There are additional steps that can be taken if needed, and facilities are available to accomplish these, including burning the shredded paper and mixing it with water to speed its deterioration. Over the past several years, vendors specializing in onsite paper destruction have become commonplace. These vendors bring trucks to a client’s site and collect paper that is then shredded onsite before being taken to a facility that recycles, burns, or otherwise disposes of the waste in a secure manner.

For more information about data disposal, see Chapter 57 in this *Handbook*.

36.7 CONCLUDING REMARKS. The security of stored data is of critical importance. More data breaches occur against data in unsecured storage locations than is compromised during transit. With proper data storage security there is less risk to data from all kinds of threats, internal and external. Using secure channels for writing data to disk and protecting the disks themselves is of increasing importance, as attackers usually have one of two goals—causing systems or data to be made unavailable, or compromising the confidentiality and integrity of data. By combining secure communication channels, data encryption for data at rest, and physical protection of data storage devices, the security of information can be better assured.

7. Preston et al., *Storage Security Handbook*.
8. For example, observations in June 2013 showed that mounting an entire 7 GB partition encrypted by Symantec PGP Desktop v10.20.0 took ~7 seconds. In comparison, the same 7 GB of data encrypted using WinZip and 256-bit AES encryption took about an hour to decrypt *in toto* on a 7200 rpm two-disk performance RAID 0 set running under 64-bit Windows 7 Professional SP 1 on a 3.2 GHz AMD Phenom™ II X4 955 quad-core processor with 12 GB of RAM. Copying a 1.23 GB file took 85 seconds (~15 MB/sec) on the PGP encrypted volume (located on the RAID 0 hard drive) but only 20 seconds (~63 MB/sec) on the RAID 0 itself.

37 · 2 PKI AND CERTIFICATE AUTHORITIES

37.1 INTRODUCTION. In the 1990s, the use of encryption across the Internet consisted mainly of individuals with Pretty Good Privacy (PGP) and later the Gnu Privacy Guard (GnuPG, originally abbreviated GPG) exchanging secure email and each maintaining a private *web of trust*, today's use of encryption encompasses a much wider range of elements, including proofing, issuance, revocation, identification, federation, bridging, encryption, digital signing, and a myriad of ancillary processes. In fact, what the user experiences is just the tip of the required support structure. Proper management of information involved in an encryption infrastructure (or cryptosystem) is about trust, what is required to establish that trust, and how much to grant.

Back then, the prime use of encryption was outside the network perimeter, where unprotected data sent and received by the organization over public networks were perceived as most vulnerable to disclosure, modification, insertion, deletion, and replay attacks. To protect the data being transported over untrusted networks, the only practical and cost-effective technology is cryptography. Cryptography is at the heart of both virtual private networks (VPNs) and public key infrastructures. For further information on encryption, see Chapter 7. For a review of cryptography, see Chapter 7 in this *Handbook* and *Applied Cryptography* by Bruce Schneier.¹

37.1.1 Symmetric Key Cryptography. Symmetrical cryptography (also known as *single key* or *secret key*) uses the same key to encrypt cleartext into ciphertext and to decrypt ciphertext back into cleartext. This process is illustrated in Exhibit 37.1.

Although symmetric cryptography (e.g., Advanced Encryption Standard [AES], Data Encryption Standard [DES], Rivest Cipher 4 [RC4]) has specific advantages in that it has a dense keyspace (any integer) and is computationally very fast, it has a fundamental weakness: Both the originator and each recipient must have the key. Key sharing has two management issues:

1. Key exchange must be performed: Somehow each user must have the same key. This exchange is generally accomplished out of band.
2. There is weak confidentiality, control, or authentication: Anyone with the symmetric key could have encrypted the cleartext or decrypt the ciphertext.

37.1.2 Public Key Cryptosystem. In contrast to secret key cryptosystems, public key cryptosystems (PKCs) use pairs of related keys that are generated together. It is accepted that it is infeasible to generate one key from the other. The ciphertext produced by one key can be decrypted only with the other member of the same key

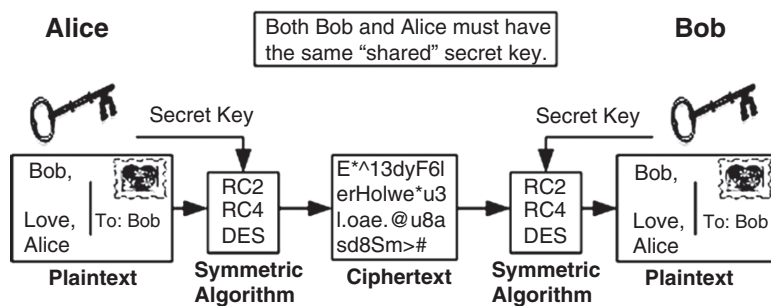

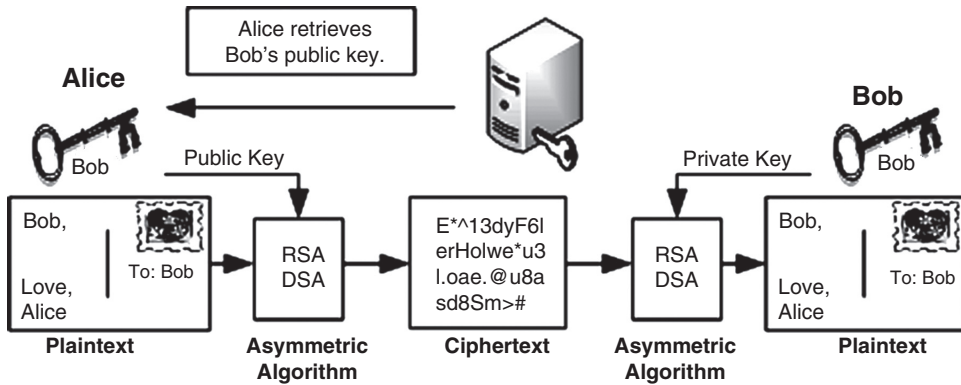

EXHIBIT 37.1 Symmetric (Secret) Key Encryption

**EXHIBIT 37.2** Asymmetric or Public Key Encryption

pair. One of these keys is kept secret (the *private* key) and the other is published for all to use (the *public* key). It does not matter which is designated as which, but once designated, the key cannot be changed. In practice, encryption with one key is often faster than with the other. This one is generally selected as the public key.

In the simplest form, to conceal a message in transit so that only the desired recipient may read it, the cleartext is encrypted using the recipient's public key, as shown in Exhibit 37.2. Only the recipient's secret key can decrypt the transmitted ciphertext. Similarly, to verify message integrity and authenticity, it is possible to encrypt information with a sender's private key. This allows anyone with access to that sender's public key to validate the message by decrypting the ciphertext successfully.

37.1.3 Advantages of Public Key Cryptosystem over Secret Key Cryptosystem. For securing data transmissions, public key cryptosystems are preferred over secret key cryptosystems for these reasons:

- Public key cryptosystems require fewer keys to manage: Each party (n) has a key pair, so the total number of keys is $2n$, instead of being proportional to n^2 as for secret key cryptosystems.
- Because private keys need not be distributed or otherwise managed, public key cryptosystems require only demonstrated integrity and authenticity of the public keys themselves. Users (the *relying parties*) must have assurance that their public keys truly belong to the publishers. This requires signing by a trusted third party or by a mutually trusted source.
- Because no secret keys are transmitted over any network, PKCs are not susceptible to compromise even when public keys have to be changed. PKCs can be used to encrypt temporary keys (*session keys*) that can be used one time for secret key cryptography to obviate the heavier computational load of the PKC.
- To encrypt a message so that multiple PKC users can receive and decipher the ciphertext securely, PKC software can create a session key. This secret key is then encrypted with each recipient's public key separately and sent with the ciphertext to all recipients without compromising confidentiality. Each recipient can then extract the key used to encrypt the file.

37 · 4 **PKI AND CERTIFICATE AUTHORITIES**

EXHIBIT 37.3 Symmetric versus Asymmetric Encryption

Type	Keyspace	Speed
Asymmetric	Sparse	Slow
Symmetric	Dense	Fast

PKC-based digital signatures can also provide the basis for nonrepudiation in the event of a dispute. Only the possessor of a private key could have sent a message decrypted by its public key. In contrast, because of the use of shared secrets, symmetric secret key cryptosystems alone cannot reasonably support nonrepudiation.

37.1.4 Combination of the Two. At this point, it may be easiest to consider the elements of the different types of cryptography, as shown in Exhibit 37.3.

The difference is similar to that between electronic data interchange and e-commerce. Symmetric encryption is good for a very few exchanges with people you trust; asymmetric encryption is good for many, many small exchanges with people or devices you may have never met.

Today, the most common use is to combine both types: For a document to be emailed securely, a symmetric algorithm is selected and a random key generated. The document is encrypted using the symmetric algorithm and key. The symmetric key is then encrypted with the asymmetric public key of each recipient and is then added as a header to the document.

For digital signing, a similar mechanism is used except that a hashing algorithm (e.g., Secure Hash Algorithm [SHA]) is used to create a hash value of the document, and the hash is then encrypted (signed) with the private key of the originator and accompanies the document. The originator’s public key can be used to decrypt (verify) the hash, and the hash is used to verify the integrity of the document.

37.2 NEED FOR PUBLIC KEY INFRASTRUCTURE. The PKC depends on the integrity of each public key and of that public key’s binding to a specific entity, such as a person, an institution, or a network component. Without mechanisms for ensuring integrity and authenticity, a relying party is vulnerable to masquerading attacks through public key substitution.

To illustrate, suppose that ABC Company wants to send a confidential message to XYZ Corp. that no one else can read. ABC could use XYZ’s public key to encrypt the message, although, for the sake of efficiency, ABC probably would use a symmetric algorithm to encrypt the message and the public key algorithm to encrypt the symmetric key. However, if ABC can be tricked into using an attacker’s public key as if it were XYZ’s public key, then the attacker would be able to decrypt the message. This technique is known as public key *spoofing*.

Such public key spoofing by the attacker would, however, make it impossible for XYZ to read the message from ABC, as was originally intended. Therefore, such an attack probably would continue with the attacker reencrypting ABC’s message, using XYZ’s real public key, and sending it on to XYZ. Such interception and reencryption is an example of a *man-in-the-middle* attack. However, if the sender also signed the original message, this is something that the attacker could not duplicate, so the message could not be changed but only intercepted.

Another example of breaching the connection between a public key and its owner involves digital signature verification. Suppose ABC wants to verify XYZ's signature. If the attacker could trick ABC into using the attacker's public key as if it were XYZ's public key, then the attacker would be able to sign messages masquerading as XYZ using the attacker's private key. ABC would unknowingly use the replaced public key and be spoofed into thinking that the message actually was signed by XYZ.

This same problem exists with the core of Internet commerce today, Secure Sockets Layer v2 (SSLv2). SSLv3 and Transport Layer Security (TLS) can prevent this, but then every participant must have a certificate trusted by the other party. This is where the concept of a *trust chain* comes in. If a trusted third party has signed XYZ's public key, then the attacker would also have to have a key signed by the same authority as well. Otherwise, a warning would appear that the key was not recognized.

A serious issue is the sheer number of certificate authorities (over 100) built into most browsers, from a variety of countries. The browser trusts all certificates issued by any of these by default, and not all are necessarily worthy of trust.

In summary, both for digital signature and encryption services, the relying party must use the public key of the correct party in order to maintain security. There are various manual, electronic, and hybrid mechanisms for the distribution of public keys in a trusted manner, so that the relying party can be sure to have the correct public keys of the subscribers. These mechanisms for distribution and binding of public keys are known as a Public Key Infrastructure [PKI]).

The beauty of a signed public key is that the trust is inherent with the signature provided the signer is trusted. Unlike a *web of trust*, such as that used by the original PGP which requires all keys be accepted individually by each user, with a *chain of trust* a single signer (the root certificate authority) can provide trust to millions of certificates. Trust need not be absolute; it may be contextual. For example, a certificate signed by an employer can be trusted for elements relating to employment but not for credit cards. See the discussion of trust levels in Section 37.6.1.

37.3 PUBLIC KEY CERTIFICATE. The technique that is most scalable uses a public key certificate issued by a trusted party called the certification authority (CA). A CA issues public key certificates to the various subscribers by putting together subscriber information and signing the information using the CA's private key. The generally accepted standard for public key certificates is the X.509 version 3,² as defined in RFC 5280 and subsequent text.

Note: Hierarchical structures may use one or more *root* CAs and each Root CA may have multiple *intermediate* CAs which issue the end user and server certificates

X.509 certificates are expressed in Abstract Syntax Notation 1 (ASN.1), which is a complex binary notation. In order to be passed through email, certificates are usually MIME (aka Base 64) encoded, expressing the binary syntax in ASCII characters.³

The advantage to using a CA and a chain of trust is that by trusting the root, the user automatically trusts all keys that it has issued whether or not the user has ever seen them.

Each CA's certificate may contain this key information:

- Version number of certificate standard
- Certificate serial number (unique for every certificate issued by the CA)
- Algorithm and associated parameters used by CA to sign the certificate
- CA name

37 · 6 PKI AND CERTIFICATE AUTHORITIES

- Validity period for the certificate
- Subscriber name
- Subscriber public key, public key algorithm, and associated parameters
- CA unique identifier (optional)
- Subscriber unique identifier (optional)
- Extensions (optional)
- CA's digital signature

The relying parties require the CA's public key so that they can verify the digital signatures on the certificates issued by the CA. The relying party must trust the CA's public key, most likely obtained during the registration process. Once the signatures are verified, relying parties can use the subscriber name and subscriber public key in the certificate with as much confidence in the accuracy of the information as they have in the trustability of the CA.

In some situations, a CA may need to revoke the binding between a subscriber and that subscriber's public key. For example, the subscriber private key may be compromised (i.e., there may be reason to believe that the secret key has fallen into the hands of someone else). Since a public key certificate is an electronic object and can reside in several places at the same time, it is neither practical nor possible to recall, delete, or erase all the copies of the subscriber certificate in a distributed environment. Thus, to invalidate a public key certificate by severing the binding between the subscriber and the subscriber public key, the CA creates a list of invalid certificates. This list is called a *certificate revocation list* (CRL). The relying parties must check that a certificate is not on the CRL prior to using the public key in the certificate. If the certificate is on the CRL, the relying party must not use it. The CA signs the CRL to allow the relying parties to verify the CRL's integrity and authenticity. The key information in the X.509 version 2 CRL is:

- Version number of CRL standard
- Algorithm and associated parameters used by CA to sign the certificate
- CA name
- This CRL issuance time
- Next CRL issuance time (optional)
- List of revoked certificates (listing these items for each certificate):
 - Certificate serial number
 - Time CA was notified of revocation
 - Extensions related to the revoked certificate (optional)
- Extensions related to CRL (optional)
- A's digital signature

It is important that a certificate contain only those elements specifically required for operation and that these be used properly otherwise confusion and improper/unexpected use may result.

Probably the most misused element is the *Key Usage* extension. (It is used so badly that often a second extension, the *Extended Key Usage*, is used to clarify the first.) The most common error is to have the *Non-Repudiation Bit* set on a key intended for

identity only. Nonrepudiation should be asserted only on a key intended as a legal signature, not for identity alone.

A dangerous extension (and one that really does not belong in a user certificate) is the *SMIME Capabilities* extension. This only has meaning in the context of specific email clients but can cripple the use of encryption. Although it may have had some use in early mail applications, today it only establishes a maximum allowed symmetric encryption strength, which may be less than desired. If this extension is not present, RFC 5280 requires a default to triple-DES.

In the case of certificates, less is more. The minimum number of fields and extensions that is required for the assertions the certificate is intended to make is best. PKI systems in the past have failed when too many, and sometimes mission-conflicting extensions, were added.

Particular care needs to be taken that the CA server vendor chosen does not add anything not specified by the certificate template in the Certificate Policy.

37.4 ENTERPRISE PUBLIC KEY INFRASTRUCTURE. The *use* of a certificate is relatively simple, but establishing trust that the certificate is valid and appropriate for use requires a complex set of back-office elements, illustrated in Exhibit 37.4. Each group of users covered by a CA is called a *domain*. Subscribers in a domain receive public key certificates from the appropriate CA. The CA is responsible for generation of subscriber certificates and for CRL generation. The CA posts these signed objects to the repository where the relying parties can obtain them. The CA also archives the certificates and CRLs in case they are required in the future to resolve disputes among the subscribers and the relying parties.

The registration authority (RA) is the trusted representative of the CA and is responsible for authenticating the subscriber identity. The RA typically performs these functions:

- Authenticates (proofs) the subscriber's claimed identity. For example, the RA could require the subscriber to provide a valid photo ID, such as a driver's license or a passport for minimum assurance. Both I-9 authentication, as required by the

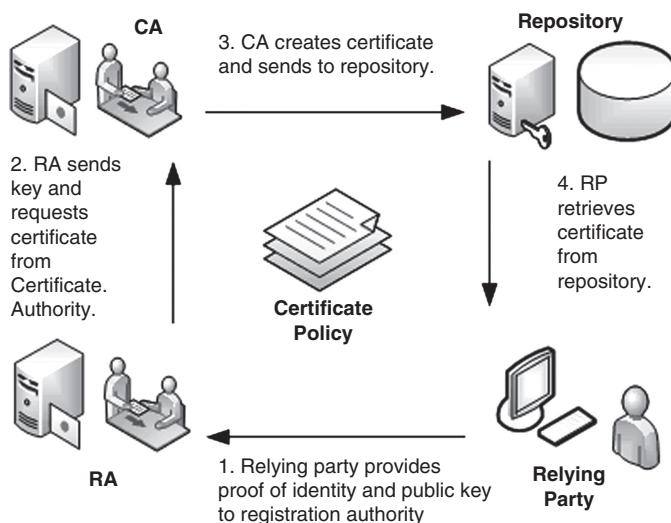

EXHIBIT 37.4 Certificate Issuance Cycle

37 · 8 PKI AND CERTIFICATE AUTHORITIES

Immigration Reform and Control Act (IRCA), and a Local Agency Check or a National Agency Check (LAC/NAC) plus “Need to Know” may be required for a higher level.⁴

- Obtains the subscriber public key from the subscriber.
- Provides the CA public key to the subscriber. A trust anchor is a CA’s public key that the relying party trusts. This trust generally is established by obtaining the public key from a trusted source using trusted means, such as physical hand-off or via Secure Sockets Layer (SSL) from a trusted or known Website. The CA public key becomes a subscriber trust anchor.
- Sends the certificate creation request to the CA. Typically, the RA creates an electronic mail message containing the subscriber name and the subscriber public key, digitally signs the message, and sends the message to the CA. Other transport means, such as manual or on the Web, also are appropriate as long as there is assurance that the subscriber identity and the public key are not changed. X.509 standard does not specify a protocol for certificate generation requests. The Public Key Infrastructure for X.509 Certificate (PKIX) working group of the Internet Engineering Task Force (IETF) has developed Internet standards in this area.⁵

37.5 CERTIFICATE POLICY. To ensure the security of the PKI, the PKI components need to operate with a high degree of security. To ensure this:

- Private keys must be kept confidential.
- Private keys must be used only by the owners of the keys.
- Trust anchors’ public key integrity must be ensured.
- Initial authentication of the subscriber (private key holder and the subject of the public key certificate) must be strong so that identity theft does not occur at the point of certificate creation.
- CA and RA computer systems and applications must be protected from tampering.
- Requirements for level of trust must be clearly defined

The Certificate Policy (CP) must specifically enumerate the certificate contents, both fields and extensions. Anything absent from the CP should not be found in the certificate.

In addition to the security requirements and in order to facilitate electronic commerce, the PKI must address obligations of all parties and their liabilities in case of dispute. These issues of security, liability, level of trust, and obligations are articulated in a CP.

According to the X.509 standard, a CP is “a named set of rules that indicates the applicability of a certificate to a particular community and/or class of application with common security requirements.”⁶ A certificate user may use a CP to decide whether a certificate, and the binding implied between the certificate and its owner, is sufficiently trustworthy for a particular application. The CP addresses security and obligations of all PKI components, not just the CA; this includes the CA, RA, repository, subscriber, and relying party.

A more detailed description of the practices followed by a CA in issuing and managing certificates is contained in a certification practice statement (CPS) published by or referenced by the CA. According to the American Bar Association’s *Digital*

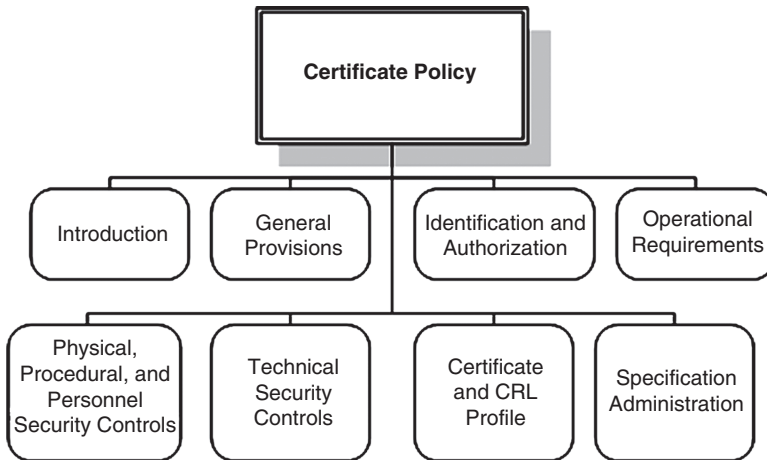

EXHIBIT 37.5 Elements of a Comprehensive Certification Practice Statement

Signature Guidelines (hereinafter referred to as *ABA Guidelines*), “a CPS is a statement of the practices which a certification authority employs in issuing certificates.”⁷

Although a CP and a CPS both address the same topics, the CP defines the security requirements and obligations for an enterprise PKI, and the CPS describes how these requirements are satisfied by the enterprise PKI.

The CP and CPS also are used differently. The CP forms the basis for cross-certification across enterprise boundaries to facilitate secure, inter-enterprise electronic commerce. An object identifier (OID) pointing to the CP (which may be a Universal Resource Locator [URL]) is used to create a certificate that can be put into the “Certificate Policies” extension of X.509 certificates. The OID thus enables relying parties to learn the care taken during the generation of certificates, recommended usage, and obligations of the various parties.

Since certificates can be created with different levels of trust and can be either based in software or hardware (more secure), often the “Certificate Policies” extension is the only indicator of the level of trust that should be placed in a certificate.

The CPS enables PKI personnel to use and administer the PKI components. The CPS also forms the basis for compliance audits in order to ensure that the PKI components are operating in accordance with the stipulations of the CPS. Exhibit 37.5 illustrates the components of a comprehensive CPS. Components are divided further into subcomponents, which in turn are divided into elements. Components may be appropriate for various PKI entities but may be applied in the same way or differently. For example, technical security controls may apply to CA, RA, subscribers, and relying parties. These controls may be different for each of these entities, being most stringent for the CA, then the RA, and then the subscribers and relying parties.⁸

A sample policy may be found at www.verisign.com/repository/vtnCp.html

37.6 GLOBAL PUBLIC KEY INFRASTRUCTURE. The principles of an enterprise PKI with a single CA can be extended to support global, secure, electronic commerce by relying on multiple CAs and/or CAs to certify other CAs and each other. How the CAs cross-certify each other is also called *trust model*, *trust graph*, or *PKI architecture*. For one person to communicate securely with another, there must be a

37 · 10 PKI AND CERTIFICATE AUTHORITIES

EXHIBIT 37.6 Trust Level Determination

Category	Required Trust Level			
	1	2	3	4
Inconvenience or distress	Low	Med	High	High
Financial loss	Low	Med	Med	High
Harm to agency programs or public interests	N/A	Low	Med	High
Personal safety	N/A	N/A	Low	Med/high
Civil or criminal violations	N/A	Low	Med	High
Information classification				
Confidentiality	Low	Med	High	High
Integrity	Low	Med	High	High

Note: the trust **level** is sometimes confused with trust **factors** (something you have, something you know, something you know). A Smart Card may be a Level 3 (Medium, hardware) but part of a two factor (username, smartcard) authentication.

trust path from the trust anchor(s) of the relying party to the subscriber whose signature needs to be verified or to whom an encrypted message is to be sent.

37.6.1 Levels of Trust. As referenced in Office of Manpower and Budget Memorandum OMB M04-04, Section 2.1, there are four basic levels of trust⁹:

- Level 1.** Little or no confidence in the asserted identity’s validity
- Level 2.** Some confidence in the asserted identity’s validity
- Level 3.** High confidence in the asserted identity’s validity
- Level 4.** Very high confidence in the asserted identity’s validity

Each level requires a different initial authentication of identity, and higher levels (or those used for classified information) require background investigations. Level 3 is also known as Medium Assurance and is divided into two forms: (1) software (certificates and keys can be exported and moved between devices) and (2) hardware (certificates may be exported but keys and cryptographic functions are performed on a specific hardware device [e.g., a smart card, USB token, or PC-Card device]). Most commercial PKI uses the equivalent of the Medium level of assurance.

Exhibit 37.6 shows one way to determine the required trust level as a function of threat of misuse.¹⁰

37.6.2 Proofing. Each assurance level has a proofing (also known as *vetting*) requirement that increases with the trust level involved, as shown in Exhibit 37.7. Essentially none is required for level 1 (Basic) while extensive in-person requirements exist for level 4 (High).

37.6.3 Trusted Paths. The trust model can be viewed as a chain, with its tail a certificate-issuing CA and its head the subscriber (i.e., the subject of the certificate). The subscriber can be another CA or an end entity. To ascertain the trustworthiness of a certificate, it is necessary to start with the relying party trust anchor and to follow in the direction of the chain until the subscriber (of interest to the relying party) is reached.

EXHIBIT 37.7 Trust Levels and Proofing

Level	Title	Proofing	Authentication
1	Default	Anonymous allowed.	None
2	Basic	Simple assertion—may be online.	Password
3	Medium (software)	I-9 employment eligibility verification and authorization. Must be in person.	Software certificate
3	Medium (hardware)	I-9 employment eligibility verification and authorization. Must be in person. Biometrics may be captured.	Hardware certificate
4	High	National agency check or local agency check, background investigation, and authorization required. Final proofing must be in person.	Hardware certificate

Global secure communications require that there be a trust path from every subscriber to every other subscriber.

The relying party can start with its trust anchor and verify the certificates issued by the trust anchor. Once that happens, the public keys can be trusted and used to verify the certificates issued by these CAs. This can be done recursively by the relying party until the public key certificate of the subscriber of interest is verified. Then the subscriber public key can be used to verify digital signatures and to perform encryption. Exhibit 37.8 illustrates this pathway. The arrows represent certificates. This is called a *certification path*.

37.6.4 Trust Models. Examples of trust models within PKI that relate to the trust in a certificate and are different from proofing (trust of an identity) include:

- Strict hierarchy
- Hierarchy
- Bridge

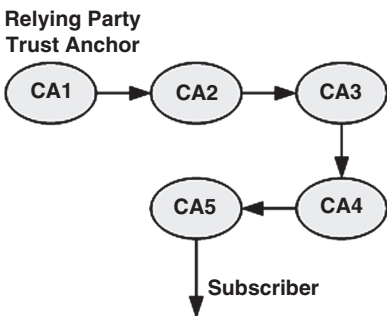

EXHIBIT 37.8 Trust Path through Multiple Trusting Certificate Authorities

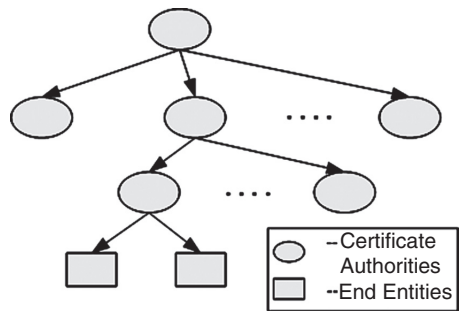

EXHIBIT 37.9 Strict Hierarchical Trust Chain

- Multiple trust anchors
- Mesh (aka anarchy or web)
- Combination

37.6.4.1 Strict Hierarchy. Exhibit 37.9 illustrates a strict hierarchy. It is a tree structure with a single root. In a strict hierarchy, for two parties to communicate with each other securely, they require the public key of their common ancestor as the trust anchor. Verifiable certificate chains require that the parties have a common ancestor. For all parties to communicate securely with each other, they require the single root as the trust anchor, since it is the only common trust anchor.

37.6.4.2 Hierarchy. In a (nonstrict) hierarchy, the subordinate CAs certify their parents. Since the directed graph is bidirectional, any CA can be the trust anchor for the relying parties. But from practical, operational, and performance (i.e., certificate path length) viewpoints, the local CA should be the trust anchor. The local CA is the CA that issued a certificate to the relying party.

37.6.4.3 Bridge. Another trust model is the bridge. Under this model, one CA cross-certifies with each CA from various domains. The domains can be organizations or vertical segments, such as banking or healthcare. Exhibit 37.10 illustrates the bridge CA. The bridge CA is not the trust anchor for any relying party. A CA in the domain of the relying party is the trust anchor.

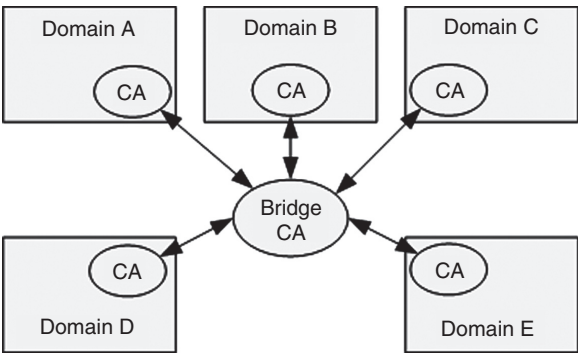

EXHIBIT 37.10 Bridge CA

Within a domain, there are no constraints on the trust model. The domain PKI itself could be organized as any of the trusted models, including bridge, leading to possible layers of bridge CAs.

37.6.4.4 Multiple Trust Anchors. Another alternative is for the relying party to obtain the public keys of the various CAs in a trusted manner and then use those public keys as trust anchors. This approach is attractive when the CAs cannot, or are not willing to, cross-certify, and the relying party needs to communicate securely with the subscribers in the domains of the originating CAs. This approach is called *multiple trust anchors*. Each trust anchor representing a domain could be a single CA or a PKI with a collection of CAs in a trust model.

37.6.4.5 Mesh. The final example of trust model is a mesh (aka *web* or *anarchy*). The term “mesh” describes any depiction representing trust among CAs or certificates without any particular rules or patterns. This model sometimes is known as a *web of trust* and is particularly associated with the original design of Pretty Good Privacy, one of the first popular systems implementing public key certificates. Within this structure, each recipient must explicitly trust each other participant. The major problem is that it does not scale very well beyond a few hundred users.

37.6.5 Choosing a Public Key Infrastructure Architecture. Whether a domain (enterprise) chooses a single CA or multiple CAs for its intradomain operation should be determined from a variety of factors, including:

- Management culture
- Organization politics
- Certification path size
- Subscriber population size
- Subscriber population distribution
- Revocation information

In many situations, the politics or management structure may dictate that there be multiple CAs within the domain. In other words, organizations at business-unit level, regional office level, corporate level, or national level may want to create a CA in order to provide them with a certain degree of control, independence, autonomy, and prestige. How these CAs are organized (bilateral cross-certification, hierarchy, etc.) also will depend on the management and political landscape of the domain. The trust model should be such that it keeps the certification path size manageable; otherwise, end users will see unacceptable performance degradation in obtaining certificates and CRLs and in verifying digital signatures on the certificates and the CRLs.

Similarly, large subscriber populations may require more than a single CA in order to ensure that the CA can manage the subscribers and to keep the CRL size small. If CA products that issue partitioned CRLs are selected, the CRL sizes can be kept manageable even for a very large subscriber population. For further discussion of the CRL issue, see Section 37.7 on revocation alternatives.

When considering interdomain cross-certification, similar issues should be considered.

37.6.6 Cross-Certification. In the simplest form, cross-certification consists of two CAs that certify each other by issuing each other a certificate. The certificates can be stored in specific attributes of the directory entry in a certificate; examples include the cross-certificate attribute pair or the CA certificate.

There are two practical problems with cross-certification. One deals with the commercial products. If the two domains use different products, their CAs may not be able to exchange information to cross-certify, and their directories may not be able to chain to permit the relying parties to retrieve certificates.

The other problem is operational. Before certifying another CA, the certificate-issuing CA needs to make sure that the subject CA is operating in accordance with the acceptable controls, articulated in a CP. The issuing CA asserts the appropriate CP in the “certificate policies” extension of the X.509 version 3 certificate of the subject CA.

In practice, the two CAs cross-certify each other after reviewing each other’s CP and after ensuring that the CPs can be claimed to be equivalent. This does not mean that all the security controls and obligations are identical, but they need to offer roughly similar amounts of trust and of obligations and similar liability and financial relief.

When two CAs cross-certify each other, the trust generally is for a limited set of policies through assertions in “certificate policies” extensions, and trust is only bilateral. In other words, trust will not commute; it will remain between the two CAs. The CAs ensure this by inhibiting policy mapping through the “policy constraints” extension. Policy constraint extensions permit differing policy-mapping inhibitions down the certificate chain. In most direct cross-certifications, policy mapping should be inhibited immediately. In the case of cross-certification using the bridge CA model, in order to take advantage of the policy-mapping services of the bridge CA, the policy-mapping inhibition should be different for one certificate (namely the bridge CA certificate).

In addition, the two CAs should use the “name constraints” extension in the X.509 version 3 certificates to ensure that they trust the other domain for the names over which the other has control. The use of this extension also minimizes the chances of name collision.

Exhibits 37.11 and 37.12 illustrate cross-certification examples. These examples are for illustrative purposes only and do not represent real-world entities.

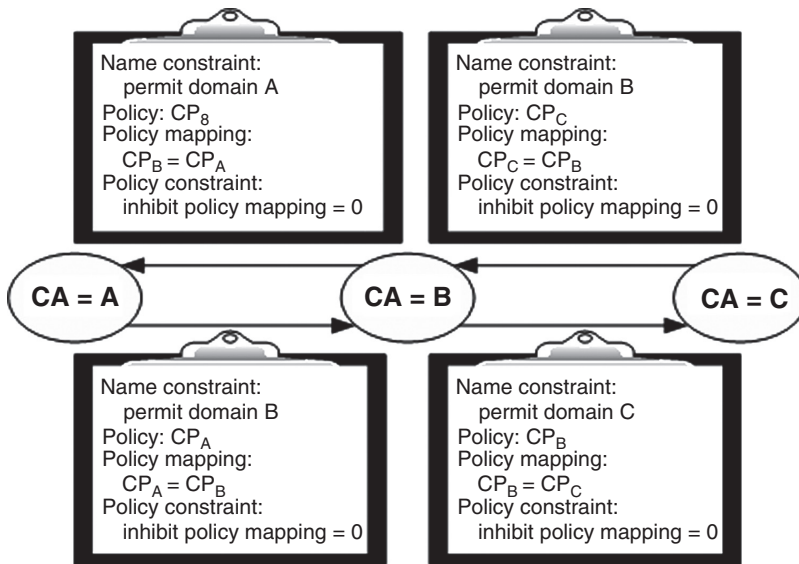

In the case of bilateral cross-certification, policy mapping should be inhibited immediately by using a value of “0” in the “inhibit policy mapping” field of the policy constraints extension in X.509 certificates. When bridge CA is used for interdomain interoperability, a value of “1” should be used in this field. This will permit the issuing CA domain to map its policies to the bridge CA policies and then permit the bridge CA to map its policies to the subject CA domain, in effect mapping from the issuing CA domain to the subject CA domain.

As long as the issuing CA uses its control on inhibit policy mapping, the bridge CA need not use inhibit policy mapping to control the mapping inhibition.

37.6.7 Public Key Infrastructure Interoperability. The complexity of the technology, standards, and products of PKI technology from one domain to another and from one product to another sometimes creates interoperability problems. Yet without interdomain interoperability there can be no global trust, only individual trust.

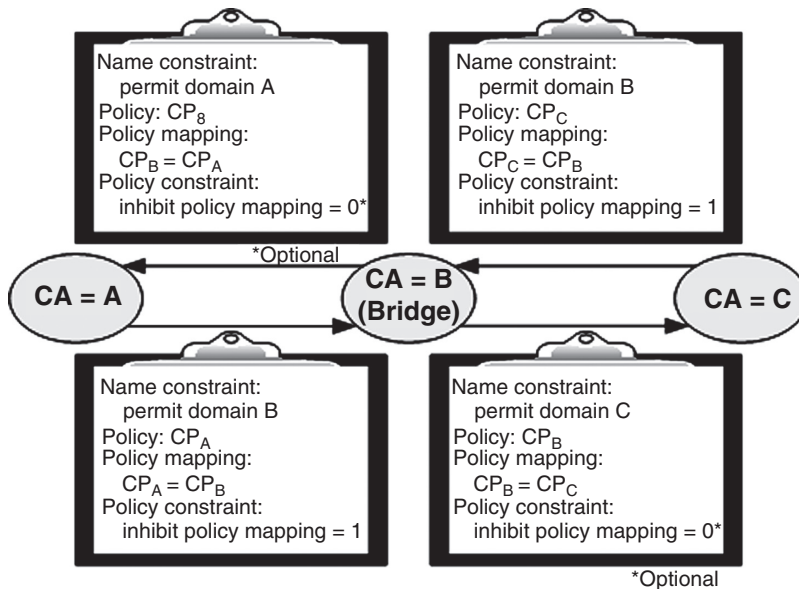

These factors play a critical role in ensuring PKI interoperability:

- Trust path
- Cryptographic algorithms

**EXHIBIT 37.11** Trust Chain Mapping with Dissimilar Policies

- Certificate and CRL formats
- Certificate and CRL dissemination
- Certificate policies
- Names

37.6.7.1 Trust Path. The communicating parties must be able to form trust paths from their trust anchors to their subscribers. This can be achieved through multiple trust anchors, cross-certification, and other trust models described earlier.

**EXHIBIT 37.12** Policy Mapping with a Bridge

37.6.7.2 Cryptographic Algorithms. The communicating parties must implement the cryptographic algorithms, such as hashing, digital signatures, key encryption, and data encryption, used by each other.

In addition, the parties should be able to communicate to each other the algorithms they use. In X.509 certificates and CRL, this information may be contained in the objects themselves, as in the *algorithm* field. In X.509 certificates, for the information being communicated, algorithms such as the digital signature and key encryption algorithm may be carried in the end-entity certificate. The hashing algorithm and the data encryption algorithm can be part of the implicit agreement between the parties or can be carried with the information being communicated. The information also can be obtained from the *supported algorithms* attribute of the X.500 directory entry of the user, although this option is not widely used.

Although the expected public key algorithms used by the CA to create the certificate must be discernible by the recipient (in order to understand the certificate contents), it is important that the certificate not make any assertions as to the symmetric algorithms that may be used. The certificate should be application-agnostic and not impose any rules on applications when not necessary.

In all these situations, the algorithm is identified using the object identifiers. Different organizations may register the same algorithm under their OID arc. Thus, it is important that either the two domains use the same OID for the algorithms, or that their software interpret the multiple OIDs as the same algorithm. For this reason, OID proliferation for algorithms is not recommended.

Variants of the same base algorithm further exacerbate the problems of algorithm interoperability. For example, subtle padding and other differences exist between definitions of the RSA algorithm in the Public Key Cryptography Standards (PKCS) and in the American National Standards Institute (ANSI) X9 committee. Similarly, the Diffie-Hellman algorithm has various modes and various ways to reduce the calculated secret to symmetric key size (i.e., ways to make session keys smaller). Any of these differences in algorithms must be documented through different OIDs so that the OID invokes the appropriate implementation.

It is important that extensions be chosen carefully. Those pertaining to algorithms often have meaning within the context of a particular application. As mentioned earlier, a good example of an extension that should not be placed in a certificate is the *SMIME Capabilities* extension, since it does not set minimum expectations and instead may limit the symmetric key length that can be used by applications.

Such application-specific extensions should be avoided in user/subscriber certificates. The algorithms and key lengths used by the public key (asymmetric) elements are specified in the *Field* values such as *Subject Public Key Information*.

37.6.7.3 Certificate and Certificate Revocation List Format. The communicating parties must share, or must be able to understand, each other's certificate and CRL formats. The most common way to achieve this is to use a common standard, such as X.509. Many times this has not been sufficient due to the ambiguity in the standard and associated encoding schemes, although, over time, those bugs have been worked out. The primary reason today why certificates and CRLs issued by one product may not be understood by another is that either one or both are not compliant with the standard, or one product does not implement all the features of the standard used by the other product.

37.6.7.4 Certificate and Certificate Revocation List Dissemination.

The communicating parties must obtain the certificates and CRLs issued by the various CAs in each other's domain. These certificates and CRLs may be obtained from a repository such as an X.500 and Lightweight Directory Access Protocol (LDAP) server. Alternatively, the certificates and CRLs can be carried as part of the communication protocol between the parties, for example, as defined in S/MIME (Secure/Multipurpose Internet Mail Extension) version 3.

The X.500 and LDAP repositories are based on hierarchical databases. Each node in the hierarchical tree structure belongs to an object class. The node's object class determines the attributes that are stored for that node. Examples of attributes are job title, phone number, fax number, and the like. Certificates and CRLs are also attributes.¹¹

X.500 and LDAP have defined a standard schema for PKI certificates and CRLs. For certificates, these attributes are *userCertificate*, *cACertificate*, and *crossCertificatePair*. The end-entity certificates should be stored in *userCertificate* attribute. All CA certificates should be stored in the forward element of the *crossCertificatePair* attribute of the subject CA. In addition, all certificates issued to the CAs in the same domain should be stored in the *cACertificate* attribute of the subject CA.

Various revocation lists should be stored in the *cRL*, *aRL*, and *deltaCRL* attributes of the issuing CA as applicable.

If the certificates and CRLs are not stored in these standardized attributes, the relying-party software may not be able to obtain these objects. Furthermore, X.500 directory products still may not always interoperate due to additional complexity of the X.500 standard and to product differences. When implementing X.500 directories and connecting X.500 directory products from different vendors, implementers should allow time to make the products and directories interoperate.

37.6.7.5 Certificate Policies. In order to trust and cross-certify each other, the CAs in two domains need to operate under similar policies. Users in the two domains should be able to accept or reject certificates of each other's domains based on the security requirements of the application, and on the policy under which the certificates were issued.

In order to determine the similarity, or equivalence, of the policies of the two domains, the CP should be written using the IETF standard RFC-2527 framework. The CP is represented using an OID in the certificate. To ensure that the user software accepts and rejects certificates based on the application requirements and on the CP, PKI products should be selected and configured so that the CA asserts the certificate policies, policy mapping, and policy constraints extensions appropriately. The user's PKI-enabling software must process these extensions appropriately and fully in compliance with the requirements of X.509 certificate-path validation rules.

37.6.7.6 Names. The communicating domains must not assign the same name to two different entities. X.500 distinguished names (DNs) are steps in that direction but not sufficient to achieve this.

To illustrate the point, consider, for example, CygnaCom, a company incorporated in the Commonwealth of Virginia. While it is highly unlikely that there is another CygnaCom in Virginia, there is no assurance that there is no CygnaCom incorporated in other U.S. states. Thus, it would be possible that c=US, O=CygnaCom could be asserted by the CAs for several different domains.

In order to avoid this name collision and ambiguity, the *name constraints* extension in X.509 should be used. The CA for one domain can prevent any other entity from using a name registered in that domain. The issuing CA (CA “Y” in this example) uses the *name constraints* extension to assert priority and control over the specified identifier. For example, the first CA that certifies a company called *CygnaCom* in its domain should set the *name constraint* attribute in its certificate for its *CygnaCom* stating that only its *CygnaCom* is allowed to issue certificates under the name space *c=US, O=CygnaCom*. If another *CygnaCom* were to come along, CA “Y” would ask the second *CygnaCom* to choose another name in order to avoid name collision. Although this example focuses on the DN, the *name constraint* can be used for any hierarchical name forms, including DN, RFC 822-compliant names, and others.

PKI products should be selected and configured so that the CA asserts the *name constraints* extension appropriately. The user’s PKI-enabling software must process this extension appropriately and fully in compliance with the requirements of X.509 certificate-path validation rules.

37.7 FORMS OF REVOCATION. As discussed earlier, a PKI includes mechanisms for key revocation. It is necessary to make provisions for the revocation of compromised keys in order to maintain the trust relationships of any PKI employed in a real-world environment.

The first form of revocation designed was the CRL. It seems the most appropriate form of revocation, given the distributed authentication framework of PKI. The CRL mechanism allows the CA to generate the objects and the relying parties to process them securely without worrying about the security of the servers or system that supply the CRL, and without concerns about the network(s) over which the CRL has traveled.

37.7.1 Types of Revocation-Notification Mechanisms. However, there have been several concerns about the CRL, and these concerns have led to other forms of revocation-notification mechanisms. Many of these mechanisms are variations on the CRL in the sense that these are revocation lists, but they are not complete. The second category of revocation mechanisms defers the processing of revocation information to a server for example, through the Online Certificate Status Protocol (OCSP); see RFC 2560. A third category of mechanisms lets the users check the status of a single certificate from the directory and allows the CA to update the status of that certificate in the directory. A final category lets a CA or another trusted server organize the revocation information in a B-tree.

Which mechanism(s) to choose depends on a variety of factors, such as:

- The communication model (i.e., which class of users is communicating with which other class). For example, if a user communicates with several users who are subscribers to the same CA, a single CRL from that CA will provide relevant information about all those targeted users. If a user is communicating with users who belong to different CAs, each CRL provides information about only one user.
- The directory architecture: Where they are located and what portions of the directory information is replicated or shadowed?
- The communication bandwidth available.
- The bind time (i.e., the time to set a connection with the repository in order to perform retrievals and updates) to access the repository.
- The size of the revocation response from the repository (e.g., the CRL size).

- The processing load on the repository, especially for digital signature *generation* on the revocation information.
- The processing load on the user workstation, especially for digital signature *verification* on the revocation information.

37.7.2 Certificate Revocation Lists and Their Variants. The first set of mechanisms, CRL and its various forms, is the most versatile, effective, and recommended approach for revocation notification. Like X.509 certificates, CRLs are expressed in ASN.1 format. There are several basic types of CRL, and they should be carefully considered, based on the user communication model and anticipated revocation rate:

- Full and complete CRL
- Authority revocation list (ARL)
- Distribution-point CRL
- Delta CRL

37.7.2.1 Full and Complete CRL. The full and complete CRL is a CRL that contains the revocation information for all certificates issued by a CA. This type of CRL is rarely seen; instead a normal CRL includes only information about revoked certificates and not currently valid ones. Expired certificates are not included, and revoked certificates will drop off the CRL when they expire.

37.7.2.2 Authority Revocation List. The ARL is a CRL that contains the revocation information for all the CA certificates issued by a CA; that is, the ARL is a subset of CRL for certificates issued to the CAs only. The ARL is a very desirable mechanism for these reasons:

- It is likely to be short. A CA is likely to certify fewer CAs than other types of subscribers. Also, given that CAs are expected to operate with a great deal of vigilance, and given that CAs are not going to be revoked for reasons such as name change or organizational affiliation change, CAs will be revoked far less often than the end entities. These factors will contribute to making the ARL very small.
- For all of the certificates except one, only the ARL needs to be checked, since in a certificate path all but the last certificate is issued to a CA.

Due to a security flaw in X.509 version 1, a CA should never issue ARLs defined using that version. In X.509 version 1, there is no difference between the CRL format and the ARL format. Since both CRLs and ARLs are signed by the same CA, if an adversary (directory or network adversary) were to supply an ARL to the relying party in lieu of a full CRL, the relying party would have no way of knowing that it had received an ARL instead of the requested CRL. The ARL would not have end-entity revocation information and therefore could mislead the relying party into using the revoked certificate of an end entity.

The X.509 version 2 ARL fixes this security flaw using an *issuing distribution point* extension. An ARL must use this extension and assert a field that states that the list contains only CA certificates. The presence of this field in the signed ARL tells the

37 · 20 PKI AND CERTIFICATE AUTHORITIES

relying party that it is not a full CRL. Now, if an adversary were to supply an ARL in lieu of a CRL, the relying party would detect this substitution by using the *issuing distribution point* field.

This is one of the several security reasons that PKI-enabling software must be able to process the various extensions properly in accordance with the requirements stated in X.509 standard.

37.7.2.3 Distribution-Point CRL. Distribution-point CRL is a mechanism that has several useful functions:

- To replicate a CRL
- To consolidate revocation information from the various CAs so that the relying parties need to obtain only one CRL
- To partition the revocation information for the subscribers of a CA into multiple smaller pieces

This latter function, partition, is achieved by asserting the *CRL Distribution Point* extension in the certificate that points to the name entry under which revocation information for the certificate will appear. The partitioned CRL will assert the same name in the *Distribution Point* field of the *issuing distribution point* extension in the CRL.

Since all the partitioned (distribution point) CRLs are signed by the same CA, it is not sufficient for the relying party simply to validate the CA's signature on the Distribution Point CRL. The relying party must match the Distribution Point name in the *issuing distribution point* extension of the CRL with the Distribution Point name in the *distribution point* extension in the certificate.

37.7.2.4 Delta Certificate Revocation List. Yet another way to reduce the size of the CRL is to publish changes to the revocation information since the last CRL. The CRL that contains changes only is called the *delta CRL*, and the CRL to which changes are published is called the *base CRL*. The delta CRL can be applied to any of these CRLs: CRL, ARL, and Distribution Point CRL. In order to construct current revocation information, the latest delta CRL and its base must be used. There is an algorithm that could be used to allow a subset of changes to be applied to an earlier CRL that would still match the digital signature of the new CRL.

37.7.3 Server-Based Revocation Protocols. Server-based revocation uses protocols, such as On-Line Certificate Status Protocol (OCSP) and Simple Certificate Validation Protocol (SCVP). In general, these protocols suffer from several flaws, including these:

- Since the revocation information is produced at the server, the communication channel between the relying party and the server must be secured, most likely by using digital signatures.
- Signed operations will limit server scalability since digital signature generation is computationally intensive.
- Since the revocation information is produced at the server, the scheme requires a trusted server as opposed to an untrusted repository.

- Revocation of a server public key requires a method for checking the server public key status. This method is likely to use the server public key as an additional trust anchor or to rely on a CRL mechanism.
- There needs to be a nonsuppressible mechanism for the CA to provide revocation information to the trusted server; that is, the CA should know whether the revocation information has or has not reached the trusted server. Although a CA itself can act as a trusted server, this is not recommended for security reasons; in addition, we do not want to impose the high-performance requirement on the CA architecture. The trusted server must be a high-performance system.
- There are no standards in the area of CA to provide nonsuppressible mechanisms for transmitting the revocation information to the trusted server.

These mechanisms may be desirable under one of four situations:

1. Need to have thinnest possible PKI client
2. Need to generate revenue for CA services
3. Need to check changing credentials, such as available credit
4. Need to update dynamic credentials, such as the remaining credit line

The last two situations permit the trusted server to provide the revocation information and to check or change the credentials of the subscriber.

Delta CRLs and server-based revocation/authentication protocols such as OCSP (RFC 2560) are standards-compliant and can provide the same information as in the CRL for a single certificate in a significantly smaller bandwidth. They do require some form of acceptable authentication since the original CA will not be available for signing.

37.7.4 Summary of Recommendations for Revocation Notification.

The most scalable and versatile revocation-notification mechanism can be achieved by using a combination of:

- CRLs.
- Replication of the CA directory entry, at locations determined by the enterprise network topology, for fast access to CRL.
- Use of ARLs.
- Consolidation of ARLs for all CAs in a domain through the use of distribution points. Consolidation is achieved by placing the name of a CA that can revoke a certificate in the certificate's CRL *Distribution Point* extension.
- Consolidation of all the reason-codes of key compromise for all certificates in a domain through the use of the *Distribution Point* extension. This CRL can be issued very frequently to meet the freshness requirements of the domain. This mechanism makes the CRL mechanism as current as the OCSP.
- Partitioning routine revocation information using Distribution Point CRLs if CRLs become too large.

37 · 22 PKI AND CERTIFICATE AUTHORITIES

Several other techniques can help improve CRL retrieval efficiency:

- Repositories may store both enciphered CRLs to send to the relying parties and also deciphered (plaintext) CRLs to perform fast searches. Storing both forms reduces the overhead that would result from using encryption or decryption at the time of each request.
- If the repository does not store any private information, bind operations for retrieval can be configured to require no authentication, thus eliminating another potential performance bottleneck.
- CRL size can be reduced by having a short validity period for the certificates, by using a coarse domain name so that reorganization does not invalidate a name, and by allowing some changes (e.g., name change or transfer) without forcing revocation.

37.8 REKEY. The public key certificates for the subscribers have a defined validity period. Once the validity period expires, subscribers require new public key certificates. There are two primary reasons why public key certificates have a limited life. One relates to the life of a private key based on the potential cryptanalysis threat. Another reason is to help control CRL size since no certificate gets off a CRL until it expires.

No public key should be used longer than the estimated time for brute-force cryptanalysis using current technology (its *cryptanalysis threat period*). At that point, the certificate should be assigned a new public key (i.e., it should be *rekeyed*). However, before the cryptanalysis threat period expires, the same key can be renewed or *re-certified*. Certificates can be renewed easily by having subscribers send a digitally signed request to the CA or by having the CA perform automatic renewal. During renewal, any information (other than the subscriber public key) may be changed.

For the foreseeable future, the life of a 1024-bit RSA key can be expected to be 25 years. By reusing the same key with new certificates for as long as possible, the number of past keys required to be escrowed in order to retrieve or validate older files is reduced. The level of trust should also be considered when rekeying, but keys stored in tamper-resistant hardware can be expected to achieve their full lifetime.

Note: NIST SP800-78-3 recommends that after 2013 only 2048 bit keys be used.

Elements using soft keys are inherently at risk to a determined attack and should be used only for lower levels of trust.

Certificates also can be rekeyed easily by having the subscriber send a digitally signed *rekey request message* that also contains the new public key. The message is signed using the current private key so that it can be verified using the current public key. If the subscriber being rekeyed is a CA, these requirements also come into play:

- The relying parties should be able to verify certificate chains after the CA is rekeyed.
- The relying parties should be able to verify CRLs issued by the CA.
- The rekey should not have a ripple effect on the PKI. Just because one CA rekeys, other CAs or end entities should not have to rekey.
- The length of certificate paths should be minimized.
- The operational impact on the PKI entities should be minimal.

A good way to meet these requirements is for the CA to:

- Issue all current valid certificates when it rekeys, without changing the validity periods in the subscriber certificates.
- Continue to sign CRLs with all current valid private keys. This will result in multiple CRLs, all with the same information. A CA private key is considered valid until all certificates signed using that key have expired.

If the CA is a trust anchor, it can use one of two approaches to rekey itself in-band, over the untrusted network:

1. The CA can send out a rekey message that contains its new public key and is signed using the current key. The CA needs to ensure that all the subscribers receive and process the rekey message prior to expiration of the current key.
2. The CA can provide the hash of the next public key and parameters (if the cryptographic algorithm has parameters; RSA does not have parameters, but Digital Signature Standard [DSS] does) with the current key. When it is time to publish the new public key, the CA can publish a new self-signed public key certificate that contains the new public key and parameters as well as the hash of the next public key and parameters.

37.9 KEY RECOVERY. Subscriber public keys can be used to encrypt data-encryption keys (for symmetric key encryption). Such data-encryption keys are used to encrypt data quickly with the lower overhead of symmetric key encryption. Subscribers require their private keys to decrypt the data-encryption keys and thus allow decryption of the data.

It is critically important to distinguish between *signing* keys and *data-encryption* keys. The former (any key that asserts **nonrepudiation**) may *never* be subjected to key recovery; the latter *may* be protected using key-recovery techniques.

High levels of trust keys may require a separate identification key that may not be used to sign a document; this login key should have only the signing bit and not the nonrepudiation bit set in the Key Usage extension.

Sometimes a subscriber's private key token (e.g., a diskette, hard drive, smart card, etc.) may be corrupted or the subscriber may forget the password associated with the token. Similarly, sometimes a subscriber may not be available, yet the subscriber's employer may need to decrypt corporate information encrypted by the missing subscriber. Key-recovery techniques are designed to meet these emergency needs for access to encrypted information. Inherently, they provide a form of back door to the keys, but they also impose additional overhead costs. Thus, the need to provide key recovery should be balanced carefully against potential costs and complexity.

The two most popular forms of key-recovery mechanisms are:

1. **Key escrow.** Under this form, the subscriber's long-term private decryption key is provided to a trusted third party called a *key recovery agent* (KRA)
2. **Key encapsulation.** Under this form, the subscriber encrypts the data-encrypting key using the public key of the KRA so that the KRA can decrypt the data.

Of these two schemes, key escrow is becoming more widely available in the PKI products because it is simpler to implement at the infrastructure level. It is also

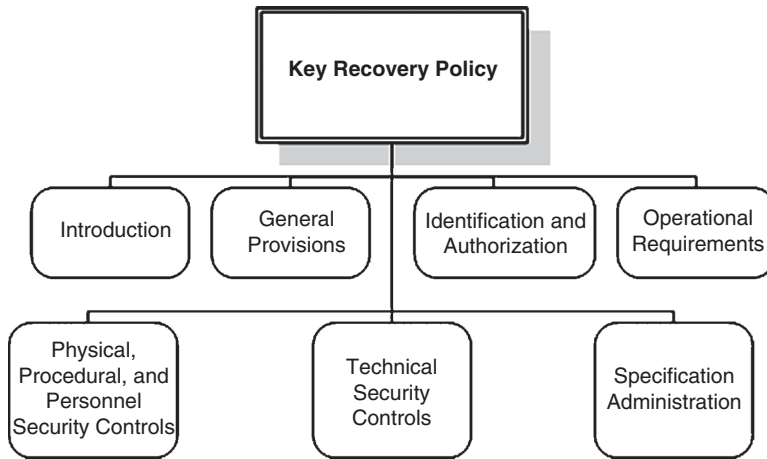

EXHIBIT 37.13 Elements of a Key Recovery Policy

independent of organization boundaries between the sender and receiver of encrypted communications. If a party's private data-encryption key is escrowed, then communications to the party can be decrypted.

Subscribers may always recover their own data-encryption key from the key-recovery system. Authorized third parties, such as a subscriber's employer, also may request keys. Such an authorized party is called a *key recovery requester* (KRR). All of the components are governed by a *key recovery policy* (KRP) and associated *key recovery practices statement* (KRPS). The KRP and KRPS are akin to the *Certificate Policy* and *Certification Practice Statement* but have some differences. One of the main differences is in the technical security-controls sections. There are several requirements to check the communication protocols among the components to ensure confidentiality, integrity, and authorization. Exhibit 37.13 illustrates the components of a key-recovery system, as would be expressed in the KRPS.

A general criticism of key recovery is that it provides secrets to a single party, namely a KRA. One way to mitigate that concern is to share the secret among multiple recipients in a way that requires cooperation (if it is authorized) or collusion (if it is not) among two or more holders of the escrowed secret. For example, superencryption (encryption of ciphertext) can make unauthorized discovery of a key more difficult. The secret key S is encrypted with one recipient's public key (say, K_1), producing a ciphertext, represented as $E(S, K_1)$, and then that ciphertext is super-encrypted using a second recipient's public key, K_2 , to produce the ciphertext $E(E(S, K_1), K_2)$. Unlike encryption of the same message for two recipients, where each recipient can decrypt the ciphertext independently, superencryption requires decryption by each recipient in the reverse order of priority. Thus, if a user encrypts a secret key using A's public key and then superencrypts the ciphertext using B's public key, key recovery requires decryption by B using the corresponding private key and then decryption of the resulting ciphertext by A with that user's private key.

To use superencryption so that fewer than all recipients may decrypt the key, the sender encrypts to a first group of recipients and then superencrypts to a second group of recipients. Thus, any one of the members of the first group and any member of the second group of recipients can cooperate to decrypt the secret key.

This technique allows key escrow even in the absence of a formal PKI, such as in informal webs of trust using PGP.

Another solution to making collusion more difficult in key escrow is to split the key using Shamir's n out of m rule.¹² In a properly implemented key-splitting scheme, parts of a secret key are distributed to m destinations and at least n recipients are required to reconstitute the secret key. Thus, $n-1$ or fewer persons colluding together cannot determine even a single bit of the escrowed key. Successful collusion requires at least n individuals. The split-key approach can be applied to key escrow, in which case the private key can be split and different splits can be provided to different KRAs. Alternatively, the split-key approach may be applied to encapsulation, where the session key can be split, and different splits can be encrypted using public keys of different KRAs.

This strategy also theoretically allows full reconstitution of the secret key to be performed by the authorized recipient of the partial keys, instead of by any of the escrow agents.

37.10 PRIVILEGE MANAGEMENT. The primary purpose of PKI is to provide entity authentication in a global, distributed environment. In most systems and applications, authentication becomes the basis for access control. There are three fundamental ways to implement access control:

1. The systems and applications can perform access control on their own. The PKI continues to provide the authentication framework.
2. The privileges, attributes, roles, rights, and authorizations can be carried in a public key certificate in the *subject directory attribute* extension.
3. The privileges, attributes, roles, rights, and authorizations can be carried in an *attribute certificate*. The X.509 standard is being revised to include the concept of attribute certificates. The attribute certificates carry privileges and authorizations instead of the public key, and thus provide a distributed authorization framework.

User login, signing, and encryption certificates should never be used to carry authorizations or application information. Where needed, separate certificates can be issued for those tasks. Such authorization certificates can be issued daily, or even for shorter periods, eliminating the need for a CRL since the certificate would expire before one would be issued. These authorization certificates could be used in place of Kerberos (the Greek mythological three-headed dog that guards the entrance to Hades) Tickets. Exhibit 37.14 summarizes the pros and cons of each of the three approaches.

These factors should be considered when architecting an access infrastructure. Although the attribute certificate seems to be the latest fad in the PKI world, users should carefully study putting privileges in public key certificates to save the cost of implementing a Privilege Management Infrastructure (PMI) over and above the cost of PKI.

37.11 TRUSTED ARCHIVAL SERVICES AND TRUSTED TIME STAMPS.

PKI technology supports global electronic commerce through the use of digital signature technology. Digital signature technology is a detection or passive mechanism. In other words, the technology does not *prevent* someone from modifying data in storage or in transit, nor from impersonating someone else. The technology merely detects that an attempt had been made to modify the data or that someone had tried to impersonate someone else.

EXHIBIT 37.14 Privilege Management

Alternative	Pros	Cons
Application-based access control	Easy to implement. Does not require additional infrastructure, so saves cost.	Need to manage privileges on an application-by-application basis. Synchronization of privileges may be hard as applications increase and as they are distributed. Security may be compromised if privileges are not removed from all applications. Higher operational costs.
Public key Certificate	Easy to add to PKI. Privileges can be managed easily by revoking certificate.	Changes in privileges require revocation of identity certificate. Sometimes this is a small price to pay for savings that result from not having to deploy and operate a separate privilege management infrastructure (PMI). Parties issuing identity certificate may not have authority to bestow privileges.
Attribute Certificate	Privileges can be managed easily by revoking attribute certificates. Change in privilege does not require revocation of public key certificate.	Cost of privilege management infrastructure (PMI).

In a court of law, digital signatures may be disputed long after they were applied, if, for example, the cryptanalysis threat period for the keys has expired. In those circumstances, producing a document with a verified digital signature may not prevent repudiation. A party could claim that the cryptanalysis threat period has passed and the private key might have been discovered or broken by an adversary.

To mitigate both of these threats—data corruption and expiry of the cryptanalysis threat period—trusted archival services are required for transactions with a potential for this kind of dispute. Such an archival service also would be able to safeguard associated certificates and CRLs. Trusted archival services should depend on controls such as physical security, stable media (e.g., write-once read-many [WORM] devices), and appropriate techniques to maintain readability despite changing technologies. Such services should be capable of error-free transcription of data on older media and of translating outdated encoding into more modern media, and into current encoding schemes. For example, Extended Binary Coded Decimal Interchange Code (EBCDIC)–encoded data on nine-track magnetic tapes could be copied onto optical disks using ASCII encoding.

A related technology is the trusted time stamp, where a trusted third party attaches the current valid time to a document and signs it to prove the existence of the document

at a given time. If the document owner does not want to reveal the contents of the document to the time stamp server, then a hash of the document may be stamped and signed instead.

In most applications, a trusted archival service may obviate the need for trusted time stamp service because, for the long term, the trusted archival service can attest to the time of the transaction. For the short term, both parties can date and digitally sign the transaction when it is consummated, rendering it valid as a contract. If the date is not acceptable to any party—it is either too far in the future or in the past—that party can either reject the transaction or invoke some dispute-resolution procedure immediately.

37.12 COST OF PUBLIC KEY INFRASTRUCTURE. One of the misconceptions about Public Key Infrastructure technology is that it is too costly, but these costs should be compared to the alternatives.

Short of taking a major risk, there is no practical technology other than cryptography to protect data in transit over untrusted network. The only choice, then, is between symmetric key cryptography and public key cryptography. Aside from the difficulties of distributing and supporting symmetric, secret keys, such cryptosystems require approximately n^2 keys for a group of n individuals who must communicate with each other.

A secret key cryptosystem requires n^2 keys to be kept confidential, with their integrity maintained; PKI requires managing only n keys. Clearly, it should be cheaper to maintain the integrity of n keys than to manage n^2 keys and their confidentiality and integrity. PKI is needed to manage the public keys.

PKI costs seem large when they must provide global trust and interoperability, something not asked of most systems or infrastructures. Currently, no other technology works as well or is as cost effective as PKI to achieve global, secure, trusted communication and electronic commerce. The alternative is to assume the risk without PKI, or to continue with the last century's approach of paper-based trust.

38.1 INTRODUCTION. The topic of secure coding cannot be adequately addressed in a single chapter. Unfortunately, programs are inherently difficult to secure because of the large number of ways that execution can traverse the code as a result of different input sequences and data values. The additional pressures to get the applications to market can also take a toll on the secure coding process.

This chapter provides a starting point and additional resources for security professionals, system architects, and developers to build a successful and secure development methodology. Writing secure code takes coordination and cooperation of various functional areas within an organization, and may require fundamental changes in the way software development currently is designed, written, tested, and implemented, as well as a change in corporate culture as it pertains to software development.

38.2 POLICY AND MANAGEMENT ISSUES. There are countless security hurdles facing those writing code and developing software. Today dependence on the

38 · 2 WRITING SECURE CODE

reliability and security of the automated system is nearly total. For an increasing number of organizations, distributed information processes, implemented via networked environments, have become the critical operating element of their business. Not only must the processing system work when needed, but also the information processed must retain its integrity so that it can be trusted in use. Because of a general lack of basic IT organizational discipline, and adherence to fundamental software and systems development and maintenance principles, most software development efforts have been significantly lacking at best. If the same inadequate practices are left unchanged in the face of increasing cyber threats, they will continue contributing to the insecure systems of tomorrow, just as they have contributed to the insecure systems of today.

The fundamental problem underlying this kind of assertion is the difficulty of justifying what are often perceived as non–revenue-generating activities and the need to get the product to market on or before delivery timelines. The difficulty also stems from the infeasibility of proving a negative. For example, one cannot prove to the uninvolved or unimpressed observer that the time, money, and human resources spent on prevention are well spent simply because a disaster or incident was averted. Such an observer will take the fact that it did not occur as evidence that the possibility never really existed, or that the problem was exaggerated. In the same way, a skeptical observer may take the absence of security breaches as evidence that no such threat existed, or that it was never as bad as claimed. The problem is exacerbated after spending time and effort on establishing security policies, security controls, and enforcement mechanisms.

In both cases, the money, time, and effort expended to prevent adverse computing consequences from harming an organization are viewed with suspicion and not qualifying at a level to justify the change in delivery schedule or funding. However, such suspicions are not new in the world of information processing. Throughout the history of IT, this attitude has existed regarding problem-prevention activities such as quality assurance, quality control testing, documentation, configuration management, change management, and other system-management controls designed to improve quality, reliability, and system maintainability.

If you consider the analogy of application development as being similar to the way a house is built, it is much harder to implement and integrate something after the fact. Security is not and should not be considered a superficial exercise similar to hanging the drapes or changing a light bulb. It is like the plumbing of a house, and it needs to be implemented with that in mind.

Problems with security are management problems. Management dictates how much time and money can be spent on security activities such as risk management and software testing. How much time and energy are invested in designing, building, testing, and fixing software is in the end a management call. Thus, the primary concern of those striving to improve software security must be the correction of these same basic and fundamental IT management defects; otherwise effective security can never be attained or maintained.

38.2.1 Software Total Quality Management. The nature of the computer security challenge is that of dynamically changing vulnerabilities and threats, based on rapidly changing technologies, used in increasingly complex business applications. Organizations need to build software around the idea of a continuous improvement model, as popularized by the total quality management (TQM) articulated in the ISO 9000 family of standards. For purposes of quality improvement, this model was viewed as a continuing cycle of plan-do-check-and-act. For software security, it can be thought of as a cycle of plan-fix-monitor-and-assess. A security management process to

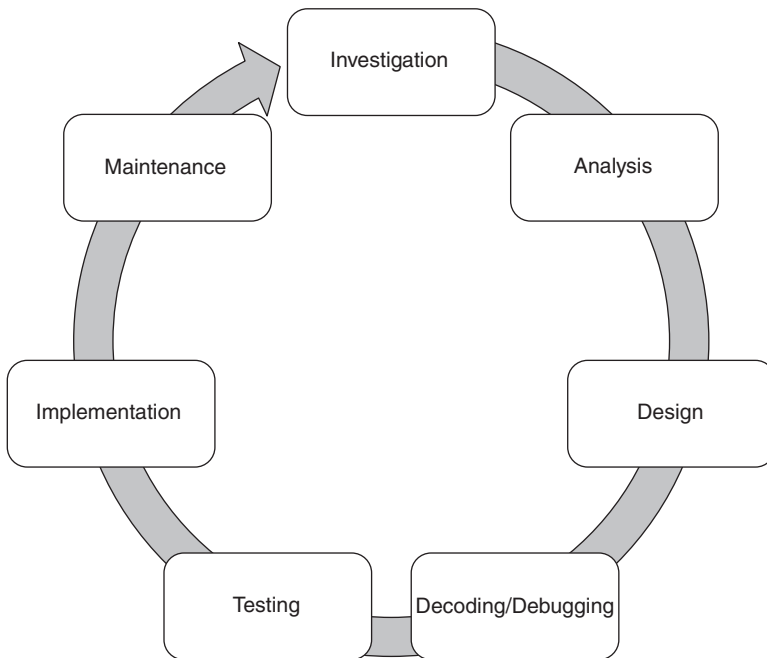

EXHIBIT 38.1 Common Lifecycle Process

execute this model must be established and integrated into the day-to-day operations of the business. Integration means that the security initiative does not stand alone as a watchdog or act merely as an audit function, and it must move away from a policing function. Security must be considered an essential part of all other systems development and management activities, including requirements definition, systems design, programming, package integration, testing, systems documentation, training, configuration management, operations, and maintenance. Security must be viewed as good architecture. In other words, security must be a part of the entire development lifecycle and management gates of the project. Exhibit 38.1 provides a common lifecycle process as described in Chapter 39.3.1.

A security management process must be designed in such a way that the activities of planning, fixing, monitoring, and assessing are accomplished in an iterative fashion for systems being defined, designed, and implemented and for systems that are currently executing the day-to-day business operations.

For many organizations, it has not been uncommon for software to be built with little or no attention to security concerns. Consequently, many business-critical applications have made their way into full production with inadequate or nonexistent security controls in place. For example, a quickly built application to resolve an initial need for tracking information within a database through a Web interface may not get all the access control configurations designed into the application that are needed for proper security. It serves a quick purpose but becomes a long-term tool because of its success. Because of the nature of business (moving from one task to the next), nothing is really done to develop it into the function it now fills. In addition, the longer the application stays in use, the greater the likelihood that the original developers are to transition, and any historical knowledge or documentation will be lost. This makes the ability to update or correct the security of the application less desirable. As a result, users or

38 · 4 WRITING SECURE CODE

hackers may be unintentionally or intentionally capable of accessing and modifying critical information within the database or within the system itself. Fortunately, this trend has started to change, but it is still in need of significant attention. Because such systems are already operating, the only way realistically to identify and assess their security risks outside of replacing the application outright with an application that includes the security requirements is to begin aggressively monitoring for intrusions and then to design and implement corrective security policies and controls based on what is discovered. The effective sequence of security activities for systems already in operational status will be to monitor current operations, assess suspicious activity, plan a corrective policy and technology control, implement the control on the system, and then monitor for continuing effectiveness.

38.2.2 Due Diligence. To address the software and code security effectively, it must become an issue for management, just as other security concerns have began to demand management attention. Business executives and IT managers are now all too familiar with the concept of due diligence as applied to the uses of information technology. Because of the potential for legal fallout, it has become necessary to view IT-related actions through the definitions of due diligence and reasonable care.

The significance of the concepts of due diligence and reasonable care is that they allow for an evolving metric against which an organization's application security deliberations, decisions, and actions can be compared. The comparison is usually against a similar organization, in like circumstances of vulnerability and threat, and with similar predictable adverse impacts on customers, partners, shareholders, employees, and the public.

For example, if one company employs a security control and does not experience any security breaches that the technique was supposed to prevent, that fact could be used to establish a baseline against which other similar organizations could be compared. If enough similar organizations employ the same technique, the security control may become categorized as a best practice for that industry.

If, however, another company in the same industry did not employ the security control and did experience security breaches of the type the technique was suppose to prevent, it might clearly indicate a lack of due diligence or reasonable care. Software security decisions and implementations are not a one-time event, but need to be under a continuous process of risk evaluation, management, and improvement. The decisions start with the selection of the development language and continue from there. The choice of an interpreted versus compiled language could have an impact not only to development skills required and timelines, but how the use of the languages libraries are use and the impact future updates can be accomplished by the customer. A good example is the recent¹ security issues that have plagued Java and Microsoft products.

It is therefore imperative, in order to demonstrate an ability to exercise continual due diligence to management, to establish a documented computer security risk management program, regardless of internal or external software development, and to integrate it into the overall management processes of the software development process. Nothing less will demonstrate that a company, and its board, is capable of assessing computer security threats and of acting in a reasonable manner.

For software developers working on commercial software for sale to a specific client under contract, or even to a wide range of customers governed by end-user license agreements, the exercise of due diligence and improved security may reduce

the risk of lawsuits claiming damages for negligence. Whether successful or not, such lawsuits are never positive publicity for makers of software products.

38.2.3 Regulatory and Compliance Considerations. Regulatory and compliance considerations have become a significant aspect to most businesses. The additional aspect of software development increases the need to be aware of the implication state, federal, or international regulation may have on a development project. Compliance with nongovernmental industries may also need to be considered.

If an organization is subject to specific regulations (e.g., Sarbanes-Oxley legislation), then documentation of the errors encountered, and the resulting internal reporting and remediation efforts, is critical. The error should clearly indicate how it was identified, who identified it, how it was reported to management, what the remediation will be, and when it is anticipated to be completed. Without these details, management may encounter significant difficulties in confirming that adequate internal control mechanisms exist, together with the appropriate and adequate involvement of management. In addition, an error could result in a control weakness being identified by the external auditors or, even worse, as a material weakness (a material weakness would be the use of a programming language that has a known inherent flaw rather than another more appropriate and without the flaw, similar to using aluminum instead of steel for a bridge), depending on its nature and severity.

Additionally, when errors are noted that affect multilocation systems or applications, the significance and materiality—that is to say the extent to which the errors impact or may impact the system or any other system to which the application interfaces—must be considered from the aspect of both the subsidiary and the headquarters locales.

Since laws differ among states and countries, what might be considered legally acceptable standards of privacy or accounting in one locale might not be acceptable elsewhere. As a result, careful consideration of the requirements and intended uses or customers must be established as part of the project initiation and due diligence processes.

38.3 TECHNICAL AND PROCEDURAL ISSUES. Security should be integrated into every stage of the application life cycle. This includes the requirements analysis, the design stage for software, and the operating system security kernel, in corporate policy development, and in human awareness, training, and education programs.

Writing secure code can be a daunting and technically challenging undertaking. That is not to say that it cannot be done, but it requires the developer to work in conjunction with the rest of the project team and other key stakeholders to meet the challenges that must be defined, reconciled, and overcome prior to the release of the software or system. The additional push to market that can drive the rapid development process can also have a negative impact on the security of the application. The problem must be dealt with in two ways, technical and procedural. Technically, the programmers must be aware of the pitfalls associated with application development and avoid them. Procedurally, the development team and organization need to adhere to a consistent methodology of development. This consistency also needs to include the identification of security risks at every stage of the process, including the requirements analysis.

38.3.1 Requirements Analysis. Security must be a part of the requirements analysis within any development project. Most application developers know that adding

38 · 6 WRITING SECURE CODE

security after the fact increases cost and time, and becomes more complicated. Requirements can be derived from different sources:

- Functional needs of the system (this includes the operating system the application will run on)
- National, international, or organizational standards or guidelines
- Regulatory restrictions
- Sensitivity level of data
- Existing security policies
- Cost/benefit analysis
- Risk rating

The purpose of analysis is to determine what information and processes are needed to support the desired objectives and functions of the software and the business model.

38.3.2 Design. The informational data gathered during the analysis gathering goes into the software design as requirements. What comes out of the analysis are the data, logic, and procedural design.

Developers take the data and the informational model data and transform them into the data structures that will be required to implement the software. The logic design defines the relationships between the major structures and components of the application. The procedural design transforms structural components into descriptive procedures. Access control mechanisms are chosen, rights and permissions are defined, any other security specifications are appraised, and solutions are determined. A work breakdown structure includes the development and implementation stages. The structure includes a timeline and detailed activities for testing, development, staging, integration testing, and product delivery.

The decisions made during the design phase are pivotal to application development. The design is the only way the requirements are translated into software components. It is in this way that software design is the foundation of the development process, and it greatly affects software quality and maintenance. If good product design is not put in place in the beginning, the rest of the development process will be that much more challenging.

38.3.3 Operating System. The operating system security kernel is responsible for enforcing the security policy within the operating system and the application. As such, the architecture of the kernel operating system is typically layered, with the kernel at the most privileged layer. This is a small portion of the operating system, but all references to information and changes to authorization pass through the kernel.

To be secure the kernel must meet three basic criteria:

1. **Completeness.** All access to information must go through the kernel.
2. **Isolation.** The kernel must be protected from unauthorized access.
3. **Verifiability.** The kernel must be proven to meet design specifications.

As mentioned, the kernel runs in the most privileged layer. Most operating systems have two processor access modes, user and kernel. General application code runs in user mode, while the operating system runs in kernel mode. Kernel mode allows

the processor full access to all system memory and CPU instructions. When applications are not written securely, this separation of modes can become compromised, enabling exploitation of vulnerabilities through arbitrary code, buffer overflows, and other techniques.

38.3.4 Best Practices and Guidelines. “Best practices” is a term that can cause vigorous debate, especially with regard to security. Best practices in general, and particularly with regard to security, often fall prey to a dogmatic, and sometimes blind, devotion to nonsensical practices that have little to do with security and more to do with faith or tradition. Regardless, best practices help provide a set of guidelines that help provide structure. In addition, best practices can be adapted to help meet the needs of a particular situation. An example would be the National Institute of Standards and Technology (NIST) Special Publication Series 800. This series provides best practices and recommendations that can be adapted or integrated into other practices to assist in improving and eliminating the tradition to a particular practice that may no longer have a legitimate use. Considering this, most general security textbooks contain recommendations on security-related aspects of programming—see, for example, Stallings—that do in fact have a very real benefit in creating more secure software.

In addition to designing security into a system from the start, there are also some obvious guidelines that will help in developing secure software:

- Impose strong identification and authentication (I&A) for critical and sensitive systems in addition to the I&A available from the operating system; ideally, use token-based or biometric authentication as part of the initialization phase of your application.
- Document your code thoroughly, including using data dictionaries for full definition of allowable input and output to functions and allowable range and type of values for all variables.
- Use local variables, not global variables, when storing sensitive data that should be used only within a specific routine (i.e., use the architecture of the process stack to limit inadvertent or unauthorized access to data in the stack).
- Reinitialize temporary storage immediately after the last legitimate use for the variable, thus making scavenging harder for malefactors.
- Limit functionality in a specific module to what is required for a specific job (e.g., do not use the same module for supervisory functions and for routine functions carried out by clerical staff).
- Define views of data in databases that conform to functional requirements and limit access to sensitive data (e.g., the view of data from a medical records database should exclude patient identifiers when a worker in the finance department is using the database for statistical aggregation).
- Use strong encryption (*not* homegrown encryption) that has industry-standard routines to safeguard sensitive and critical data on disk. Locally developed, homegrown encryption is generally not as safe.
- Disallow access by programmers to production databases.
- Randomize or otherwise mask sensitive data when generating test subsets from production data.

38 · 8 WRITING SECURE CODE

- Use test-coverage monitors to verify that all sections of source code are in fact exercised during quality assurance tests; investigate the functions of code that never is executed.
- Integrate logging capability into all applications for debugging work, for data recovery after crashes in the middle of a transaction, and for security purposes such as forensic analysis.
- Create log-file records that include a cryptographically sound message authentication code (MAC) that itself includes the MAC of the preceding record as input for the algorithm; this technique ensures that forging a log file or modifying it will be more difficult for a malefactor.
- Log all process initiations for a program and log process termination; include full details of who loaded the program or module.
- Log all modifications to records and optionally provide logging for read access as well.
- Use record-level locking to prevent inadvertent overwriting of data on records that are accessed concurrently. Be sure to unlock a sequence of locks in the inverse order of the lock sequence to prevent deadlocks. (Thus, if you lock resource A, B, and C in that order, unlock C, then B, then A.)
- Sign your source code using digital signatures.
- Use checksums in production executables to make unauthorized modifications more difficult to conceal.

Mike Gerdes, former manager at AtomicTangerine, contributed these suggestions in the course of a discussion:

- Recommend the readers adopt a practice of designing code in a more holistic fashion. A common practice is to write and test routines in a way that verifies the code processes the data in the way intended. To avoid the effects of malicious code and data input attacks, the programmer must also write code that deals with what is *not* supposed to be processed. A more complete design methodology would also include testing of all inbound information to ensure exclusion of any data which did not fit the requirements for acceptable data. This method should be applied to high-risk applications and those with an extremely arduous test cycle and will eliminate many of the common attack methods used today.
- Establish the criteria for determining the sensitivity level of information contained in, or processed by, the application and subroutines.
- If they are not already present, consider implementing formal control procedures in the software programming methodology to ensure that all data is reviewed during QA processes and to be sure it is classified and handled appropriately for the level assigned.
- Identify and include any mandatory operating system, and network security characteristics for the production system in the specifications of the software. In addition to providing the development and QA teams some definition of the environment the software is designed to run in, giving the administrator and end users an idea of what your expectations were when you created the code can be extremely useful in determining where software can, or cannot, be used.

- Where appropriate, verify the digital signatures of routines that process sensitive data when the code is being loaded for execution.
- If you include checksums on executables for production code, include routines that verify the checksums at every system restart.

The Carnegie-Mellon Software Engineering Institute Computer Emergency Response Team (CERT) provides a good “Top 10 Secure Coding Practices”² list. The list below provides some additional items to consider in addition to the items previously listed:

- Validate input from data sources. Proper input validation can eliminate many software vulnerabilities.
- Compile code using the highest warning level available for the compiler and eliminate warnings by modifying the code.
- Create a software architecture and design the software to implement and enforce security. Carnegie-Mellon has pre-established programming standard by language that can be found at www.cert.org/secure-coding/scstandards.html
- Remember the K-I-S-S (Keep It Simple, Stupid) principle. Complex designs increase the likelihood of errors or vulnerabilities and the need for security mechanisms or resulting mitigations to become more complex.
- Base access decisions on permission rather than exclusion to adhere to the principle of least privilege.
- Sanitize data sent to other systems, such as command shells, relational databases, and commercial off-the-shelf (COTS) components.
- Practice defense in depth within the application, so that if one layer of defense turns out to be inadequate, another layer of defense can prevent or limit a security flaw from becoming an exploitable vulnerability.
- Establish good quality assurance techniques to be more effective in identifying and eliminating vulnerabilities.
- Develop and/or apply a secure coding standard for your target development language and platform.
- Define security requirements at the start of the project.
- Think like a hacker and use threat modeling to anticipate the threats to which the software may be subjected. If you consider how it can be attacked, you will be able to prevent the attack before it can occur.

38.3.5 Languages. To date, no common computer languages have security specific features built-in. Java does include provisions for limiting access to resources outside the “sandbox” reserved for a process, as described in the books by Felten and McGraw. Nevertheless, Java is still one of the languages targeted as an attack vector by many malware implementations. PASCAL uses strong typing and requires full definition of data structures, thus making it harder to access data and code outside the virtual machine defined for a given process. In contrast, C and C++ allow programmers to access any region of memory at any time the operating system permits it.

Computer languages allow developers to write code as well as they can. Strongly typed languages may offer better constraints on programmers, but the essential

38 · 10 WRITING SECURE CODE

requirement is that the programmers continue to think about security as they design and build code.

There are several sets of security utilities and resources available for programmers; for example, RSA has a number of cryptographic toolkits. Some textbooks (e.g., Schneier's *Applied Cryptography*) include CD-ROMs with sample code. In addition, the Computer Emergency Response Team Coordination Center (CERT/CC) was started in December 1988 by the Defense Advanced Research Projects Agency (DARPA), which was part of the U.S. Department of Defense. CERT/CC is located at the Software Engineering Institute, a federally funded research center operated by Carnegie Mellon University.

CERT/CC studies Internet security vulnerabilities, provides services to Websites that have been attacked, and publishes security alerts. CERT/CC's research activities include the area of WAN computing and developing improved Internet security.

As mentioned in Section 38.3.4, Carnegie-Mellon has established secure coding standards based on language that can help establish a uniform set of principles and guidelines across your development group. Regardless of the language selected for software development, it is important to make the decision based on the strengths and weaknesses of the language. This means that a risk analysis needs to be a part of the design of any development project, including the selection of the development language. By understanding those strengths and weaknesses, better decisions can be made to prevent the inherent vulnerabilities within the language from becoming exposed inadvertently during development.

38.4 TYPES OF SOFTWARE ERRORS. New programmers should review the range of root causes for software errors. Such review is particularly useful for students who have completed training that did not include discussions of systematic quality assurance methodology. The next sections can serve as a basis for creating effective sets of test data and test procedures for unit tests of new or modified routines.

38.4.1 Internal Design or Implementation Errors. A general definition of a software error is a mismatch between a program and its specifications; a more specific definition is the failure of a program to do what the end user reasonably expects. There are many types of software errors. Some of the most important include:

- Initialization
- Logic flow
- Calculation
- Boundary condition violations
- Parameter passing
- Race condition
- Load condition
- Resource exhaustion
- Resource, address, or program conflict with the operating system or application(s)
- Regulatory compliance considerations
- Other errors

38.4.1.1 Initialization. Initialization errors are insidious and difficult to find. The most insidious programs save initialization information to disk and fail only the first time used—that is, before they create the initialization file. The second time a given user activates the program, there are no further initialization errors. Thus, the bugs appear only to employees and customers when they activate a fresh copy of the defective program. Other programs with initialization errors may show odd calculations or other flaws the first time they are used or initialized; because they do not store their initialization values, these initialization errors will continue to reappear each time the program is used.

38.4.1.2 Logic Flow. Modules pass control to each other or to other programs. If execution passes to the wrong module, a logic-flow error has occurred. Examples include calling the wrong function, or branching to a subroutine that lacks a RETURN instruction, so that execution falls through the logical end of a module and begin executing some other code module.

38.4.1.3 Calculation. When a program misinterprets complicated formulas and loses precision as it calculates, it is likely that a calculation error has occurred; for example, an intermediate value may be stored in an array with 16 bits of precision when it needs 32 bits. This category of errors also includes computational errors due to incorrect algorithms.

38.4.1.4 Boundary Condition Violations. Boundaries refer to the largest and smallest values with which a program can cope; for example, an array may be dimensioned with 365 values to account for days of the year, and then fail in a leap year when the program increments the day-counter to 366 and thereby attempts to store a value in an illegal address. Programs that set variable ranges and memory allocation may work correctly within the boundaries but, if incorrectly designed, may crash at or outside the boundaries. The first use of a program also can be considered a boundary condition.

One of the most important types of boundary violations is the buffer overflow. In this error, data placed into storage exceed the defined maximum size and overflow into a section of memory identified as belonging to one or more different variables. The consequences can include data corruption (e.g., if the overflow overwrites data that are interpreted as numerical or literal values) or changes in the flow of execution (e.g., if the altered data include logical flags that are tested in branch instructions).

Buffer overflows have been exploited by writers of malicious code who insert data that overflows into memory areas of interpreted programs and thus become executed as code.

All programs should verify that the data being stored in an array or in any memory location do not exceed the expected size of the input. Data exceeding the expected size should be rejected or, at least, truncated to prevent buffer overflow.

38.4.1.5 Parameter Passing. Sometimes there are errors in passing data back and forth among modules. For instance, a call to a function accidentally might pass the wrong variable name so that the function acts on the wrong values. When these parameter-passing errors occur, data may be corrupted, and the execution path may be affected because of incorrect results of calculations or comparisons. As a result, the

latest changes to the data might be lost, or execution might fall into error-handling routines even though the intended data were correct.

38.4.1.6 Race Condition. When a race occurs between event A and event B, a specific sequence of events is required for correct operation, but the program does not ensure this sequence. For example, if process A locks resource 1 and waits for resource 2 to be unlocked while process B locks resource 2 and waits for resource 1 to be unlocked, there may be a deadly embrace that freezes the operations if the processes overlap in execution. If they do not happen to overlap, there is no problem at that time.

Race conditions can be expected in multiprocessing systems and interactive systems, but they can be difficult to replicate; for example, the deadly embrace just described might happen only once in 1,000 transactions if the average transaction time is very short. Consequently, race conditions are among the most difficult to detect during quality assurance testing and are best identified in code reviews. Programmers should establish and comply with standards on sequential operations that require exclusive access to more than one resource. For example, if all processes exclusive-lock resources in a given sequence and unlock them in the reverse order, there can be no deadly embrace.

38.4.1.7 Load Condition. All programs and systems have limits to storage capacity, numbers of users, transactions, and throughput. Load errors are caused by exceeding the volume limitations of storage, transactions, users, and networks can occur due to high volume, which includes a great deal of work over a long period, or high stress, which includes the maximum load all at one time. For example, if the total theoretical number of transactions causes a demand on the disk I/O system that exceeds the throughput of the disk controller, processes will necessarily begin piling up in a queue waiting for completion of disk I/Os. Although theoretical calculations can help to identify where possible bottlenecks can occur in CPU, memory, disk, and network resources, a useful adjunct is automated testing that permits simulation of maximum loads defined by service-level agreements.

38.4.1.8 Resource Exhaustion. The program running out of high-speed memory (RAM), mass storage (disk), central processing unit (CPU) cycles, operating system table entries, semaphores, network bandwidth, or other resources can cause failure of the program. For example, inadequate main memory may cause excessive swapping of data to disk (thrashing), typically causing drastic reductions in throughput, because disk I/O is typically 1,000 times slower than memory access.

38.4.1.9 Interapplication Conflicts. With operating systems (OS) as complex as they are, OS manufacturers routinely distribute the code requirements and certain parameters to the application software manufacturers, so that the likelihood of program conflicts or unexpected stoppages are minimized. While this certainly helps reduce the number of problems and improves the forward and backward compatibility with previous OS versions, even the OS vendors on occasion experience or cause difficulties when they do not conform to the parameters established for their own programs.

38.4.1.10 Other Sources of Error. It is not unusual for errors to occur where programs send bad data to devices, ignore error codes coming back, and even try to use devices that are busy or missing. The hardware might well be broken, but the

software also is considered to be in error when it does not recover from such hardware conditions.

Additional errors can occur through improper builds of the executable; for example, if an old version of a module is linked to the latest version of the rest of the program, the wrong sign-on screens may pop up, the wrong copyright messages may be displayed, the wrong version numbers may appear, and various other inaccuracies may occur.

38.4.1.11 User Interface. Generally speaking, the term “user interface” denotes all aspects of a system that are relevant to a user. It can be broadly described as the user virtual machine (UVM). This would include all screens, the mouse and keyboard, printed outputs, and all other elements with which the user interacts. A major problem arises when system designers cannot put themselves in the user’s place and cannot foresee the problems that technologically challenged users will have with an interface designed by a technologically knowledgeable person.

Documentation is a crucial part of every system. Each phase of development—requirements, analysis, development, coding, testing, errors, error solutions and modifications, implementation, and maintenance—needs to be documented. All documents and their various versions need to be retained for both future reference and auditing purposes. Additionally, it is important to document the correct use of the system and to provide adequate instructional and reference materials to the user. Security policies and related enforcement and penalties also need to be documented. Ideally, the documentation should enable any technically qualified person to repair or modify any element, as long as the system remains operational.

38.4.1.12 Functionality. A program has a functionality error if performance that can reasonably be expected is confusing, awkward, difficult, or impossible. Functionality errors often involve key features or functions that have never been implemented. Additional functionality errors exist when:

- Features are not documented.
- Required information is missing.
- A program fails to acknowledge legitimate input.
- There are factual errors or conflicting names for features.
- There is information overload.
- The material is written to an inappropriate reading level.
- The cursor disappears, or is in the wrong place.
- Screen displays are wrong.
- Instructions are obscured.
- Identical functions require different operations in different screens.
- Improperly formatted input screens exist.
- Passwords or other confidential information are not obscured or protected adequately.
- Tracing the user data entry or changes is unavailable or incomplete.
- Segregation of duties is not enforced. (This can be particularly critical for organizations subject to legal and regulatory requirements.)

38.4.1.13 Control (Command) Structure. Control structure errors can cause serious problems because they can result in:

- Users getting lost in a program.
- Users wasting time because they must deal with confusing commands.
- Loss of data or the unwanted exposure of data.
- Work delay.
- Financial cost.
- Unanticipated exposure to data leakage or compromise; this can result in significant liability if consumers' personal identifying information (PII) is compromised.
- Data not being encrypted as intended or being visible to unauthorized users.

Some common errors include:

- Inability to move between menus.
- Confusing and repetitive menus.
- Failure to allow adequate command-line entries.
- Requiring command-line entries that are neither intuitive nor clearly defined on screen.
- Failure of the application program to follow the operating system's conventions.
- Failure to distinguish between source and parameter files, resulting in the wrong values being made available to the user through the interface, or failure to identify the source of the error
- Inappropriate use of the keyboard, when new programs do not meet the standard of a keyboard that has labeled function keys tied to standard meanings.
- Missing commands from the code and screens resulting in the user being unable to access information, to utilize programs, or to provide for the system to be backed up and recoverable. There are a host of other commands that can leave the system in a state of less-than-optimum operability.
- Inadequate privacy or security that can result in confidential information being divulged, in the complete change or loss of data without recoverability, in poor reporting, and even in undesired access by outside parties.

38.4.1.14 Performance. Speed is important in interactive software. If a user feels that the program is working slowly, that can be an immediate problem.

Performance problems include slow response, unannounced case sensitivity, uncontrollable and excessively frequent automatic saves, inability to save, and limited scrolling speed.

There are five fundamental potential bottlenecks to consider in analyzing any computer and network performance problem relating to access to and speed of:

- The central processing unit(s)
- Main memory
- Secondary memory (e.g., disk drives)

- Application design
- Network bandwidth

Slow operation can depend on (but is not limited to) the OS, the other applications running, memory saturation and thrashing (excessive swapping of memory contents to virtual memory on disk or on other, relatively slow, memory resources such as flash drives), memory leakage (the failure to de-allocate memory that is no longer needed), disk I/O inefficiencies (e.g., reading single records from very large blocks), and program conflicts (e.g., locking errors). For more information on program performance.

At another level, performance suffers when program designs make it difficult to change their functionality in response to changing requirements. In a database design, defining a primary index field that determines the sequence in which records are stored on disk can greatly speed access to records during sequential reads on key values for that index—but it can be counterproductive if the predominant method for accessing the records is sequential reads on a completely different index.

38.4.1.15 Output Format. Output format errors can be frustrating and time consuming. An error is considered to have occurred when the user cannot change fonts, underlining, boldface, and spacing that influence the final look of the output; alternatively, delays or errors when printing or saving document may occur. Errors occur when the user cannot control the content, scaling, and look of tables, figures, and graphs. Additionally, there are output errors that involve expression of the data to an inappropriate level of precision.

38.5 ASSURANCE TOOLS AND TECHNIQUES. The security community has known about buffer overflow vulnerabilities, as an example, for the past 25 or 30 years, yet the vulnerabilities are still increasing. For example, the National Vulnerability Database reported 418 new buffer overflow errors in 2013 compared with 392 in 2011. Clearly, greater efforts are necessary to teach and to enforce awareness, implementation, and testing of source code.

38.5.1 Education Resources. Build Security In (BSI) is a project of the Software Assurance program of the Strategic Initiatives Branch of the National Cyber Security Division (NCSD) of the U.S. Department of Homeland Security. BSI (<http://buildsecurityin.us-cert.gov>) contains and links to best practices, tools, guidelines, rules, principles, and other resources that software developers, architects, and security practitioners can use to build security into software in every phase of its development. BSI content is based on the principle that software security is fundamentally a software engineering problem and must be addressed in a systematic way throughout the software development life cycle.

In addition to BSI, and out of the multitudes of sites on the Web that address some facet of secure coding, some sites are listed next to assist in secure application development:

- Carnegie-Mellon Software Engineering Institute: www.cert.org/secure-coding
- FreeBSD Security Information: www.freebsd.org/security/security.html
- International Systems Security Engineering Association (ISSEA): www.issea.org
- Open Web Application Security Project: www.owasp.org

- Secure, Efficient, and Easy C Programming: <http://irccrew.org/~cras/security/c-guide.html>
- Secure Programming for Linux and UNIX HOWTO: <http://www.dwheeler.com/secure-programs/>
- Windows Security: www.windowsecurity.com
- World Wide Web Security FAQ: <http://www.w3.org/Security/Faq/>

38.5.2 Code Examination and Application Testing Techniques. Scanning once is not enough; ongoing application assessment is essential to implementing effective secure development practices and, in turn, a secure application. Like many other aspects of information technology and computer security, a layered approach to testing is also needed. As a result, there are numerous techniques and approaches, both manual and automated, to software security testing. This section will provide a cursory overview of the major techniques and approaches.

38.5.2.1 Static Analysis. Static analysis or source code review is the process of manually checking source code for security weaknesses. Sometimes looking at the code is the only way to resolve issues. Understanding the intent of the inner workings of the application can identify serious security issues that cannot be identified any other way.

Some issues that are particularly conducive for discovery through static analysis include concurrency problems, flawed business logic, access control problems, backdoors, Trojans, Easter eggs, time/logic bombs, and other forms of malicious code.

38.5.2.2 Binary Code Analysis. Binary code analysis utilizes tools that support analysis of binary executables such as decompilers, disassemblers, and binary code scanners. This is to say that binary analysis is the reverse engineering of the executable. The least intrusive technique is binary scanning. Binary scanners analyze machine code to model a language-neutral representation of the program's behaviors, control/data flows, call trees, and external function calls. An automated vulnerability scanner then traverses the model in order to locate vulnerabilities caused by common coding errors and simple back doors.

The next least intrusive technique is disassembly of the binary. The binary code is reverse engineered to an intermediate assembly language, but the disadvantage of disassembly is that it requires an expert who both thoroughly understands that particular assembler language and who is skilled in detecting security-relevant constructs within assembler code.

The most intrusive reverse engineering technique is decompilation of the code. The binary code is reverse engineered completely to source code, which can then be subjected to the same security code review techniques and other white box tests as original source code. Note, however, that decompilation is technically problematic in that the quality of the source code generated through decompilation is often very poor. As a result, code is rarely as navigable or comprehensible as the original source code. The analysis of decompiled source code will always be more difficult and time consuming than that of the original source code. For this reason, the use of decompilation for security analysis should only be used for the most critical systems.

Another point to consider regarding reverse engineering is that it may also be legally prohibited. A majority of software vendors' license agreements prohibit reverse engineering. In addition, many software vendors repeatedly cite the Digital Millennium

Copyright Act (DMCA) of 1999 as justification, even though the DMCA explicitly exempts reverse engineering and encryption research from the prohibitions against copy protection circumvention.

38.5.2.3 White Box Approach. White box testing strategy deals with the internal logic and structure of the code. White box testing is also known as glass, structural, open box, or clear box testing. In order to implement white box testing, the tester has to deal with the code, and therefore needs to possess knowledge of coding and logic (i.e., internal working of the code). White box tests also need the tester to look into the code and to find out which unit/statement/chunk of the code is malfunctioning.

Advantages of white box testing are:

- It becomes very easy to find out which type of input/data can help in testing the application effectively.
- It helps in optimizing the code.
- It helps in removing the extra lines of code, which can bring in hidden defects.

Disadvantages of white box testing are:

- A skilled tester is needed to carry out this type of testing, which increases the cost.
- It is nearly impossible to look into every bit of code to find hidden errors that may create problems, resulting in failure of the application.

38.5.2.4 Black Box Approach. Black box testing is testing without knowledge of the internal workings of the item being tested. Black box testing is also known as behavioral, functional, opaque box, and closed box. For this reason, the tester and the programmer can be independent of one another, avoiding programmer bias toward his own work. Test groups are often used. Due to the nature of black box testing, the test planning can begin as soon as the specifications are written.

Advantages of black box testing are:

- It is more effective on larger units of code than glass box testing.
- The tester needs no knowledge of implementation, including specific programming languages.
- Tester and programmer are independent of each other.
- Tests are done from a user's point of view.
- It will help to expose any ambiguities or inconsistencies in the specifications.
- Test cases can be designed as soon as the specifications are complete.

Disadvantages of black box testing are:

- Only a small number of possible inputs can actually be tested; to test every possible input stream on a complex system would take nearly forever.
- Without clear and concise specifications, test cases are hard to design.
- There may be unnecessary repetition of test inputs if the tester is not informed of test cases the programmer has already tried. It is always critical to validate any

testing claims through reports or result output to help avoid duplication. Likewise, it is always important to rerun tests that may have ambiguous results.

- It may leave many program paths untested.
- It cannot be directed toward specific segments of code that may be very complex.

38.5.2.5 Gray Box—Blended Approach. Gray box testing is a software testing technique that uses a combination of black box testing and white box testing. Gray box testing is not black box testing, because the tester does know some of the internal workings of the software under test. In gray box testing, the tester applies a limited number of test cases to the internal workings of the software under test. In the remaining part of the gray box testing, the tester takes a black box approach in applying inputs to the software under test and observing the outputs.

38.5.2.6 Fault Injection. There are two primary categories of fault injection: source code or binary fault injection. Fault injection is used to induce stress in the software, create interoperability problems among components, simulate faults in the execution environment, and thereby revealing safety-threatening faults that are not made apparent by traditional testing techniques. Security extends standard fault injection by adding error injection, enabling testers to analyze the security impacts of the behaviors, and state changes resulting in the software when exposed to changes in the environment data. These data changes are meant to simulate the types of faults that would occur during unintentional user errors or intentional attacks on the software through its environment, including attacks on the environment itself. A data change is simply an alteration of the data the execution environment passes to the software, or between software components. Fault injection reveals both the effects of security faults on individual component behaviors, and the behavior of the system as a whole.

Binary fault injection is useful when performed as part of penetration testing to enable the tester to obtain a more holistic picture of how the software responds to attacks. However, faults should not be limited to simulating real world attacks. Fault injection scenarios should be designed to give a complete understanding of the security impacts that the application's behaviors, states, and properties exhibit under all possible operating conditions.

The main challenges in fault injection testing are determining the most meaningful combination and volume of faults to inject and, as with all tests, interpreting the results. Furthermore, just because fault injection does not cause the software to behave in a nonsecure manner or fail in a nonsecure state, this cannot be interpreted to mean that the software will perform equally when exposed to the more complex inputs it typically receives during execution.

38.5.2.7 Fuzzing. Fuzz testing or fuzzing is a technique that is often automated or semi-automated, that involves providing invalid, unexpected, or random data to the inputs of a computer program. The program is then monitored for exceptions, failing built-in code assertions, or for finding potential memory leaks. There are two forms of fuzzing, mutation-based and generation-based, which can be employed as part of white, black, or grey box testing.

The idea behind fuzz testing is to look for interesting program behavior that results from noise injection and may indicate the presence of vulnerabilities or faults. Fuzzing

applications, fuzzers, are generally specific to a particular type of input and written to test a specific program; they are not easily reusable, but file formats and network protocols are the most common targets of testing. Any type of program input can be fuzzed, including items not normally considered “input” (e.g., databases, shared memory, etc.). The value is the specificity, that is to say, fuzzing can often reveal security vulnerabilities that generic testing tools such as vulnerability scanners and fault injectors cannot. On the other hand, completely random fuzzing is a typically ineffective way to uncover problems in an application, and as a result fuzzing technology has evolved to include more intelligent techniques.

38.5.2.8 Vulnerability Scanning. Automated vulnerability scanning is an automated scanning technique for application level software, as well as for Web servers, database management systems, and some operating systems. The tools scan the application software for input and output of known patterns associated with known vulnerabilities. The vulnerability patterns, or signatures, are similar to the signatures used by virus scanners, or the coding constructs searched for by automated source code scanners, making the vulnerability scanner, essentially, an automated pattern-matching tool. Some Web application vulnerability scanners additionally attempt to perform automated stateful assessment using simulated reconnaissance attack patterns and fuzzing techniques to probe for known or common vulnerabilities.

Like any signature-based scanner, vulnerability scanners can report false positives. As a result, the tester must have enough software and security expertise to meaningfully interpret the scanner’s results to limit the false positives or negatives, to prevent the creation of an incident where it does not exist. This is why it is important to use a layered approach and combine different test techniques to examine the software for vulnerabilities.

Vulnerabilities in software are often masked by environmental protections such as network and application-level firewalls. Furthermore, environment conditions may create unique vulnerabilities that cannot be found by a signature-based tool, but using a combination of other black box tests, most especially penetration testing of the deployed software in the actual target environment. Vulnerability scanners are most effective as part of:

- Security assessments of binary components;
- Or before penetration testing (to eliminate the need to run penetration test scenarios for common vulnerabilities).

38.5.2.9 Software Penetration Testing. Penetration testing has been a common technique to test network security for many years and is also known as black box testing and ethical hacking. As described in the black box approach, penetration testing is essentially the testing of a running application (without knowing the inner workings of the application) to identify vulnerabilities. In penetration testing, the whole software system is a “live” environment. Typically, the penetration team would have access to the application like typical users. The testers then act like an attacker, attempting to find and exploit potential vulnerabilities.

Penetration testing should focus on aspects of system behavior, interaction, and vulnerability that cannot be observed through other testing techniques performed outside of a live environment. That means that the penetration should subject the system to

sophisticated multi-pattern attacks designed to trigger complex behaviors across system components. In addition, the testing should attempt to find security problems likely to originate in the architecture and design, rather than coding flaws, since this type of problem tends to be overlooked by other testing techniques. This also means test plan should include worst-case scenarios that reproduce threat vectors considered highly damaging, such as an insider threat scenario.

Many people use application penetration testing as the primary testing technique and while it has a place in a testing program; it should not be considered the primary or only testing technique. Penetration testing can potentially lead to a false sense of security. Just because an application passes a penetration test, it does not mean it is vulnerability free. Likewise, if an application fails, it is a strong indication that there are serious problems with it. However, focused penetration testing, which is testing that attempts to exploit vulnerabilities detected in previous tests, can be useful in detecting if those vulnerabilities are actually fixed within the code.

38.5.3 Standards and Best Practices. Testing is a complete software engineering discipline in its own right. Volumes have been written about the various techniques that software engineers use to test and validate their applications. Some basic best practices can be employed regardless of the testing methodology selected. These are:

- Perform automated testing.
- Make a test plan.
- Follow a specific methodology.
- Test at every stage.
- Test all system components.

In addition to these best practices, use of these standards can provide additional resources:

- ISO 17799, Information Technology: Code of Practice for Information Security Management
- ISO/IEC 15408, Evaluation Criteria for IT Security (the Common Criteria)
- SSE-CMM, System Security Engineering Capability Maturity Model
- ISO/IEC WD 15443, Information Technology: Security Techniques

38.6 CONCLUDING REMARKS. Computer security practitioners and top-level managers must understand that IT management deficiencies, left unchanged, will sabotage efforts to establish and sustain effective computer security programs. Furthermore, it is incumbent on those coding to help steer the project and educate management toward a model that is inclusive of security throughout the development life cycle.

The costs of neglecting security at the start will continue to be a serious issue until software security is fully integrated into every aspect of the development life cycle. Security must be built in, and building security into systems starts with the software development teams, practices, and techniques used to build those systems.

39.1 INTRODUCTION. Software development can affect all of the six fundamental principles of information security as described in Chapter 3 in this *Handbook*, but the most frequent problems caused by poor software involve integrity, availability, and utility.

Despite the ready availability of packaged software on the open market, such software frequently has to be customized to meet its users’ particular needs. Where this is not possible, programs must be developed from scratch. Unfortunately, during any software development project, despite careful planning, unforeseen problems inevitably arise. Custom software and customized packages frequently are delivered late, are faulty, and do not meet specifications. Generally, software project managers tend to underestimate the impact of technical as well as nontechnical difficulties. Because of this experience, the field of software engineering has developed; its purpose is to find reasonable answers to questions that occur during software development projects.

39.2 GOALS OF SOFTWARE QUALITY ASSURANCE. In the IEEE *Glossary of Software Engineering Terminology*, quality is defined as “the degree to which a system, component, or process meets customer or user needs or expectations.” In accordance with this definition, software should be measured primarily by the degree to which user needs are met. Because software frequently needs to be adapted to changing requirements, it should be adaptable at reasonable cost. Therefore, in addition to being concerned with correctness, reliability, and usability, the customer also is concerned with testability, maintainability, portability, and compliance with the established standards and procedures for the software and development process. Software quality assurance (SQA) is an element of software engineering that tries to ensure that software meets acceptable standards of completeness and quality. SQA acts as a watchdog overseeing all quality-related activities involved in software development.

The principal goals of SQA are:

- Uncover all of a program’s problems.
- Reduce the likelihood that defective programs will enter production.
- Safeguard the interests of users.
- Safeguard the interests of the software producer.

39.2.1 Uncover All of a Program’s Problems. Quality must be built into a product. Testing can only reveal the presence of defects in the product. To ensure quality, SQA monitors both the development process and the behavior of software. The goal is not to pass or certify the software; the goal is to identify all the inadequacies and problems in the software so that they can be corrected.

39.2.2 Reduce the Likelihood that Defective Programs Will Enter Production. All software development must comply with the standards and policies established within the organization to identify and eliminate errors before defective programs enter production.

39.2.3 Safeguard the Interests of Users. The ultimate goal is to achieve software that meets the users' requirements and provides them with needed functionality. To meet these goals, SQA must review and audit the software development process and provide the results of those reviews and audits to management. SQA, as a functioning department, can be successful only if it has the support of management and if it reports to management at the same level as software development. Likewise, each SQA project will possess specific attributes, and the SQA program should be tailored to accommodate project needs. Characteristics to be considered include: mission criticality, schedule and budget, size and complexity of project, and size and competence of project staff organization.

39.2.4 Safeguard the Interests of Software Producers. By ensuring that software meets requirements, SQA can help prevent legal conflicts that may arise if purchased software fails to meet contractual obligations. When software is developed in-house, SQA can prevent the finger-pointing that otherwise would damage relations between software developers and corporate users.

39.3 SOFTWARE DEVELOPMENT LIFE CYCLE. Good software, whether developed in-house or bought from an external vendor, needs to be constructed using sound principles. Because software development projects often are large and have many people working on them for long periods of time, the development process needs to be monitored and controlled.

Although progress of such projects is difficult to measure, using a phased approach can control the projects. In a phased approach, a number of clearly identifiable milestones are established between the start and the finish of the project. A common analogy that is used is that of constructing a house, where the foundation is laid initially and each phase of construction is achieved in an orderly and controlled manner. Frequently, with both house construction and software development, payments for phases are dependent on reaching the designated milestones.

When developing systems, we refer to the phased process as the system development life cycle (SDLC). The SDLC is the process of developing information systems through investigation, analysis, design, coding and debugging, testing, implementation, and maintenance. These seven phases are common, although different models and techniques may contain more or fewer phases.

Generally, milestones identified in the SDLC correspond to the points in time when specified documents become available. Frequently, the documents explain and reinforce the actions taken during the just-completed phase of the SDLC. We therefore say that traditional models for the phased development are document driven to a large extent.

There are problems and drawbacks inherent in the document-driven process. The method of viewing the development process via the SDLC is not totally realistic to the actual projects. In reality, errors found in earlier phases are noted, and fixes are developed, prototyping is introduced, and solutions are implemented. This, in effect, is more than what is assumed will be necessary in the debugging and maintenance phases. Also, often the problems are solved before those later phases are reached. Because of

39 · 4 SOFTWARE DEVELOPMENT AND QUALITY ASSURANCE

the recognition that much of what in traditional models is referred to as maintenance is really evolution, other models of the SDLC, known as evolutionary models, have been developed.

In traditional models, the initial development of a system is kept strictly separate from the maintenance phase. The major goal of the SDLC is to deliver a first production version of the software system to the user. It is not unusual for this approach to result in excessive maintenance costs to make the functioning or final system fit the needs of the real user. There are other models available, and it is necessary, for each project, to choose a specific SDLC model. To do this, it is necessary to identify the need for a new system and to follow this by identifying the individual steps and phases, possible interaction of the phases, the necessary deliverables, and all related materials.

There are five major system development techniques:

1. Traditional systems development life cycle (SDLC)
2. Waterfall model (a variant of the traditional SDLC)
3. Rapid application development (RAD)
4. Joint application development (JAD)
5. Extreme programming

Although these five development techniques frequently are seen as mutually exclusive, in truth they represent solutions that place different emphasis on common elements of systems design. Defined at different times, each methodology's strengths demonstrate the technology, economics, and organizational issues that were current at the time the methodology was first defined.

Software generally is constructed in phases, and tests should be conducted at the end of each phase before development continues in the next phase. Four major phases that are always present in software construction are:

1. The analysis phase, where software requirements are defined
2. The design phase, based on the previously described requirements
3. The construction, programming, or coding phase
4. The implementation phase, where software is actually installed on production hardware and finally tested before release to production

The programming phase always includes unit testing of individual modules and system testing of overall functions. Sometimes, in addition to testing during programming and implementation, a fifth phase, solely devoted to functional testing, is established. Review and modification generally follow all phases, where weaknesses and inadequacies are corrected.

39.3.1 Phases of the Traditional Software Development Life Cycle.

The seven phases discussed here comprise the most common traditional SDLC:

1. Investigation
2. Analysis
3. Design
4. Decoding and debugging

5. Testing
6. Implementation
7. Maintenance

From this traditional model, other models with fewer or more phases have been developed.

39.3.1.1 Investigation. This phase involves the determination of the need for the system. It involves determining whether a business problem or opportunity exists and conducting a feasibility study to determine the cost effectiveness of the proposed solution.

39.3.1.2 Analysis. Requirements analysis is the process of analyzing the end users' information needs, the environment of the organization and the current system, and developing functional requirements for a system to meet users' needs. This phase includes recording all of the requirements. The documentation must be referred to continually during the remainder of the system development process.

39.3.1.3 Design. The architectural design phase lists and describes all of the necessary specifications for the hardware, software, people and data resources, and information products that will satisfy the proposed system's functional requirements. The design can best be described as a blueprint for the system. It is a crucial tool in detecting and eliminating problems and errors before they are built into the system.

39.3.1.4 Coding and Debugging. This phase involves the actual creation of the system. It is done by information technology professionals, sometimes on staff within a company and sometimes from an external company that specializes in this type of work. The system is coded, and attempts are made to catch and eliminate all coding errors before the system is implemented.

39.3.1.5 Testing. Once the system is created, testing is essential. Testing proves the functionality and reliability of the system and acts as another milestone for finding problems and errors before implementation. This phase is instrumental in determining whether the system will meet users' needs. The testing should be documented in a project plan format as to the

- Objective of the testing
- Scope
- Expected results
- Test plan
- Test cases; ideally, the end users and/or business process owner(s) should be involved so that the test cases represent real-life situations as much as possible
- Test results and analysis
- Conclusion and determination of next steps
- End user/business process owner [signed] acceptance of the test results

39 · 6 SOFTWARE DEVELOPMENT AND QUALITY ASSURANCE

These steps help ensure that the tests align with the users' needs and that the results are representative of what can be expected.

39.3.1.6 Implementation. Once the previous five phases have been completed and accepted, with substantiating documentation, the system is implemented and users are permitted to utilize it.

39.3.1.7 Maintenance. This phase is ongoing and takes place after the system is implemented. Because systems are subject to variances, flaws, and breakdowns, as well as difficulties when integrating with other systems and hardware, maintenance continues for as long as the system is in use.

39.3.2 Classic Waterfall Model. Although phased approaches to software development appeared in the 1960s, the waterfall model, attributed to Roy Royce, appeared in the 1970s. The waterfall model demands a sequential approach to software development and contains only five phases:

1. Requirements analysis phase
2. Design
3. Implementation
4. Testing
5. Maintenance

39.3.2.1 Analysis or Requirements Analysis. The waterfall model emphasizes analysis as part of the requirements analysis phase. Since software is always part of a larger system, requirements are first established for all system elements, and then some subset of these requirements is allocated to software. Identified requirements, for both the system and the software, are then documented in the requirements specification. A series of validation tests is required to ensure that, as the system is developed, it continues to meet these specifications.

The waterfall model includes validation and verification in each of its five phases. This means that in each phase of the software development process, it is necessary to compare the obtained results against the required results. Testing is done within every phase to answer this question and does not occur strictly in the testing phase that follows the implementation phase.

39.3.2.2 Design. The design phase is actually a multistep process focusing on data structure, software architecture, procedural detail, and interface characterization. During the design phase, requirements are translated into a representation of the software that then can be assessed for quality before actual coding begins. Once again, documentation plays an important role because the documented design becomes a part of the software configuration. Coding is incorporated into the design phase instead of being a separate phase. During coding, the design is translated into machine-readable form.

39.3.2.3 Implementation. During the implementation phase, the system is given to the user. Many developers feel that a large problem with this model is that the system is implemented before it actually is ready to be given to the user. However, waterfall model advocates claim that the consistent testing throughout the development

process permits the system to be ready by the time this phase is reached. Note that in the waterfall model, the implementation phase precedes the testing phase.

39.3.2.4 Testing. Although testing has been going on during the entire development process, the testing phase begins after code has been generated and the implementation phase has occurred. This phase focuses on both the logical internals of the software and the functional externals. Ideally, the end users and the process/business owners should be enlisted to assist in this phase, since they usually:

- Are familiar with the business requirements
- Know how the current software and hardware operates
- Know what types of activity are anticipated and planned
- Provide the ultimate acceptance approval of the software and hardware

Although not directly required by many of the regulatory reviews, involving the end users and process owners provides the IT area with additional resources, not only from a human resource perspective but also from a business knowledge and regulatory compliance perspective.

39.3.2.5 Maintenance. The maintenance phase reapplies each of the preceding life cycle steps to existing programs. Maintenance is necessary because of errors that are detected, necessary adaptation to the external environment, and functional and performance enhancements required and requested by the customer.

The waterfall model is considered to be unreliable, partly due to failure to obey the strict sequence of phases advocated by the traditional model. In addition, the waterfall model often fails because it delivers products whose usefulness is limited when requirements have changed during the development process.

39.3.3 Rapid Application Development and Joint Application Design.

Rapid application development (RAD) supports the iteration and flexibility necessary for building robust business process support. RAD emphasizes user involvement and small development teams, prototyping of software, software reuse, and automated tools. Activities must be carried out within a specified time frame known as a time box. This approach differs from other development models where the requirements are fixed first and the time frame is decided later. RAD, in an effort to keep within the time box and its immovable deadline, may sacrifice some functionality.

RAD has four phases within its cycle:

1. Requirements planning
2. User design
3. Construction
4. Cutover

The main techniques used in RAD are joint requirements planning (JRP) and joint application design (JAD). The word “joint” refers to developers and users working together through the heavy use of workshops. JAD enables the identification, definition, and implementation of information infrastructures. The JAD technique is discussed with RAD because it enhances RAD.

39 · 8 SOFTWARE DEVELOPMENT AND QUALITY ASSURANCE

39.3.4 Extreme Programming. A form of *agile software development* that has gained popularity in the last two decades is *extreme programming* (XP). Programmers work closely with each other and the users to produce usable code quickly. Unit tests and integrated integration tests are constructed before the coding and constantly applied throughout the development process. A variant of the method is known as *Scrum*.

39.3.5 Importance of Integrating Security at Every Phase. Security should never be something added to software at the end of a project. Security must be considered continuously during an entire project in order to safeguard both the software and the entire system within which it functions. Regardless of which software development model is used, it is essential to integrate security within each phase of development and to include security in the testing at each phase. Rough estimates indicate that the cost of correcting an error rises tenfold with every additional phase. For example, catching an error at the analysis phase might require only several minutes—time for a user to correct the analyst—and therefore may cost only a few dollars. Catching the same error once it has been incorporated into the specifications document might cost 10 times more; after implementation, as much as 1,000 times more (this excludes any compliance-related penalties, losses, or loss responsibility).

39.4 TYPES OF SOFTWARE ERRORS

39.4.1 Internal Design or Implementation Errors. A general definition of a software error is a mismatch between a program and its specifications; a more specific definition is “the failure of a program to do what the end user reasonably expects.” There are many types of software errors. Some of the most important include:

- Initialization
- Logic flow
- Calculation
- Boundary condition violations
- Parameter passing
- Race condition
- Load condition
- Resource exhaustion
- Resource, address, or program conflict with the operating system or application(s)
- Regulatory compliance considerations
- Other errors

39.4.1.1 Initialization. Initialization errors are insidious and difficult to find. The most insidious programs save initialization information to disk and fail only the first time they are used—that is, before they create the initialization file. The second time a given user activates the program, there are no further initialization errors. Thus, the bugs appear only to employees and customers when they activate a fresh copy or installation of the defective program. Other programs with initialization errors may show odd calculations or other flaws the first time they are used or initialized; because

they do not store their initialization values, these initialization errors will continue to reappear each time the program is used.

39.4.1.2 Logic Flow. Modules pass control to each other or to other programs. If execution passes to the wrong module, a logic-flow error has occurred. Examples include calling the wrong function, or branching to a subroutine that lacks a RETURN instruction, so that execution falls through the logical end of a module and begins executing some other code module.

39.4.1.3 Calculation. When a program misinterprets complicated formulas and loses precision as it calculates, it is likely that a calculation error has occurred; for example, an intermediate value may be stored in an array with 16 bits of precision when it needs 32 bits. This category of errors also includes computational errors due to incorrect algorithms.

39.4.1.4 Boundary Condition Violations. The term “boundaries” refers to the largest and smallest values with which a program can cope; for example, an array may be dimensioned with 365 values to account for days of the year and then fail in a leap year when the program increments the day-counter to 366 and thereby attempts to store a value in an illegal address. Programs that set variable ranges and memory allocation may work within the boundaries but, if incorrectly designed, may crash at or outside the boundaries. The first use of a program also can be considered a boundary condition.

39.4.1.5 Parameter Passing. Sometimes there are errors in passing data back and forth among modules. For instance, a call to a function accidentally might pass the wrong variable name so that the function acts on the wrong values. When these parameter-passing errors occur, data may be corrupted and the execution path may be affected because of incorrect results of calculations or comparisons. As a result, the latest changes to the data might be lost or execution might fall into error-handling routines even though the intended data were correct.

39.4.1.6 Race Condition. When a race occurs between event A and event B, a specific sequence of events is required for correct operation, but this sequence is not ensured by the program. For example, if process A locks resource 1 and waits for resource 2 to be unlocked while process B locks resource 2 and waits for resource 1 to be unlocked, there will be a deadly embrace that freezes the operations.

Race conditions can be expected in multiprocessing systems and interactive systems, but they can be difficult to replicate; for example, the deadly embrace just described might happen only once in 1,000 transactions if the average transaction time is short. Consequently, race conditions are among the least tested.

39.4.1.7 Load Condition. All programs and systems have limits to storage capacity, numbers of users, transactions, and throughput. Load errors can occur due to high volume, which includes a great deal of work over a long period of time, or high stress, which includes the maximum load all at one time.

39.4.1.8 Resource Exhaustion. The program’s running out of high-speed memory (random access memory, or RAM), mass storage (disk), central processing unit (CPU) cycles, operating system table entries, semaphores, or other resources

39 · 10 SOFTWARE DEVELOPMENT AND QUALITY ASSURANCE

can cause failure of the program. For example, inadequate main memory may cause swapping of data to disk, typically causing drastic reductions in throughput.

39.4.1.9 Interapplication Conflicts. With operating systems (OS) as complex as they are, OS manufacturers routinely distribute the code requirements and certain parameters to the application software manufacturers, so that the likelihood of program conflicts or unexpected stoppages are minimized. Although this certainly helps reduce the number of problems and improves the forward and backward compatibility with previous OS versions, on occasion even the OS vendors experience or cause difficulties when they do not conform to the parameters established for their own programs.

39.4.1.10 Other Sources of Error. It is not unusual for errors to occur where programs send bad data to devices, ignore error codes coming back, and even try to use devices that are busy or missing. The hardware might well be broken, but the software also is considered to be in error when it does not recover from such hardware conditions.

Additional errors can occur through improper builds of the executable; for example, if an old version of a module is linked to the latest version of the rest of the program, the wrong sign-on screens may pop up, the wrong copyright messages may be displayed, the wrong version numbers may appear, and various other inaccuracies may occur.

39.4.1.11 Regulatory Compliance Considerations. If an organization is subject to Sarbanes-Oxley (SOX), then documentation of the errors encountered and the resulting internal reporting and remediation efforts is critical. The error should clearly indicate how it was identified, who identified it, how it was reported to management, what the remediation will be, and when it is anticipated to be completed. Without these details, management may encounter significant difficulties in confirming that adequate internal control mechanisms exist and that it is informed and involved appropriately and adequately. Also, an error could result in a control weakness being identified by the external auditors or, even worse, as a material weakness, depending on its nature and severity.

Additionally, if and when errors are noted that affect multilocation systems or applications, the significance and materiality must be considered from the aspect of both the subsidiary and the headquarters locales. Since laws differ among states and countries, what might be considered legally acceptable standards of privacy or accounting in one locale might not be acceptable elsewhere.

39.4.2 User Interface. Generally speaking, the term “user interface” denotes all aspects of a system that are relevant to a user. It can be broadly described as the user virtual machine (UVM). This would include all screens, the mouse and keyboard, printed outputs, and all other elements with which the user interacts. A major problem arises when system designers cannot put themselves in the user’s place and cannot foresee the problems that a technologically challenged user will have with an interface designed by a technologically knowledgeable person.

Documentation is a crucial part of every system. Each phase of development—requirements, analysis, development, coding, testing, errors, error solutions and modifications, implementation, and maintenance—needs to be documented. All documents and their various versions need to be retained for both future reference and auditing purposes. Additionally, it is important to document the correct use of the system and

provide adequate instructional and reference materials to the user. Security policies and related enforcement and penalties also need to be documented. Ideally, the documentation should enable any technically qualified person to repair or modify any element, as long as the system remains operational.

39.4.2.1 Functionality. A program has a functionality error if performance that can reasonably be expected is confusing, awkward, difficult, or impossible. Functionality errors often involve key features or functions that have never been implemented. Additional functionality errors exist when:

- Features are not documented.
- Required information is missing.
- A program fails to acknowledge legitimate input.
- There are factual errors or conflicting names for features.
- There is information overload.
- The material is written to an inappropriate reading level.
- The cursor disappears or is in the wrong place.
- Screen displays are wrong.
- Instructions are obscured.
- Identical functions require different operations in different screens.
- Improperly formatted input screens exist.
- Passwords or other confidential information are not obscured or protected adequately.
- Tracing the user data entry or changes is unavailable or incomplete.
- Segregation of duties is not enforced. (This can be particularly critical for organizations subject to the Health Insurance Portability and Accountability Act [HIPAA], SOX, International Organization for Standardization [ISO] 17799, and/or the Gramm-Leach-Bliley Act [GLBA].)

39.4.2.2 Control (Command) Structure. Control structure errors can cause serious problems because they can result in:

- Users getting lost in a program
- Users wasting time because they must deal with confusing commands
- Loss of data or the unwanted exposure of data
- Work delay
- Financial cost
- Unanticipated exposure to data leakage or compromise; this can result in significant liability if consumers' personal identifying information (PII) is compromised
- Data not being encrypted as intended or being visible to unauthorized users

Some common errors include:

- Inability to move between menus
- Confusing and repetitive menus

39 · 12 SOFTWARE DEVELOPMENT AND QUALITY ASSURANCE

- Failure to allow adequate command-line entries
- Requiring command-line entries that are neither intuitive nor clearly defined on screen
- Failure of the application program to follow the operating system's conventions
- Failure to distinguish between source and parameter files, resulting in the wrong values being made available to the user through the interface, or failure to identify the source of the error
- Inappropriate use of the keyboard when new programs do not meet the standard of a keyboard that has labeled function keys tied to standard meanings
- Missing commands from the code and screens, resulting in the user being unable to access information, to utilize programs, or to provide for the system to be backed up and recoverable, as well as a host of other commands that leave the system in a state of less-than-optimum operability
- Inadequate privacy or security that can result in confidential information being divulged, the complete change or loss of data without recoverability, poor reporting, and even undesired access by outside parties

39.4.2.3 Performance. Speed is important in interactive software. If a user feels that the program is working slowly, that can be an immediate problem. Slow operation can depend on (but is not limited to) the OS, the other applications running, memory allocation, memory leakage, and program conflicts. At another level, performance suffers when program designs make it difficult to change their functionality in response to changing requirements. Performance errors include slow response, unannounced case sensitivity, uncontrollable and excessively frequent automatic saves, inability to save, and limited scrolling speed.

39.4.2.4 Output Format. Output format errors can be frustrating and time consuming. An error is considered to have occurred when the user cannot change fonts, underlining, boldface, and spacing that influence the final look of the output; alternatively, delays or errors when printing or saving document may occur. Errors occur when the user cannot control the content, scaling, and look of tables, figures, and graphs. Additionally, there are output errors that involve expression of the data to an inappropriate level of precision.

39.5 DESIGNING SOFTWARE TEST CASES

39.5.1 Good Tests. No software program can ever be tested completely, since it would not be cost effective or efficient to test the validity, parameters, syntax, and boundaries of every line of code. Even if all valid inputs are defined and tested, there is no way to test all invalid inputs and all the variations on input timing. It is also difficult, if not impossible, to test every path the program might take, find every design error, and prove programs to be logically correct. Nevertheless, a good test procedure will find most of the problems that would occur, allowing the designers and developers to correct those problems and ensure that the software works properly. Generally, OS and application manufacturers classify the severity level of errors encountered, and many (as evidenced by the frequency and content of program patches) correct only the most serious ones that either they or the users notice.

Over the past several years, there has been an increasing debate on whether software vulnerabilities should be publicized immediately by researchers, or if the researchers should automatically notify and give the manufacturer time to correct the flaw. Generally, from a casual review of the vulnerabilities discovered concerning Microsoft's Internet Explorer version 6 over the past few years, the trend appears to have been that the researcher notifies Microsoft and allows Microsoft a varying period of time to create and distribute the patch (e.g., three to six months) before the researcher publicly announces the weakness. This trend is based on published reports in the technical news media.

Whenever you expect the same results from two tests, you consider the tests equivalent. A group of tests forms an equivalence class if the tester believes that the tests all test the same thing, and if one test catches or does not catch a bug, the others probably will do the same. Classical boundary tests check a program's response to input and output data; equivalence tests, however, teach a way of thinking about analyzing programs that enhances and strengthens test planning.

Finding equivalence classes is a subjective process. Different people analyzing the same program will come up with different lists of equivalence classes because of what the programs appear to achieve. Test cases often are lumped into the same equivalence class when they involve the same input variables, result in similar operations, affect the same output variables, or handle errors in the same manner.

Equivalence classes can be groups of tests dealing with ranges or multiple ranges of numbers, members of a group, and even time determined. Equivalence classes are generally the most extreme values, such as the biggest, smallest, fastest, and slowest. When testing, it is important to test each edge of an equivalence class, on all sides of each edge. Testers should use only one or two test cases from each equivalence class because a program that passes the tests generally will pass any test drawn from that class. Invalid input equivalence classes often allow program bugs to be overlooked during debugging.

39.5.2 Emphasize Boundary Conditions. Boundaries are crucial for checking each program's response to input and output data. Equivalence class boundaries are the most extreme values of the class; for example, boundary conditions may consist of the biggest and smallest, soonest and latest, shortest and longest, or slowest and fastest members of an equivalence class.

Tests should include values below, at, and above boundary values. Additionally, they should be tested at various user levels (e.g., administrator, root or super user, data entry, and read-only access). This testing must ensure that there are no conditions at any level that permit unintended access or unauthorized escalation of privileges.

When programs fail with nonboundary values, they generally fail at the boundaries too. Programs passing these tests probably also will pass any other test drawn from that class. Tests should also be able to generate the largest and smallest legitimate output values, remembering that input-boundary values may not generate output-boundary values.

Today, the most prevalent security breaches involve buffer overflows in active code (ActiveX and Java), in which inadequate bounds checking on input strings allows overflowing text to be interpreted as code that then can carry out improper operations. Restrictions on input length and type would prevent these exploits. Such overflows can result in the exposure of consumers' PII and incurring unwanted liability for the exposure; currently, the liability exists principally at the state level and may include criminal sanctions, depending on the state in which the consumers reside.

39.5.3 Check All State Transitions. All interactive programs move from one state to another. A program's state is changed whenever something causes the program to alter output (e.g., to display something different on the screen) or to change the range of available choices (e.g., displaying a new menu of user options).

To test state transitions, the test designer should lay out a transition probability matrix to show all the paths people are likely to follow. State transitions can be complex and often depend not on the simple choices provided but on the numbers the user enters. Testers often find it useful to construct menu maps that show exactly where to go from each choice available.

Menu maps also can show when and where users go when menu or keyboard commands take them to different states or dialogs. Maps are particularly handy when working with spaghetti code (code that has been poorly designed or badly maintained so that logical relationships are difficult to see); maps allow the designer or user to reach a dialog box in several ways and then proceed from the dialog box to several places. For spaghetti code, the menu maps afford a simpler method of spotting relationships between states than trying to work exclusively from the program itself because the map shows transition between states on paper or on screen. After mapping the relationships, the designer or user can check the program against the map for correctness.

Full testing theoretically requires that all possible paths are tested. However, in practice, complete testing may be unattainable for complex programs. Therefore, it makes sense to test the most frequently used paths first.

39.5.3.1 Test Every Limit. It is necessary to test every limit on a program's behavior that is specified by any of the program's documents. Limits include the size of files, the number of terminals, the memory size the program can manage, the maximum size it requires, and the number of printers the program can drive. It is important to check on the ability of the program to handle large numbers of open files on an immediate basis and on a long-term, continuing basis as well. Load testing is actually boundary condition testing and should include running tests the program ought to pass and tests the program should not pass.

For Web applications, tools exist to simplify this task, as some will check the boundaries and limits of fields at varying depths of data entry to test the protections against buffer overflow, invalid data, and incorrect data syntax; such tools include but are not limited to WebInspect by Spi Dynamics.

39.5.3.2 Test for Race Conditions. After testing the system under "normal" load, it should be tested for race conditions. A "race condition" is usually defined as anomalous behavior due to unexpected critical dependence on the relative timing of events. Race conditions generally involve one or more processes accessing a shared resource such as a file or variable, where this multiple access has not been properly controlled. Systems that are vulnerable to races, especially multiuser systems with concurrent access to resources, should undergo a full cycle of testing under load. Race conditions sometimes can be identified through testing under heavy load, light load, fast speed, slow speed, multiprocessors running concurrent programs, enhanced and more numerous input/output devices, frequent interrupts, less memory, slower memory, and related variables.

39.5.4 Use Test-Coverage Monitors. For complex programs, path testing usually cannot or would not test every possible path throughout a program for practical

as well as cost-effectiveness reasons. A more practical glass box approach (i.e., with knowledge of the internal design of a program) is to use the source code listing to force the program down every branch visible in the code. When programmers add special debugging code during development, a unique message will print out or be added to a log file whenever the program reaches a specified point. Typically, such messages can be generated by calling a print routine with a unique parameter for each block of code. When source code is compiled, many languages permit a switch to be set to allow conditional compilation, so that a test version of the code contains active debugging statements whereas a production version does not. For interpreted code, such as most fourth-generation languages, similar switches allow for inclusion or activation of debugging instructions.

Since distinct messages are planted, it is possible to know exactly what point in the program the test has reached. Programmers specifically insert these messages at significant parts of the program. Once these messages have been added, anyone can run the program and conclude whether the different parts actually have run and been tested.

Special devices or tools also can be used to add these messages to the code automatically. Once source code is fed to such a coverage monitor, it analyzes the control structures in the code and adds probes for each branch of the program. Adding these probes or lines of code is called instrumenting the program. It is possible to tell that the program has been pushed down every branch when all the probes have been printed. Besides instrumenting code, a good coverage monitor can capture probe outputs, perform analyses, and summarize them. Some coverage monitors also log the time used for each routine, thus supporting performance analysis and optimization.

A coverage monitor is designed for glass box testing, but knowledge of the internals of the program under test is not needed in order to use the monitor. The coverage monitor counts the number of probe messages, reports on the number of probes triggered, and even reports on the thoroughness of the testing. Because it is possible for the coverage monitor to report on untriggered branches, the monitor can find and identify code that does not belong, such as routines included by default but never used or deliberately inserted undocumented code (a Trojan horse). Some commercially available coverage monitors are, unfortunately, themselves full of bugs. It is important to obtain a full list of the known bugs and patches from the developer. In addition, such tools should themselves be tested with programs that contain known errors, in the process known as seeding, to verify their correctness.

39.5.5 Seeding. Quality assurance procedures themselves benefit from testing. One productive method, known as seeding, is to add known bugs to a program and measure how many of them are discovered through normal testing procedures. The success rate in identifying such known bugs can help estimate the proportion of unknown bugs left in a program. Such seeding is particularly important when establishing automated testing procedures and test-coverage monitors; also, it is useful for SOX or other compliance-related testing.

39.5.6 Building Test Data Sets. One of the most serious errors in quality assurance is to allow programmers to use production data sets for testing. Production data may include confidential information that should not be accessible to programming staff, so access should be forbidden not only to production data but even to copies of production data, or even to copies of subsets or samples from production data. However, *anonymizing* processes applied to copies of production data (e.g., scrambling names

39 · 16 SOFTWARE DEVELOPMENT AND QUALITY ASSURANCE

and addresses of patients in a medical records database) may produce test data sets suitable for use in quality assurance.

Alternatively, if the organization has a test system that is completely (logically and physically) segregated from the production system, using historical data may be appropriate. In doing so, particular care and appropriate documentation must be maintained to ensure that there is no chance of the test system interfacing with the production system. A side benefit of such testing is that it may help the organization's SOX or HIPAA periodic testing and documentation regarding the availability, utility, and integrity of backup media and systems.

39.5.7 Fuzzing. A useful addition to the techniques described above is the automated injection of random data into the input stream. *Fuzzing* can support the planned challenges to a system with unexpected inputs that programmers may not have thought of.

39.6 BEFORE GOING INTO PRODUCTION

39.6.1 Regression Testing. Regression testing is fundamental work done by glass box and black box testers. The term is used in two different ways. The first definition involves those tests where an error is found and fixed and the test that exposed the problem is performed again. The second definition involves finding and fixing an error and then performing a standard series of tests to make certain the changes or fix made did not disturb anything else.

The first type of regression testing serves to test that a fix does what it is intended to do. The second type tests the fix and also tests the overall integrity of the program. It is not unusual for people who mention regression testing to be referring to both definitions, since both involve fixing and then retesting. It is recommended that both types of testing be done whenever errors are fixed. If an organization is subject to SOX or HIPAA, appropriate documentation should be maintained that details the test methodology, the sample selection, the frequency, the results, and the remediation (if any).

39.6.2 Automated Testing. In some enterprises, every time a bug is fixed, every time a program is modified, and every time a new version is produced, a tester runs a regression test. All of this testing takes a considerable amount of time and consumes both personnel and machine resources. In addition, repetitive work can become mind-numbing, so testers may accidentally omit test cases or overlook erroneous results.

To cut down on the time consumption of personnel and the repetitive nature of the task, it is possible to program the computer to run acceptance and regression tests. This type of automation results in execution of the tests, collection of the results, comparison of the results with known good results, and a report of the results to the tester.

Early test automation consisted essentially of keyboard macros or scripts, with limited capacity for responding to errors; typically, an error would produce invalid results that would be fed into the next step of processing and lead to long chains of meaningless results. Slightly more advanced test harnesses would halt the test process at each error and require human intervention to resume. Both methods were of only modest help to the test team. However, today's test-automation software can include test databases that allow orderly configuration of tests, specific instructions for restarting test sequences after errors, and full documentation of inputs and results. For realistic load testing, some systems can be configured to simulate users on workstations, with

scripts that define a range of randomly generated values, specific parameter limits, and even variable response times. Large-scale load testing can connect computers together through networks to simulate thousands of concurrent users and thus speed identification of resource exhaustion or race conditions.

Test automation can be well worth the expenditures required. Automated testing is usually more precise, more complete, faster, and less expensive than the tests done by human personnel. Typically, automated tests can accomplish tenfold or hundredfold increases in the number of tests achievable through manual methods. In addition to freeing personnel to do more rewarding work, such methods greatly reduce overall maintenance costs due to detection of errors before systems reach production. Additionally, for regulatory purposes, the automated testing requires significantly less sampling, documentation, and testing. Appropriate management review and reporting of results still are required, as is documentation of remediation follow-up.

39.6.3 Tracking Bugs from Discovery to Removal. Finding a bug is not enough. Even eliminating a bug is insufficient. A system also must allow the causes of each bug to be identified, documented, and rectified. For these reasons, it is important to track and document all problems from the time of their discovery to their removal, to be certain that the problems have been resolved and will not affect the system. Too, this provides important historical records in diagnosing and remediating incidents and provides appropriate documentation for audit and regulatory purposes.

Problem-tracking systems must be used to report bugs, track solutions, and write summary reports about them. An organized system is essential to ensure accountability and communication regarding the bugs. Typical reports include: where bugs originate (e.g., which programmers and which teams are responsible for the greatest number of bugs); types of problems encountered (e.g., typographical errors, logic errors, boundary violations); and time to repair. However, problem-tracking systems can raise political issues, such as project accountability, personal monitoring, control issues, and issue remediation regarding the data in the database and who owns them.

Once a tracking system is established, a bug report is entered into the database system and a copy goes to the project manager, who either prioritizes it and passes it along or responds to it personally. Eventually, the programmers will be brought into the loop, will fix the problem, and will mark the problem as fixed. The fixed problem then is tested and a status report is issued. If a fix proves not to work, that becomes a new problem that needs to be addressed.

39.7 MANAGING CHANGE. Many people may be involved in creating and managing systems; whenever changes are made to the system, those changes need to be managed and monitored in an organized fashion to avoid chaos.

39.7.1 Change Request. The change request is an important document that requests either a fix or some other change to a program or system. Information contained on the change request form generally includes who is requesting the change, the date the request is being made, the program and area affected, the date by which the change is needed, and authorization to go ahead and make the change.

Most companies have paper forms that are retained for monitoring and auditing purposes. As the popularity of digital signatures grows and society continues to move toward a paperless office, it seems logical that some of these change requests eventually will become totally automated.

39.7.2 Tracking System. The tracking system may be manual, automated, or a combination of methods; for regulatory and control purposes, a system that incorporates automated tracking is best, since it reduces the chance for error, and it can enhance follow-up and remediation. Regardless of how it is kept, the original change form generally is logged into a system, either manually filed or entered into an automated database by some identifying aspect, such as date, type of change, or requesting department.

The system is used to track what happens to the change. When an action is taken, information must be entered into the system to show who worked on the request, what was done, when action was taken, what the result of the action was, who was notified of the actions taken, whether the change was accepted, and related information. This information is crucial in ensuring that issues are managed appropriately, escalated as needed to senior management, and tracked until remediated.

39.7.3 Regression Testing. When a change or fix has been made, regression testing verifies that the change has indeed been made and that the program now works in the fashion desired, including all other functions. The successful completion of the testing should be documented in writing; this can be through the tracking system or in documentation appended to the tracking system entry.

39.7.4 Documentation. Documentation is crucial when considering, approving, and implementing changes. If information is retained strictly in an individual's head, what happens when the individual goes on vacation, is out sick, or leaves the enterprise permanently? What if the individual simply does not remember what changes were made, or when; how does an organization know who was involved, what actually was done, and who signed off that the changes were made and accepted?

Undocumented changes can result in:

- System crashes
- Inconsistent data entry
- Inappropriate segregation of duties
- Data theft or corruption
- Embezzlement
- Other serious crimes

Lack of documentation can mean that unauthorized changes were made and likely can result in regulatory and audit violations. Undocumented changes may violate segregation of duties (e.g., a person might be informally approving changes to his or her own account, approving changes carried out by a supervisor, or authorizing changes by a person who is not under the responsibility of the approver).

Lack of documentation is often a violation of corporate policy and is often cited in audits; it often will cause significant difficulties regarding SOX, GLBA, and HIPAA compliance efforts and reviews, since management's assertions might not be supported adequately. Because constructing adequate documentation after the fact is almost impossible (and frequently can be considered to be falsification of records in sectors such as financial services), documentation must proceed in step with every phase of a system's development and operation. Thereafter, documentation must be retained according to company policy and legal requirements.

39.8 SOURCES OF BUGS AND PROBLEMS. Locating and fixing bugs is an important task, but it is also essential to try to determine where and why the bugs and related problems originated. By finding and studying the source, often it is possible to prevent a recurrence of the same or similar type of problem.

39.8.1 Design Flaws. Design flaws often occur because of poor communication between users and designers. Users are not always clear about what they want and need, while designers misunderstand, misinterpret, or simply ignore what the users relate to them. Within the design process, even when users' feelings and requirements are known and understood, design flaws can occur. However, they are easier to identify and remedy if the appropriate documentation is affected. Without the proper documentation, it may not be possible to identify the source of an error; this can result in patches or remedies that need to be patched. Often flaws result from attempts to comply with unrealistic delivery schedules. Managers should support their staff in resisting the pressure to rush through any of the design, development, and implementation stages.

39.8.2 Implementation Flaws. Whenever a program is developed and implemented, there are time limits and deliverable dates. Most problems during development cause delay, so developers and testers often are rushed to get the job done. Sometimes they sacrifice the documentation, the review portion of the project, or even cut short testing, leaving unrecognized design and implementation flaws in place. Managers should emphasize the value of thorough review and testing, and allocate enough time to avoid such blunders.

39.8.3 Unauthorized Changes to Production Code. If problems are traced to unauthorized changes, project managers should examine their policies. If the policies are clear, perhaps employee training and awareness programs need improvement. Managers also should examine their own behavior to ensure that they are not putting such pressure on their staff that cutting corners is perceived to be acceptable.

39.8.4 Insufficient or Substandard Programming Quality. A programmer can make or break a program and a project. Programmers play essential roles in software development. Therefore, it is important that all programmers on a project be capable and reliable. Project programmers should be carefully screened before being placed on a software development project to ensure that their skills meet project requirements. Sometimes holes in programmers' skills can be filled with appropriate training and coaching. However, if problems appear to be consistent, management may want to check a programmer's background to verify that he or she did not falsify information when applying for the job. Truly incompetent programmers need to be removed from the project. Additionally, if management suspects that the programming quality is inadequate, then it should consider having an independent programmer review the code, performing particularly rigorous quality assurance (QA) testing.

39.8.5 Data Corruption. Data corruption can occur because of poor programming, invalid data entry, inadequate locking during concurrent data access and modification, illegal access by one process to another process data stack, and hardware failures. Data corruption can occur even when a program is automatically tested or run without human intervention. In any event, when searching for the sources of bugs and other problems, it is important to do a careful review of the data after each round of testing, in order to identify deviations from the correct end state. The review should

be documented appropriately and escalated to management; it then will assist the regulatory compliance efforts.

39.8.6 Hacking. When bugs and problems do occur, hacking—both internal and external—should be considered a possibility and searched for by reviewing the logs of who worked on the software and when that work was done. Managers should be able to spot the use of legitimate IDs when the individuals involved were on vacation, out sick, or not available to log on for other reasons.

Archiving logs and retrieving them is an increasingly critical capability, aside from the regulatory requirements of SOX, HIPAA, GLBA, and so on. Logs are often used for:

- Incident response activities, particularly in determining:
 - If an incident occurred
 - When an incident occurred
 - What happened prior to and subsequent to when an incident is suspected to have occurred
- Research; this can be to review performance capabilities or issues of hardware or software or networking

To ensure that the logs are available when needed, the organization needs a sound strategy that preserves and archives logs periodically, so that an attacker or a system anomaly does not wipe them from the system's hard drive. Although there are many means to accomplish this, a frequently used inexpensive method involves establishing a log server. For example, an organization might identify a discarded desktop computer, outfit it with a new, high-speed, high-capacity optical read-only memory (ROM) drive, and increase memory capacity (if needed). By routing the logs to the optical drive frequently and recording them throughout the day (perhaps multiple times during an hour) and changing the optical disk at least daily, the organization will create a forensically sound archive that can be duplicated easily for research, law enforcement, or legal use. Often the daily logs volume will not fill a DVD or a CD. However, having the regular routine of changing the media daily helps ensure that the media does not reach its capacity at an inopportune time—indeed, if a worm such as Blaster or Nimda infects the organization, then the logs likely will swell rapidly. Too, if an attacker within the system stops the logging, the organization should encounter less difficulty determining the date, time (or time period), and extent of the intrusion because ROM cannot be overwritten, in contrast with read-write (RW) media.

Unauthorized changes to code and data sometimes can be identified even if the perpetrator stops the logging and deletes or modifies log files. One method is to create checksums for production or other official versions of software and to protect the checksums against unauthorized access and modification using encryption and digital signatures. Similarly, unauthorized data modifications sometimes can be made more difficult by creating checksums for records and linking the checksums to time and data stamps and to the checksums for authorized programs. Under those conditions, unauthorized personnel and intruders find it difficult to create valid checksums for modified records. Other products, such as intrusion detection systems (IDSs) or intrusion prevention systems (IPSs), may be useful in an organization's protection and risk-management strategy.

39.9 CONCLUSION. This chapter has presented a comprehensive overview of the software development and quality assurance processes that must be utilized when developing, implementing, and modifying software. Software development involves more than simply selecting and utilizing an approach such as the traditional, waterfall, or RAD methodology. It means working as a team to develop, review, refine, and implement a viable working product. Many good techniques and products can be applied to both the SDLC and the quality assurance portions of producing software; some of the key elements are good documentation, allowing sufficient time for testing in the development and maintenance processes, building good tests, establishing test data, automating testing, and keeping track of change requests.

40.1 INTRODUCTION. *Vulnerabilities* are flaws that can be exploited by a malicious entity to gain greater access or privileges than it is authorized to have on a computer system. *Patches* are additional pieces of code developed to address problems (commonly called “bugs”) in software. Patches correct security and functionality problems in software and firmware. *Patch management* is the process for identifying, acquiring, installing, and verifying patches for products and systems. Patch management is a security practice designed to proactively prevent the exploitation of IT vulnerabilities that exist within an organization. The expected result is to reduce the time and money spent dealing with vulnerabilities and the exploitation of those vulnerabilities. Proactively managing vulnerabilities of systems will reduce or eliminate the potential for exploitation and involve considerably less time and effort than responding after an exploitation has occurred.

This chapter is designed to assist organizations in implementing patch and vulnerability remediation programs. It first explains the importance of patch management and then discusses the challenges inherent in performing patch management. Next, the chapter provides an overview of enterprise patch management technologies and gives recommendations for their use. It also seeks to inform the reader about possible measures and metrics for enterprise patch management.¹

40.2 THE IMPORTANCE OF PATCH MANAGEMENT. From a security perspective, patches are most often of interest because they are mitigating software flaw vulnerabilities; applying patches to eliminate these vulnerabilities significantly reduces the opportunities for exploitation. Also, patches are usually the most effective way to mitigate software flaw vulnerabilities, and are often the only fully effective solution. Sometimes there are alternatives to patches, such as temporary workarounds involving software or security control reconfiguration, but these workarounds often negatively impact functionality.

Patches serve other purposes than just fixing software flaws; they can also add new features to software and firmware, including security capabilities. New features can also be added through upgrades, which bring software or firmware to a newer version in a much broader change than just applying a patch. Upgrades may also fix security and functionality problems in previous versions of software and firmware. Also, vendors often stop supporting older versions of their products, which includes no longer releasing patches to address new vulnerabilities, thus making older versions less secure over time. Upgrades are necessary to get such products to a supported version that is patched.

As Section 40.3 of this chapter explains, there are several challenges that complicate patch management. If organizations do not overcome these challenges, they will be unable to patch systems effectively and efficiently, leading to easily preventable compromises. Organizations that can minimize the time they spend dealing with patching can use those resources for addressing other security concerns. Already many organizations have largely operationalized their patch management, making it more of a core IT function than a part of security. However, it is still important for all organizations to carefully consider patch management in the context of security because patch management is so important to achieving and maintaining sound security.

Patch management is required by various security compliance frameworks, mandates, and other policies. For example, NIST Special Publication (SP) 800-53² requires the SI-2, Flaw Remediation security control, which includes installing security-relevant software and firmware patches, testing patches before installing them, and incorporating patches into the organization's configuration management processes. Another example is the Payment Card Industry (PCI) Data Security Standard (DSS),³ which requires that the latest patches be installed and sets a maximum time frame for installing the most critical patches.

40.3 THE CHALLENGES OF PATCH MANAGEMENT. This section briefly examines the challenges inherent in performing patch management. These are the challenges that the patch management technologies discussed in Section 40.4 of this chapter are trying to solve.

40.3.1 Timing, Prioritization, and Testing. Timing, prioritization, and testing are intertwined issues for enterprise patch management. Ideally, an organization would deploy every new patch immediately to minimize the time that systems are vulnerable. However, in reality this is simply not possible because organizations have limited resources, which makes it necessary to prioritize which patches should be installed before other patches. Further complicating this is the significant risk of installing patches without first testing them, which could cause serious operational disruptions, potentially even more damaging than the corresponding security impact of not pushing the patches out. Unfortunately, testing patches consumes even more of the limited resources and makes prioritization even more important. For patch management, timing, prioritization, and testing are often in conflict.

Product vendors have responded to this conflict by bundling patches for their products. Instead of releasing dozens of patches one at a time over a period of three months, necessitating testing and patch deployment every few days, a vendor might release their patches in a single bundle once a quarter. This allows an organization to perform testing once and roll out patches once, which is far more efficient than testing and rolling out all the patches separately. It also reduces the need to prioritize patches—the organization just needs to prioritize the bundle instead of separately prioritizing each patch it contains. Vendors who bundle patches tend to release them monthly or quarterly, except for cases when an unpatched vulnerability is actively being exploited, in which case they usually issue the appropriate patch immediately instead of delaying it for the next bundle.

There is a downside to patch bundling; it lengthens the time from the discovery of a vulnerability to the time a patch for it becomes publicly available. If an attacker discovers the same vulnerability before the patch is released, the attacker may have a longer window of opportunity to exploit the vulnerability because of the intentional delay in releasing the patch. However, there are two mitigating factors here. One is that if exploitation is known to be occurring, the vendor is likely to release the patch immediately. The other factor is that patches may be installed more quickly if they are bundled than if they are all released separately. So that effectively helps to shrink the window of opportunity for vulnerabilities associated with bundled patches.

There are even more issues to consider with timing. The release of a patch may provide attackers with the information that they need to exploit the corresponding vulnerability (e.g., reverse engineer the vulnerability from the patch), meaning that a newly released patch might need to be applied immediately to avoid compromises. However, if a vulnerability is not being exploited yet, organizations should carefully weigh the security risks of not patching with the operational risks of patching without performing thorough testing first. In some operational environments, such as virtual hosts with snapshot capabilities enabled, it may be preferable to patch without testing as long as the organization is fully prepared to roll back the patches if there are usability or functionality problems caused by them.

Another fundamental issue with timing is forcing the implementation of changes to make a patch take effect; this can require restarting a patched application or service, rebooting the operating system, or making other changes to the state of the host. Ultimately what matters is not when the patch was installed, but when the patch actually takes effect. In some cases it may make more sense to mitigate a vulnerability through an alternative method, at least until patches are fully operational. An example is changing configuration settings for vulnerable software to temporarily block vulnerable application functionality. Each mitigation option has different implications for the security, functionality, and operations of the vulnerable host, so it is not a trivial

40 · 4 **MANAGING SOFTWARE PATCHES AND VULNERABILITIES**

matter to select one option over others. Also, if configuration settings are changed, this necessitates preserving the old setting values and restoring them at the appropriate time. Another problem with changing configuration settings is that they often require a state change to the host to take effect, such as restarting an application. Implementing configuration changes may be as disruptive to the operations of a host as installing a patch.

Forcing the implementation of changes that requires rebooting the operating system can be problematic when the host requires authentication before booting, such as the use of full disk encryption (FDE) software. Organizations using FDE software or other technologies that require authentication before booting should carefully consider the impact that these technologies may have on patch installation.

Prioritizing which patches to apply and when to apply them is closely related to timing, but there are other considerations as well. It can depend on the relative importance of the vulnerable systems (for example, servers versus clients) and the relative severity of each vulnerability (e.g., vulnerability severity metrics such as the Common Vulnerability Scoring System [CVSS]). Another consideration is dependencies that patches may have on each other; installing one patch may require installing other patches first, and in some cases restarting an application or rebooting a host multiple times to make the patches take effect sequentially.

In summary, organizations should carefully consider the relevant issues related to timing, prioritization, and testing when planning and executing their enterprise patch management processes.

40.3.2 Patch Management Configuration. Another major challenge in enterprise patch management is that there are usually multiple mechanisms for applying patches. For example:

- A piece of software may be able to automatically update itself.
- A centralized OS management tool may be able to initiate patching.
- Third-party patch management applications may be able to initiate patching.
- Network access control, health check technologies, and similar technologies may be able to initiate patching.
- A user may be able to manually direct software to update itself.
- A user may be able to manually install a patch or a new version of the software.

Having multiple ways of applying patches can cause conflicts. Multiple methods might each try to patch the same software, which is particularly problematic when the organization doesn't want certain patches applied because of issues with those patches, testing delays, etc. Multiple methods can also cause patches to be delayed or missed, because each tool or administrator may assume another one is already taking care of a particular patch. Organizations should identify all the ways in which patches could be applied and act to resolve any conflicts among patch application methods.

A related problem with patch management configuration is that users may override or circumvent patch management processes. If users are able to make changes to their hosts' software, such as altering settings (e.g., enabling direct updates, disabling patch

management software), installing old versions of software, and uninstalling patches, they can undermine patch management integrity. To address these problems, organizations should ensure that users cannot disable or otherwise negatively affect enterprise patch management technologies, and organizations should perform continuous monitoring of enterprise patch management technologies to identify any issues that occur.

40.3.3 Alternative Host Architectures. Enterprise patch management is relatively straightforward when all of the hosts are fully managed and running typical applications and operating systems on a regular platform. When alternative host architectures are employed, patch management can be considerably more challenging. Examples of these architectures include the following:

Unmanaged hosts. As discussed in Section 40.3.2 of this chapter, it can be much more difficult to control patching when hosts are not centrally managed (i.e., users manage their own hosts).

Out-of-office hosts (e.g., telework laptops). Hosts on other networks are not protected by the enterprise's network security controls (firewalls, network intrusion detection systems, vulnerability scanners, etc.).

Nonstandard IT components (e.g., appliances). On such hosts, it's often not possible to patch individual applications independently. Rather, the organization must wait for the component vendor to release updated software.

Mobile devices. Smartphones, tablets, and other mobile devices (excluding laptops) typically run mobile operating systems, and patching for these devices is fundamentally different. It is often necessary to connect the mobile device to a desktop or laptop and to acquire and download updates through that desktop or laptop. Some mobile devices can directly download updates, but this can be problematic because of bandwidth considerations (such as taking a long time to download large updates and paying data charges for the downloads). Another option for keeping mobile devices updated is the use of enterprise mobile device management software. Enterprise mobile device management software is used to manage mobile devices, even personally owned devices not controlled by the organization. It can install, update, and remove applications, and it can restrict enterprise access if the phone's operating system and mobile device management software are not up to date. See Section 3 of SP 800-124 Revision 1, Guidelines for Managing and Securing Mobile Devices in the Enterprise, for more information.

Operating system (OS) virtualization. Patches need to be maintained for every OS image and snapshot used for full virtualization. Patching capabilities are often built into virtualized environments, such as the ability to patch offline images and quarantine dormant virtual machine instances. See NIST SP 800-125, Guide to Security for Full Virtualization Technologies, for additional information—specifically, Section 3.3 discusses virtual machine image and snapshot management.

Firmware. Firmware updates, such as updating the system BIOS, generally require special privileges and involve different procedures than other types of updates. See NIST SP 800-147, BIOS Protection Guidelines, for additional information on BIOS updates.

40 · 6 MANAGING SOFTWARE PATCHES AND VULNERABILITIES

Organizations should carefully consider all alternative host architectures in use for the enterprise when designing enterprise patch management policies and solutions.

40.3.4 Other Challenges. This section briefly discusses other challenges not covered earlier in this section.

40.3.4.1 Software Inventory Management. Enterprise patch management is dependent on having a current and complete inventory of the patchable software (applications and operating systems) installed on each host. This inventory should include not only which software is currently installed on each host, but also what version of each piece of software is installed. Without this information, the correct patches cannot be identified, acquired, and installed. This inventory information is also necessary for identifying older versions of installed software so that they can be brought up to date. A major benefit of updating older versions is that it reduces the number of software versions that need to be patched and have their patches tested.

40.3.4.2 Resource Overload. Enterprise patch management can cause resources to become overloaded. For example, many hosts might start downloading the same large patch (or bundle of patches) at the same time. This could consume excessive network bandwidth or, if the patches are coming from an organization patch server, overwhelm the resources of that server. Organizations should ensure that their enterprise patch management can avoid resource overload situations, such as by sizing the solution to meet expected volumes of requests, and staggering the delivery of patches so that the enterprise patch management system does not try to transfer patches to too many hosts at the same time.

40.3.4.3 Installation Side Effects. Installing a patch may cause side effects to occur. A common example is the installation inadvertently altering existing security configuration settings or adding new settings. This may create a new security problem in the process of fixing the original vulnerability via patching. Organizations should be capable of detecting side effects, such as changes to security configuration settings, caused by patch installation.

40.3.4.4 Patch Implementation Verification. As discussed in Section 40.3.1 of this chapter, an installed patch might not take effect until the affected software is restarted or other state changes are made. It can be surprisingly difficult to examine a host and determine whether or not a particular patch has taken effect. This is further complicated when there is no indication for a patch when it would take effect (reboot required/not required, etc.). One option is to attempt to exploit the vulnerability, but this is generally only feasible if an exploit already exists, and there are substantial risks with attempting exploitation, even under highly controlled conditions. Organizations should use other methods of confirming installation, such as a vulnerability scanner that is independent from the patch management system.

40.3.4.5 Application Whitelisting. Application whitelisting technologies can conflict with patch management technologies because the application whitelisting technologies function based on known characteristics of executables and other application components, which may be changed by patching. If the vendor is providing the whitelist information, the vendor will have to acquire the patch, record its files' characteristics, and send the corresponding information to customers. If the organization

is building its own whitelist information, it will have to acquire each patch, record its files' characteristics, and update its whitelists with the new information. Either method may cause problematic delays for organizations that apply patches quickly, especially automatically; patched software may be seen as unknown software and prohibited from running.

To avoid these problems with updates, most application whitelisting technologies offer maintenance options. For example, many technologies allow the administrator to select certain services (e.g., patch management software) to be trusted updaters. This means that any files that they add to or modify on a host are automatically added to the whitelist. Similar options are available for designating trusted publishers (i.e., software vendors), users (such as system administrators), sources (such as trusted network paths), and other trusted entities that may update whitelists. Organizations using application whitelisting technologies should ensure that they are configured to avoid problems with updates.

40.4 ENTERPRISE PATCH MANAGEMENT TECHNOLOGIES. This section provides an overview of enterprise patch management technologies. It discusses their composition, focuses on the security and management capabilities that they provide, and gives recommendations for their use.

40.4.1 Components and Architecture. Enterprise patch management technologies are similar architecturally to other enterprise security solutions: one or more centralized servers that provide management and reporting, and one or more consoles. Enterprise patch management technologies can also be offered as a managed service. What distinguishes enterprise patch management technologies from each other architecturally are the techniques they use to identify missing patches. The three prevalent techniques are agent-based, agentless scanning, and passive network monitoring. Many products support only one of these techniques, while other products support more than one. All the techniques are explained in more detail in the following subsections. Organizations should carefully consider the advantages and disadvantages of each technique when selecting enterprise patch management technologies.

40.4.1.1 Agent-Based. An agent-based patch management technology requires an agent to be running on each host to be patched, with one or more servers that manage the patching process and coordinate with the agents. (Note that agent-based patch management technology is built into some operating systems.) Each agent is responsible for determining what vulnerable software is installed on the host, communicating with the patch management servers, determining what new patches are available for the host, installing those patches, and executing any state changes needed to make the patches take effect (e.g., application restart, OS reboot). Each agent runs with administrator privileges so it can perform these actions. The patch management server is responsible for providing the agents with information on vulnerable software and available patches, including where patches can be acquired and what state changes are needed.

Compared to agentless scanning and passive network monitoring, agent-based patch management technologies are strongly preferred for hosts that are not on the local network all the time, such as telecommuter laptops and smartphones.

There are a few limitations to agent-based patch management technologies. Hosts that don't permit direct administrator access to the operating system, such as many

40 · 8 MANAGING SOFTWARE PATCHES AND VULNERABILITIES

appliances, generally cannot run agents. Also, agents may not be available for all of the organization's platforms.

40.4.1.2 Agentless Scanning. An agentless scanning patch management technology has one or more servers that perform network scanning of each host to be patched and determine what patches each host needs. Generally, agentless scanning requires the servers to have administrative privileges on each host, so that they can return more accurate scanning results and they have the ability to install patches and implement state changes on the hosts (application restarts, OS reboots, etc.).

The main advantage of agentless scanning is that it doesn't require the installation and execution of an agent on each host.

One of the primary limitations of agentless scanning is that it omits hosts not on the local network, such as telecommuter laptops and mobile devices. Also, network security controls (e.g., host-based firewalls) and network technologies (e.g., network address translation) may inadvertently block scanning or otherwise negatively affect scanning results. Agentless scanning may also negatively impact operations by consuming excessive amounts of bandwidth. Finally, agentless scanning may not support all of the organization's platforms.

40.4.1.3 Passive Network Monitoring. Passive network monitoring technologies for patch management monitor local network traffic to identify applications (and in some cases, operating systems) that are in need of patching.

These technologies can be effective at identifying hosts that are not being maintained by other patch management solutions (agent-based, agentless scanning). They do not require any privileges on the hosts to be monitored, so they can be used to monitor the patch status of hosts that the organization does not control (unmanaged systems, visitor systems, contractor systems, etc.).

The primary disadvantage of passive network monitoring is that it only works with software where you can identify the version based on its network traffic (assumed to be unencrypted). Also, of course, it only works with hosts on the local network.

40.4.2 Security Capabilities. This section describes common security capabilities provided by patch management technologies, divided into three categories: inventory management, patch management, and other.

40.4.2.1 Inventory Management Capabilities. Patch management technologies typically have capabilities for identifying which software and versions of software are installed on each host, or alternately, just identifying vulnerable versions of software that are installed. In addition, some products have features for installing new versions of software, installing or uninstalling software features, and uninstalling software.

40.4.2.2 Patch Management Capabilities. Patch management technologies obviously provide a range of patch management capabilities. Common features include identifying which patches are needed, bundling and sequencing patches for distribution, allowing administrators to select which patches may or may not be deployed, and installing patches and verifying installation. Many patch management technologies also allow patches to be stored centrally (within the organization) or downloaded as needed from external sources.

40.4.2.3 Other Capabilities. Many host-based products that have patch management capabilities also provide a variety of other security capabilities, such as antivirus software, configuration management, and vulnerability scanning. Further discussion of these capabilities is outside the scope of this chapter.

40.4.3 Management Capabilities. Once a patch management technology has been selected, its administrators should design a solution architecture, perform testing, deploy and secure the solution, and maintain its operations and security. This section highlights issues of particular interest with the management—the implementation, operation, and maintenance—of patch management technologies, and provides recommendations for performing them effectively and efficiently.

40.4.3.1 Technology Security. Deploying enterprise patch management tools within an enterprise can create additional security risks for an organization; however, a much greater risk is faced by organizations that do not effectively patch their systems. Such tools usually increase security far more than they decrease security, especially when the tools contain built-in security measures to protect against security risks and threats. The following are some risks with using these tools:

- A patch may have been altered (inadvertently or intentionally).
- Credentials may be misused.
- Vulnerabilities in the solution components (including agents) may be exploited.
- An entity could monitor tool communications to identify vulnerabilities (particularly when the host is on an external network).

Organizations should reduce these risks through the application of standard security techniques that should be used when deploying any enterprise-wide application. Examples of countermeasures include the following:

- Keeping the patching solution components tightly secured (including patching them)
- Encrypting network communications
- Verifying integrity of patches before installing them
- Testing patches before deployment (to identify corruption)

40.4.3.2 Phased Deployment. Organizations should deploy enterprise patch management tools using a phased approach. This allows process and user communication issues to be addressed with a small group before deploying the patch application universally. Most organizations deploy patch management tools first to standardized desktop systems and single-platform server farms of similarly configured servers. Once this has been accomplished, organizations should address the more difficult issue of integrating multiplatform environments, nonstandard desktop systems, legacy computers, and computers with unusual configurations. Manual methods may need to be used for operating systems and applications not supported by automated patching tools, as well as some computers with unusual configurations; examples include embedded systems, industrial control systems, medical devices, and experimental systems. For such computers, there should be a written and implemented procedure for the manual patching process.

40.4.3.3 Usability and Availability. Organizations should balance their security needs with their needs for usability and availability. For example, installing a patch may “break” other applications; this can best be addressed by testing patches before deployment. Another example is that forcing application restarts, OS reboots, and other host state changes is disruptive and could cause loss of data or services. Again, organizations need to balance the need to get patches applied with the need to support operations. A final example, particularly important for mobile devices, is the acquisition of updates over low-bandwidth or metered connections; it may be technically or financially infeasible to download large patches over such connections. Organizations should make provisions for ensuring that their enterprise patching solution works for mobile hosts and other hosts used on low-bandwidth or metered networks.

40.5 METRICS AND MEASURES. As explained in Section 3.3 of NIST SP 800-55 Revision 1, Performance Measurement Guide for Information Security, there are three types of measures:

1. Implementation measures are used to demonstrate progress in implementing security programs, specific security controls, and associated policies and procedures...
2. Effectiveness/efficiency measures are used to monitor if program-level processes and system-level security controls are implemented correctly, operating as intended, and meeting the desired outcome...
3. Impact measures are used to articulate the impact of information security on an organization’s mission...⁴

Regarding these types of measures, “less mature information security programs need to develop their goals and objectives before being able to implement effective measurement. More mature programs use implementation measures to evaluate performance, while the most mature programs use effectiveness/efficiency and business impact measures to determine the effect of their information security processes and procedures.” Accordingly, organizations should implement and use appropriate measures for their enterprise patch management technologies and processes.

Examples of possible implementation measures include:

- What percentage of the organization’s desktops and laptops are being covered by the enterprise patch management technologies?
- What percentage of the organization’s servers have their applications automatically inventoried by the enterprise patch management technologies?

Examples of possible effectiveness/efficiency measures include:

- How often are hosts checked for missing updates?
- How often are asset inventories for host applications updated?
- What is the minimum/average/maximum time to apply patches to X% of hosts?
- What percentage of the organization’s desktops and laptops are patched within X days of patch release? Y days? Z days? (where X, Y, and Z are different values, such as 10, 20, and 30).

- On average, what percentage of hosts are fully patched at any given time? Percentage of high impact hosts? Moderate impact? Low impact?
- What percentage of patches are applied fully automatically, versus partially automatically, versus manually?

Examples of possible impact measures include:

- What cost savings has the organization achieved through its patch management processes?
- What percentage of the agency's information system budget is devoted to patch management?

41.1 INTRODUCTION. For over three decades, malware has been a persistent, annoying, and costly threat, and there is no end in sight to the problem. There are many vendors offering to provide a cure for viruses and malware, but the mere existence of these software pests is understandably vexing to those charged with system security.

Initially, most viruses were not designed to cause harm but were created more to gain notoriety for the creator or as a prank. Because these early viruses were designed to subvert legitimate program operations across multiple systems, they were more likely to cause unexpected problems because the virus writers didn't do exhaustive testing. These viruses, and later some Trojans, often damaged data and caused system downtime. The cleanup required to recover from even a minor virus infection was expensive in terms of lost productivity and unbudgeted labor costs.

Viruses and Trojan behavior have merged, and now both are considered as part of the larger family referred to as malware. No longer is malware just written for a virus writer's 15 minutes of fame; today, malware is created primarily for financial gain. Malware can still cause damage, but now it is more likely to have been created

to steal valuable information or the resources of an infected computer. Malware can steal valuable data for sale on underground markets, send spam from a compromised machine, or install software designed to eavesdrop on an affected user's activities, to name a few examples. Some malware programs can give full access to a hacker to control infected machines, and malware continues the trend of controlling affected machines in a "botnet." These collections of hijacked computers are used for a variety of activities, such as launching attack or sending spam. A botnet makes use of the increased power of networked computers, while making it more difficult to trace a suspected attacker. For more information about malware, see Chapters 16, 17, and 20 in this *Handbook*.

Because of this shift to a financial motivation for malware writing, something of an open-source community has sprung up to develop new malware. There have been two major areas where development has been most notable: evasion of traditional antivirus defenses and distribution by exploiting vulnerabilities in common software. In their efforts to evade traditional antivirus defenses, criminals often slightly modify and compress malware with *packers*, which frequently use sophisticated obfuscation or anti–reverse-engineering techniques. The primary focus of today's malware writers is to avoid the newsworthy outbreaks of the past, staying under the radar to accomplish targeted attacks (*phishing* and *spear phishing*). Some of the most common malware families now have as many as tens of thousands of variants with hundreds of variants being released each day. Once they are in a system, they often employ stealth techniques such as kernel-mode rootkits to hide themselves from the operating system and from many antivirus (AV) products.

New malware programs are being developed every day because vulnerabilities in software programs are so numerous, and it is often weeks between the time a vulnerability is discovered and the time that the vendor issues a security patch. Even more often, patches are announced by vendors but not implemented by users. Malware writers take advantage of these vulnerabilities and time lags, so research into vulnerabilities is imperative in order to create effective defenses with antivirus programs. A layered defense against malware infection is essential and should employ a modern antivirus scanner as well as a firewall and data encryption.

Although the threat of new malware remains, and its growth has become exponential, the technology deployed to defend computers against viruses and malware is one of the least understood aspects of security architecture. As a result, antivirus defenses are often set up improperly. This chapter describes available antivirus technologies and how they work and outlines methods for their effective application within a comprehensive program of computer security.

41.1.1 Antivirus Terminology. The acronym AV is widely used to describe the industry, the products (also sometimes abbreviated AVPs), and the programs that have been developed to defeat computer viruses.

Early AV programs used simple hard- and floppy-drive scans to search for a specific text string hidden within a specific file or a boot sector. This is the origin of the term *AV scanner*, which is now widely used as a generic term for all AV programs. That is how the term is used in this chapter, although it should be pointed out that many of today's AV scanners do much more than merely scan for known malware, and detection may now include unwanted programs as well as suspicious file activities.

When exploring AV product literature, it is common to see statements about the number of viruses and Trojans that exist. It is not unusual to see estimates of the total number of malware variants in the hundreds of millions, and six-digit estimates

of the number of new malware added every day. AV vendors' methods for counting differ from one to the next, and these numbers tell us very little about their detection capability. It is far more instructive to rely on the reports of reputable AV testing labs to get a clear idea of a product's effectiveness, than to rely on these numbers.

41.1.2 Antivirus Issues. In the early days of viruses, aside from having the ability to spread to other machines, there was little benefit in keeping a virus on a machine for any length of time. During the early days, viruses were relatively easy to find, because a virus usually caused noticeable damage that made users aware that their systems were infected. At other times, an unmistakable message or image appeared on the screen, alerting users to the infection. As virus writers discovered a monetary benefit to remaining on a system as long as possible, the number of affected machines increased tremendously. Viruses and malware have become complex, are adept at disguising themselves, and are not as easy to find and eradicate. To counter this problem, AV scanners have become sophisticated logic machines. This new level of complexity, of both the problem and the solution, has made it even more confusing for users. Too many people fail to understand the importance of having up-to-date AV products. Users do not know what to look for, and do not understand that viruses and malware do not announce their presence.

Modern AV software has an automatic-update capability, which has made updating a less labor-intensive process. Updates are the key to keeping systems malware-free because updates give the AV program the information necessary to find the newest viruses and malware. Unfortunately, because malware is released at such a prodigious pace, even daily updates of a traditional string-based scanner may not be enough to keep systems totally clear of threats. Many AV products now support essentially constant contact with the developers' servers and verify checksums on the servers to identify changes requiring a download. These methods allow updates within minutes of any change with no inconvenience to the users.

Most AV scanners look at what has happened before (i.e., known behavior of known malware), in order to detect infections. Although AV products now attempt to anticipate new threats, that is not their strong point. Additionally, many consumers who buy a new computer receive a working AV product with their purchase, but they do not choose to buy a subscription for AV updates once their free use period expires. They do not understand why they have to pay for something that seems to be working, and they are lulled into a false sense of security by thinking that their AV product is doing its job. Consumers who bring work from unprotected home computers into the office can quickly infect an entire network.

Security products historically have suffered from a lack of upper-management support because they are often viewed as high-cost/low-return items, and they are given a low priority in the security budget. The information technology (IT) team of an organization needs resources for things like identifying and patching vulnerable systems, monitoring and managing machines entering their network, monitoring suspicious behavior identified by firewalls, AV products, and security scanners. Considering the wide array of AV products from which to choose, and the large number of patches introduced each day, many system administrators despair. They will install and patch just what they have time for, and consider it good enough.

41.2 ANTIVIRUS BASICS. AV scanners are a bit like police officers walking the beat. They try to watch everything that is going on around them, look out for suspicious behavior, and attempt to intercede when they think something bad is happening or about

to happen. Both the police and AV scanners look for certain patterns and behaviors, and they leap into action when a suspect crosses a predetermined threshold of acceptability. Like the police, AV scanners sometimes reach the wrong conclusions. These errors are usually caused by insufficient data or by new and unexpected behavioral patterns.

Malware detection is an inexact science, and it is impossible to create an AV scanner with a 100 percent success rate. It is simply not possible to know the intent of every bit of code that enters a computer, and it is not feasible to test every bit of code before it executes. To do so would require that the AV scanner demand so much of the processing power of the CPU that valid programs would not be able to execute. Malware behaviors are subject to broad variations, and many use stealth or cloaking techniques to hide from the operating system and even from the AV scanner itself. There are no longer hard-and-fast rules that a user can apply to determine if a system harbors malware.

41.2.1 Early Days of AV Scanners. When viruses first started appearing with regularity in the late 1980s, their detection and eradication was relatively straightforward, but not necessarily easy. The viruses were quite simple and normally did not spread very quickly. The AV community quickly researched them, determined what made them work, and published effective fixes in short order. These fixes tended to be written for a specific virus and could not disinfect other viruses, even if they were of similar types. Most of the work fell on users to identify which virus (or type of virus) they thought they had and then search for a program that would fix it. Because Internet connectivity was not as prevalent as it is now, users frequently spent much time calling friends and associates in the hope that they could forward a disk copy of the necessary AV program. Additionally, there were no naming conventions for viruses, and it was difficult to determine with any conviction that the fix obtained would actually work.

Viruses of that period generally inserted their code in predictable sections of a program. The early scanners ran a search for a specific string of characters. If they found it, they would delete the virus code and attempt to restore the host program to its original uninfected form. Failing that, the scanner would usually advise the user that disinfection was incomplete and that they should delete the infected application and reinstall it.

As the number of viruses began to climb, software companies that had ventured into the AV market began to realize that creating and distributing individual fixes was no longer feasible. Instead, they began to develop more comprehensive scanners that could look for more viruses, both old and new. The new generations of scanners were comprised of two components: the scanning engine and the signature files. Each component was entirely dependent on the other to work. The engine consisted of the user interface and the application that scanned the system for viruses. The signature files were a database of the *fingerprints* (unique segments of code) of known viruses. Although some of these early scanners did a good job, many did not. None of the early AV scanners was able to catch all known viruses.

41.2.2 Validity of Scanners. The vendors of software scanners in the late 1980s and early 1990s faced a number of obstacles. It seemed there was a new AV vendor appearing every month, and the market became highly competitive as user awareness of the virus problem grew. Given this competitive state, there was vast dissension among the AV community as to how viruses for research should be stored and tested. Many AV vendors kept a library of viruses for their own use, and this fact was used in their marketing. Claims that one program worked better than another because it checked for more viruses were misleading because no one knew how many

viruses existed. There was simply no method of commercial or independent testing to check the validity of claims made by the AV product vendors. Additionally, there was a problem of naming the viruses. Each vendor created its own names for viruses, and it was not uncommon for one virus to be known by several names.

The AV vendors also disagreed on how AV scanners should operate in principle. Some vendors felt that AV scanners should only look for new viruses, and others felt that a good product should search for both old and new viruses. While this argument raged, viruses looked as though they would eventually gain the upper hand, especially as virus writers began to use underground bulletin boards, and later the Internet, to share and distribute virus code.

With no standards for the AV products, the public had little to go by other than the vendors' marketing copy and the advice of other users. However, if a recommendation was made by a friend for Brand X Antivirus because no viruses were found on the friend's system, it was possible that no viruses had ever been introduced in the friend's system at all, and Brand X could not find old viruses, new viruses, or any viruses at all.

Two things happened that revolutionized the AV scanner market. In 1993, Joe Wells, a research editor with a business magazine, began collecting viruses and virus reports from experts around the world and began assembling a library of these viruses. He named this library of viruses the *WildList* and made it available to legitimate AV researchers. His list divided viruses into those known to have infected systems (in the wild) and those that had been written but were not actively infecting (in the zoo). A naming convention of viruses also began to emerge in order to maintain an efficient and searchable database.

The other notable event was the development of commercial AV testing and certification by a company known as the National Computer Security Association (NCSA), which is now known as ICSA Labs. The NCSA started a consortium of AV vendors that, for a fee, submitted their products to be tested. NCSA and Joe Wells began collaboration for the use of his *WildList*, and Dr. Richard Ford, a noted virus expert, created a virus-testing laboratory for NCSA. Dr. Ford fashioned an environment in which AV scanners were put through their paces to see if they could detect all of the viruses in the *WildList*. AV vendors submitted their products every time a new version of their product was about to be released. Although the original test results were dismal (many scanners could not detect more than 80 percent of the viruses in the list), an environment had been created in which measurable improvements in the effectiveness of AV technology could be achieved. Naturally, the public and the press began to look for AV products that had been certified by NCSA. Eventually, other commercial and independent test laboratories independently developed their own certification and testing schemes to help users find reliable AV products.

Before long, other testing organizations joined the fray and AV products increased in complexity. It was clear that there was a need for testing standards to help users distinguish effective, unbiased tests from those that did not clearly demonstrate the capabilities of AV products. A group of AV researchers, academics, testers, and other interested parties created an organization to develop such standards, called the Anti-Malware Testing Standards Organization (AMTSO). This group has published a number of papers outlining considerations for how to produce or distinguish a good test from an inadequate one. These papers are meant to help both testers and those people reading tests.

41.2.3 Scanner Internals. As was noted earlier, an AV scanner cannot simply put each program into a computer's RAM and test it for malware before the program is

allowed to execute. To do that would require almost all the resources of the CPU, and users would have a system that operated at a snail's pace.

In order to operate efficiently, AV scanners have had to go to great lengths to improve their speed in order to check for the vast number of existing malware without bringing the entire system to a halt. Using sophisticated elimination methods to exclude signatures whose characteristics do not match those of the file being scanned, helps keep speeds reasonable.

There are five basic types of detection within a modern AV product. Most people are familiar with signature-based detection, which is also known as specific detection, but this is not the only technique in place anymore. AV products may use some or all of these five basic methods of operation:

1. **Specific detection.** Looking for known malware
2. **Generic detection.** Looking for infections by variants of known malware
3. **Heuristics.** Scanning for previously unknown viruses by noting suspicious behavior or file structures, as described more fully in Section 41.3.3
4. **Intrusion prevention.** Monitoring known-suspicious system changes and behaviors to prevent suspected malware
5. **Reputation.** Detecting malware by a file or Website's reputation, based on a number of factors including the number of times the file or Website has been downloaded, customer reports, or age of a Website

41.2.4 Antivirus Engines and Antivirus Databases. The AV engine and its signature database work in concert to prevent and detect malware trying to enter a system. The engine generally provides a library of commonly used functions. It consists of dozens of complex searching algorithms, CPU emulators, and various forms of programming logic. The engine determines which files to scan, which functions to run, and how to react when suspected malware is found. However, the engine knows absolutely nothing about the malware themselves and is almost useless without the signature database.

The signature database contains the fingerprints (snippets of distinctive code) of hundreds of millions of malware variants. As new malware and variants appear at an accelerating rate, it is imperative that the signature database be updated often. In 1995, the experts advised updating the database files at least once a month, but with so many viruses appearing each day, users today are advised to update at least daily—and ideally, to allow constant updates controlled by their AV product. AV manufacturers now provide products that check for updates automatically and download changes whenever a user is connected to the Internet. Some vendors also provide cloud-based signature databases so that computers that are connected to the Internet can check against a more-frequently updated set of signatures that are hosted on vendors' own remote systems.

The signature database also contains the rule sets used in heuristic scans. These types of scans can be slower and more intrusive than simple signature scans, and their design and implementation vary greatly between products. Most products now give users configurable options to lessen or increase heuristics as desired. Although signature scans can be considered a heuristic in themselves, the term is more commonly used to identify the more complex AV functions that attempt to locate viruses by identifying suspicious behavior and/or file structure.

Because the distinction between a scanning engine and a signature database is not obvious to many system administrators, many religiously update the database but are unaware that the engine also may need updating. This is a poor strategy that can result in many viruses slipping by the scanner undetected.

41.3 SCANNING METHODOLOGIES. AV products are configurable by the user or the system administrator to scan upon startup, constantly, or on demand. To be at its most effective, a scanner should be set to a continuous or “on access” scan, with a periodic, scheduled scan set to occur when the system is on but not in use. Users running less-optimized AV programs may find that this degrades system performance. Some scanners need to use much of the system’s memory on continuous scans in order to be able to test sections of code, which may make the applications noticeably slower when they first run. Therefore, a happy medium must be found—the AV scanner must be able to protect the system, while the user must be able to have full use of the system.

There is no one scanning method that is superior to the others. All of the scanning methods have their advantages and disadvantages, but none is able to detect malware with unfailing accuracy. A scan is looking for code and behaviors that have been noticed in other malware, and if a new malware exhibits new, previously unknown behaviors, it can pass by undetected. Therefore, most AV scanners do not rely on only one scanning method to detect malware, but have several included in their design.

41.3.1 Specific Detection. Each malware uses different code to perform its functions. A sequence of code that is specific to each malware is referred to as the fingerprint, or signature of that malware. To detect the presence of malware, the scanner looks for the signature, removes its code from the host file or system, and attempts to restore the infected program or system to an uninfected state. In early viruses, it was discovered that the signatures were usually found within specific areas of a program, specific to each virus. The scanners set out to inspect only those areas of a file rather than scanning an entire program from top to bottom. This saved vast amounts of time and processing power.

As malware is often static, rather than parasitic in nature, AV researchers now must get more creative to quickly identify known-bad files. But as malware authors have armored their files to make their creations difficult for researchers to analyze, this can also make a malicious file look very different from a valid document or application. As such, researchers can key in on these differences and swiftly exclude benign files.

Every vendor’s AV product has a different implementation of scanner and database, although the signature scanning technique is the most common. Signature scans can identify whether a program contains one of the many signatures contained in the database, but it cannot say for certain whether a system has actually been affected by malware (e.g., the malware may be present but not yet executed). Users can only trust the guess of the AV scanner, because the odds are in the scanner’s favor. It is possible, however, that a program that is suspected of being infected actually contains random data that only coincidentally looks like a virus signature. The legitimate program could contain instructions that by sheer chance matched the search string in the virus database. However, when there is a possibility that the code is actually from a virus, the scanner reports it as a positive hit.

False-positive reports are a possible problem of signature scanners. If users notice that their scanner falsely reports the presence of viruses too often, they view this as an annoyance, and will likely seek to disable the software or find ways of circumventing the scans.

41.3.2 Generic Detection. As was discussed earlier, malware is now often created for financial purposes, and it makes fiscal sense for its authors to get as much use as possible out of successful creations. They often make open-source code that is shared widely in the malware-author community, so that it is often updated with new functionality such as exploit-code or password-stealing capabilities, to target new games, applications, or online banking sites.

Likewise, it makes sense for AV scanners to look for common properties of popular malware families or known malicious behavior in order to proactively detect variants based on those codebases. These generic detections can vary from being more heuristic in nature to being fairly specific. For example, it could include protection as broad as buffer overflow detection to prevent certain types of exploits, to specific homegrown packers used by only one malware family.

Generic detection caused a great deal of controversy in the early days of AV products. There was concern, when most viruses spread by infecting clean files parasitically, that generic detection would require generic cleaning, which could leave host files mangled beyond repair or usability. As the vast majority of malware now infects systems rather than host files, simple deletion of malicious files and cleaning of registry entries can remove malware. But because malware is also frequently component-based, removing one threat may be only the tip of the iceberg. There may be other components that are as yet undetected, and it's best to thoroughly examine any system which has had malware detected. As such, more and more system administrators have adopted a policy of simply re-imaging affected systems rather than relying on AV products' removal procedures.

41.3.3 Heuristics. By adding heuristics to their AV scanners, vendors looked to increase the efficacy of their products. The scanners could now look for malware that are new and unknown and not contained within the signature database.

The word *heuristic* comes from a Greek word meaning "to discover." The term is used today in computer science to describe algorithms that are effective in solving complex questions quickly. A heuristic algorithm makes certain assumptions about the problem it is trying to solve. In the case of an AV scanner, it analyzes a program's structure, its attributes, and its behavior to see if these meet the rules that have been established for identifying malware, even without its specific signature being known. Basically, a heuristic algorithm works on the assumption that if it "looks like a duck, walks like a duck, and sounds like a duck, it must be a duck."

The drawback to heuristic scanning is that it makes intelligent assumptions but is nevertheless bound to make mistakes. Another problem with heuristic scanning is that, on slower systems, it may take longer to run and may require user interaction. Some users consider this intrusive and may turn off the feature. By combining both signature scanning and heuristic scanning in their products, AV vendors have increased their effectiveness and speed.

Heuristic scanners use a rule-based system to verify the existence of malware. It applies all the rules to a given program and gives the program an overall score. If the score is high, there is a good likelihood that it is malicious. Generally, the scanner first looks for features of a file that are more common to malicious files. A well-designed heuristic scanner will limit the regions of the program to be examined in order to scan the highest number of suspects in the shortest possible time. The scanner then examines the logic of the suspected program to determine if it might be trying to perform known, likely malicious actions. This type of scanning is considered to be a *static* scan. The

static method applies the rules and gives a pass/fail score to the program—whether the program has actually executed or not.

The other type of heuristic scanning is called the *dynamic method*. This method applies basically the same rules as the static method, and if the score is high, it attempts to emulate the program. Rather than examining the logic of the suspected code, the dynamic scanner runs a simulation of the virus in a virtual environment. This technique has come to be known as *sandbox* emulation, and is effective for attempting to identify new malware that does not appear in the signature database.

Neither of these heuristic scanning methods is necessarily better than the other, but in concert they give fairly good results. Although a static heuristic scan may miss some malware because they have not yet executed, the dynamic heuristic scan can catch previously unknown malware before they are allowed to execute on the system. Between heuristic and generic detections, it is becoming increasingly common for at least one AV vendor to identify any new malware as soon as it is released.

41.3.4 Intrusion Detection and Prevention. As more complex malware appears at an increasingly prodigious pace, scanning programs solely for signatures has become less effective at finding viruses. Virus authors use encryption or obfuscation techniques, or release a large number of individual variants in the hopes that the AV scanner will not find them. Today's operating systems and legitimate programs have bloated to millions of lines of code, so that finding a virus signature may be resource intensive. Because malware may steal valuable data or damage systems, it is not a good strategy to let them execute and then attempt to clean up the mess. A better strategy is to try to find malware before it has had a chance to affect a system and to prevent it from doing harm.

The use of a cyclical redundancy check (CRC), or checksums, was originally added to some security products, including AV suites, to aid in the detection and prevention of virus infections. This method tracks unauthorized file and system changes, as when malware or a hacker enters and alters a system. To track those changes, a fingerprint of each executable program and data file is computed and stored in a database when the AV product is first installed. These fingerprints are quite small, usually consisting of less than 100 bytes of information—this is the “sum” or checksum. Because malware must add or change files on a system in order to affect it, the checksums of the fingerprints are compared with any newer version. If the checksums vary, then the AV scanner runs other routines to investigate further.

In the case of intrusion-prevention systems, a behavior-based scan is executed on each new file when it is run. If certain suspicious behaviors are observed, a user may be asked whether the behavior should be allowed to continue. If a sequence of behaviors is observed that is sufficiently malicious, the program may be halted entirely. This technique has been found to be remarkably effective in preventing execution of new, unknown malware, although it shares the same sort of difficulties found with using heuristic scans. Again, as part of a complete security arsenal, it can be a valuable tool. For more information on intrusion detection and intrusion prevention, see Chapter 27 in this *Handbook*.

41.3.5 Reputation-Based Scanning. As new malware is released at such a prodigious rate, it is no longer practical for researchers to investigate each sample individually. While tens or even hundreds of thousands of samples are investigated daily, there are still a number of threats that slip through the cracks. In order to deal with this constant deluge, rather than relying solely on a handful of researchers to

look for known-malicious files or Websites, companies are beginning to rely on the general public to increase their view of the malware landscape. Reputation scanning gathers telemetry and reputation data provided by a product's users, plus information about the age of files and Websites, and then rates them as trusted, bad, or somewhere in-between. This can help a user determine whether to proceed, based on the relative risk level.

This sort of scanning has limitations. Certain types of files are unique by design, especially data files such as documents, spreadsheets, and presentations. And if a user chooses to run a file that turns out to be malicious, they're on their own when it comes to figuring out how to remove the threat from their system. But this is why AV products include a variety of different scanning technologies; to provide protections that will ideally overlap in such a way that they can catch a larger percentage of brand-new, malicious code.

41.4 CONTENT FILTERING. In the early days of virus infections, computer security experts often allayed the fears of computer users by telling them that they could never catch a computer virus from email. This assurance was based on the fact that email was almost exclusively composed of ASCII text documents, with no ability to execute program code. At the same time, the skeptics were saying “never say never.” The skeptics won.

First, there were several waves of macro virus–infected documents sent as file attachments to email. This led to the modified assurance from security experts that no one could ever catch a computer virus from an email message attachment, if the attachment was not opened. Then virus writers started embedding commands that use HTML and the scripting capability of email programs. This led to the further modified assurance from experts that a computer virus could not be caught from unopened email. This assurance in turn proved unwarranted, because email preview capabilities were exploited to trigger malicious code even without user intervention. At one point, merely highlighting a message subject in MS Outlook was enough to execute an attachment, although this default was later changed.

Virus writers also began to exploit the user's email facility by forwarding copies of the virus to entries in the user's email address book. The Melissa virus was the first virus that really leveraged email to spread rapidly. Since the Melissa virus, users have been advised to suspect just about any unsolicited email. Malware writers are always looking for new delivery methods, and they were richly rewarded when email programs began to allow executable code within the email. Although users enjoy the point-and-click convenience of this feature, it allowed new viruses to proliferate at a rate not seen before.

The Web also has seen an explosion in malicious code distribution, particularly since the advent of “Web 2.0”— social networking and collaboration sites. Through Adobe Flash, Java, and JavaScript objects that exploit vulnerabilities in Internet browsers or media-viewer software, malware can be automatically downloaded and installed on users' machine without their being aware. This is commonly referred to as a *drive-by download*.

Content filtering is one popular way of controlling Web and email threats. It consists of a server-based application that interrogates all incoming and outgoing traffic, according to its configuration and rule sets. Early versions were cumbersome to configure, due to a text-based interface that required all rules to be composed in a laborious text editor. Misconfigurations were commonplace because administrators often were not sure which of the text files was causing a failure.

The new generation of content filters has increased user friendliness, using interactive graphic user interfaces to set and adjust policies. Administrators are able to fine-tune policies so that they meet the specific needs of their organizations. For example, all email containing executable attachments may be blocked, quarantined, or simply deleted. This may be established as a rule, for some users or all users.

Content filters were particularly effective in preventing infections of email-borne viruses, even before the specific virus signature was released. For example, when the security officer of one government office heard of the Love Bug virus on the morning news, that person set the content filters to block all email attachments containing the extension “.vbs,” thus averting infection of a large network. No user interaction was required, and most users were not aware that the block had been placed. The costs and downtime of a virus attack were prevented.

The majority of threats now come from compromised legitimate Websites rather than the dark, seedy underbelly of the Internet, which changes the way products view unwanted content. Consequently, much of this content filtering technology has moved from a focus on blocking potentially malicious content to blocking Websites that are deemed inappropriate for viewing at work or by children. Many content filters come with extensive, frequently updated block-lists for porn, “hate-speech,” and other politically sensitive subjects.

41.4.1 How Content Filters Work. These applications work in the same general manner that AV scanners do. They scan all incoming data on specific ports on the server, and they compare the traffic to rules and strings in the database. Because content filters are capable of blocking more than one type of file or program, they have the ability to scan text files, graphics, zipped files, self-extractors, and various executables. Many content filters contain AV scanning components, so if traffic does contain known-malicious code, it can be intercepted and disinfected before it is sent to the recipient.

The standards for formatting email for transmission using standard protocols have long been in place and detail the type of information in every section. It is easy for a program to look for particular information within these sections to determine what is included in the message—attachments, for example. Content filters first begin by disassembling a message to look at its various parts before scanning the message for the items to be allowed or denied into the system. Before sending the message onward, it is reassembled and checked for the conditions specified in the configurations. For example, a condition may state that any attachments be stripped and deleted, that the message body be sent to the recipient, and that an outward email be sent to the sender stating that attachments are not allowed in email.

In terms of data security, a content filter adds several elements that are beyond the traditional AV scanner. For example, message and attachment content can be scanned for inappropriate material. This might be proprietary company information that employees should not be sending out via email, or it could be offensive material such as pornography, that should not be coming into the company’s email system. Content filtering also can stop the spread of common forms of spam mail, such as chain letters and get-rich-quick schemes.

41.4.2 Efficiency and Efficacy. Speed of operations is a concern with content-filtering mechanisms, given the large volume of network traffic in most organizations. However, because the operations are all contained within the server, the users will not notice any change in performance of their desktop systems; that is, the processing will

be completed before the messages are received by the client systems. For instance, in the case of email, if filtering causes mail to queue up, delivery of mail may lag for a period of time. If Websites are blocked for inappropriate content, the traffic will simply not be delivered to the user.

Content filters are also subject to the same failures as traditional AV scanners. New malware can be missed if the data is not present in the scanning database. Additionally, the configuration of the product and the application of patches and updates are crucial to its successful operation. False positives are also a problem, where a legitimate message inadvertently includes content that triggers a block. It is possible to quarantine questionable messages and have a system administrator follow up with the sender. This can lead to refinement of the filters or to the detection of serious offenses. Before a content-filtering system is deployed, it is important to put in place the response mechanisms, so that abuses of policy can be addressed appropriately. This may well involve several departments besides security, including legal and human resources.

41.5 ANTIVIRUS DEPLOYMENT. AV scanners can be installed on the desktop or on servers. Each strategy has its advantages and disadvantages. For example, if the system is server based, malware on USB thumb drives, DVDs, and CDs on the desktop will not be scanned. The consensus of most experts, however, is to use both. With the advances in AV products and network management systems, it is entirely possible to install scanners both on the desktop and on servers while still maintaining an acceptable level of control and performance.

41.5.1 Desktops Alone. If an organization's computer security policy allows unrestricted use of thumb drives, floppies, DVDs, and CDs, it imperative that AV scanners be deployed to the desktop. Unless these drives are locked or disabled, there is no way, other than scanning, to prevent users from accidentally introducing malware. The preferences of a desktop AV scanner can be set to automatically scan external media.

Updates to desktop AV scanners can now be distributed via a central server. This is particularly effective when new signature files are needed to prevent infiltration by newly discovered malware. The updates can be pushed to the desktop, and the users need not be present at the workstation, although the desktop system must be on and connected to the network at the time. If the updates are scheduled after working hours, it is important to verify that systems have updates pushed to them as soon as they log back into the network. Some AV products have management consoles that will allow this to occur automatically, rather than having someone check each system individually.

In order to prevent unauthorized AV-setup changes, it is possible to prevent the users from changing the configuration of their desktop AV scanners. Since that may not be the default installation, it must be checked. Again, with the use of a management console, it is possible to enforce security-software policies remotely.

41.5.2 Server-Based Antivirus. Many companies have sought to bolster the defenses at the perimeter of their network by installing AV products on the server where downloads are frequently stored and traffic is high. A server-based AV scanner can be configured to send alerts to administrators when suspected malware is detected. Like the desktop-based scanners, the response to malware detection can be predetermined. Many system administrators set the program to erase all infected files rather than to send them to quarantine. This strategy works to lessen the possibility that quarantined malware can be "released" by mistake.

41.5.3 Mobile Devices. With the increase in use of smartphones and tablets by individuals, organizations, and through bring-your-own-device policies, securing these devices against malware has grown in importance. Host-based intrusion detection and signature-based tools have been developed to protect such devices, but there are problems based on the security model of some operating systems (e.g., Android) because of the strict partition of memory areas controlled by applications.

41.6 POLICIES AND STRATEGIES. In the battle against malware, the promulgation of appropriate policies and the implementation of realistic plans of action are equally as important as the installation of an AV scanner. The policies should spell out in detail what actions are allowed or denied, and they should also be specific about the users' responsibilities. The policies and responsibilities should be regularly updated to reflect the realities of the changing malware landscape, especially within a company's ecosystem.

End-user AV awareness training should be high on the list of priorities in every organization. Users are more likely to cooperate in preventing and quarantining infections if they are aware of the types of malware that may affect their system and of the damage they can cause. A simple security-incident bulletin board in a central location is an easy and effective way to communicate with users. Email is probably not an effective method of distributing malware awareness information because users become confused between the education effort, actual and legitimate malware alerts, and bogus malware alerts.

The roles and responsibilities of each person within an organization should be clearly defined and communicated to the general populace. For example, the responsibilities of an average user will be different from those of a system administrator, and the responsibilities should be reflected in their roles. An individual user's role may describe the actions required of the user if malware is detected on a workstation, while the system administrator's role may describe how to handle the report from the user and prepare for removal.

Problems and catastrophes will usually occur when they are least expected, so every organization should have an emergency response plan in its policies. The emergency plan should detail the list of persons to be called in an emergency and the priority order in which they should be called.

For every major malware incident within an organization, care must be taken that a "lessons learned" session be undertaken as soon after the event as possible. No matter how well-written a policy may be, it cannot be proven effective until it is put into use. An actual infection will highlight the failures of a policy in action, which should be rectified before the next attack. For more on security policy guidelines see Chapter 4 in this *Handbook*.

For more details of computer security incident response team management, see Chapter 56 in this *Handbook*.

Management's support for such policies is vital. Support is required not only to approve the AV budget and the policies, but also to ensure that everyone abides by the policies. It is highly unlikely that users will follow a policy that upper management routinely flouts.

41.7 CONCLUDING REMARKS. Both AV technology and malware technology have progressed rapidly over time, and AV technology largely remains in step with malware technology. The success of malware is now primarily due to financial

motivation, but a large part of the reason it is such a lucrative business is that people continue to dismiss the threat of malware. However good AV technology gets, it will not make a serious dent in the malware problem unless it is appropriately implemented by organizations and properly employed by users who act responsibly. As AV technology continues to improve and becomes better understood, we hope that it will continue to be used more widely and more wisely.

42.1 INTRODUCTION. Ever since publishing and commerce were introduced to the digital world, the risks to intellectual property and to personal privacy in cyberspace have steadily escalated on comparable but separate paths. These paths have now converged. Unfortunately, many times, antipiracy efforts lead to possible breaches in personal privacy.

Efforts to stem the flow of pirated software worldwide remain mediocre in efficacy; piracy is still proving to be big business in the new millennium. According to the Business Software Alliance (BSA), the “global piracy rate hovered at 42 percent in 2011 while a steadily expanding marketplace in the developing world drove the commercial

42 · 2 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

value of software theft to \$63.4 billion.” Further, “these startling findings come from a survey of approximately 15,000 computer users in 33 countries that together make up 82 percent of the global PC market.”¹ Continuing piracy means lost jobs, wages, tax revenues, and a potential barrier to success for software start-ups around the globe.

At the same time, freedoms inherent in the Internet have made maintaining privacy of personal information a true challenge. Identity theft keeps rising, as more and more companies actively engage in the accumulation of customer data through e-commerce. By paying bills, checking medical insurance accounts, or completing taxes online, people are making their personal information available to be stockpiled, shared, and regurgitated to the point that simply “Googling” one’s identity can be a real eye opener. Technologies that aim to prevent piracy have the potential to use this wealth of available personal information in a way that significantly erodes personal privacy. In particular, some of these technologies send personally identifiable information to servers on a routine basis (see, e.g., Section 42.4.2). The idea that a corporation—or a government—could be scanning what a specific person reads, listens to, or views is grounds for concern to civil libertarians.

42.1.1 Digital Rights. In this environment of rapid change in both piracy and privacy, even the term *digital rights* is ambiguous. When software companies and music producers talk about digital rights, they mean the kinds of rights long protected by copyright, trademark, and patent law. When privacy advocates argue about digital rights, however, they may be talking about a completely different thing: that an individual does not forfeit personal rights, including the right to privacy, merely by turning on a computer.

This chapter’s primary focus is on technologies designed to protect traditional rights of content producers, but it also enumerates areas where those technologies threaten personal privacy.

42.1.2 Patent, Copyright, and Trademark Laws. There are differences among the applicable laws and the materials they protect.

Patents give owners exclusive rights to use and license their ideas and materials; patents generally protect nonobvious inventions in mechanical and electrical fields, as well as those that can be embodied in computer software and hardware.

Copyrights give owners the exclusive rights to create derivative works, to reproduce original works, and to display, distribute, and conduct their works. Copyrights apply to original works of authorship including paintings, photographs, drawings, writings, music, videos, computer software, and any other works that are fixed in a tangible medium. Copyrights, their infringement, and remedies are described in the Copyright Act of 1976.

Trademarks give owners the right to restrict the use of distinctive marks in certain contexts. These rights may apply to words, sounds, distinctive colors, symbols, and designs.

For an extensive discussion of intellectual property law, see Chapter 11 in this *Handbook*.

42.1.3 Piracy. Once thought of as a mere copyright infringement of printed matter or production of a counterfeit audiotape, piracy has grown with technology and has expanded to encompass intellectual property, digital data, DVDs, CDs, VHS, analog and high-definition TV, and streaming media.

There are several types of piracy. End user piracy occurs when end users use a single copy of software to run on several different systems, or when they distribute copies of software to others without permission of the software manufacturer. Reseller piracy occurs when unscrupulous resellers distribute multiple copies of a single software package to multiple customers, preload the same software on multiple systems, or knowingly sell counterfeit software to customers. Internet and bulletin board (BBS) piracy occurs when users download and upload copyrighted materials and use it or make it available for use by others without proper licenses.

To understand why and how piracy occurs and the enormous impact on society worldwide, we need to have a clear understanding of what we mean by the word “piracy.” Whenever information is created and published in print, on the Internet, or incorporated into software, that information may be protected by copyright, patent, or trademark law. This principle applies to a broad spectrum of material that includes, for example, the Wright Brothers’ specifications for their “Flying Machine”; Microsoft Windows software; the icon Mickey Mouse and all related materials; and television shows, plays, movies, and music created and performed live and on recordings. Making unauthorized copies of such material in any medium is referred to as *piracy*.

Within the last three years, the Software & Information Industry Association² has “filed more than 100 lawsuits in the U.S. against illegal eBay sellers as well as sellers on other websites dealing in counterfeit, OEM, academic, region-specific, and other illegal software and publications. Defendants have paid millions of dollars in damages, and, in some cases, criminal charges were pursued and defendants sentenced to jail time.”³

42.1.4 Privacy. As in many aspects of security, end users are now being called on to protect their online (and offline) identities through diligent monitoring of financial activities and through awareness programs focused on personal rights, laws, and obligations of Internet use. The average Web user today can create and publish a blog or personal video to the Web faster than that same user can apply software patches to a desktop PC. So widespread is this new facility that the law has yet to catch up with the needs and expectations of the users in online society. It is difficult to keep data private when—with a mouse click—it is easy to share personal information with the whole world.

Beyond bad personal habits that reduce privacy, however, a whole new class of applications termed *digital rights management* (DRM) collects more personal information than ever before in an effort to reduce improper use of copyrighted material. DRM products may record and report on an individual’s Web-browsing habits, types of files created and accessed by a particular program, number of uses of a particular file or program, source IP address of the user’s system, and presence (or absence) of a license for a program. In the name of protecting digital rights for content producers, the consumers of this content are being cataloged and tracked in a way that the framers of copyright laws would have been hard-pressed to imagine.

For extensive coverage of privacy issues on the Internet, see Chapter 69 in this *Handbook*.

For a glossary of terminology used in discussing digital rights management, see Section 42.9.

42.2 SOFTWARE-BASED ANTIPIRACY TECHNIQUES. A variety of software-based technical approaches are used to prevent inappropriate use of copyrighted and otherwise protected material in an organization’s networks and on the

42 · 4 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

public Internet. Current methods include ensuring proper configuration of operating systems, monitoring of installed software, encryption of content, and insertion of some sort of key or identifier in the digital product itself.

42.2.1 Organizational Policy. Controls in free-standing commercial applications represent only one of the technical means to protect digital content. Existing system controls are also useful in this regard. Operating system access controls can specify who can access particular content, while encryption supported by the OS and other applications can limit access to users who possess the appropriate key. More generally, organizational policy should specify good practices in configuring operating systems and applications in order to help protect content. Such policy includes:

- Allow users to install only software that is necessary.
- Encrypt information that should not be publicly viewable.
- Install software with the lowest possible privilege consistent with the ability to do its job.
- Disable active content (Java, JavaScript, ActiveX, cookies, etc.) wherever feasible.
- Use network operating system access controls to limit access to shared, copy-righted media to members of the organization for whom licenses are purchased.

42.2.2 Software Usage Counters. Software metering has been popular for several years. Special software monitors system usage and inventories the software on the system or network. This type of software also can be used to block or limit the use of specific software, such as browsers and games. In addition to fighting piracy, it can reduce the load on IT personnel by reducing complications due to use of unauthorized software.

42.2.2.1 Controlling Concurrent Installations. Software metering products can monitor concurrent installations even on networks used by people in different geographic areas who have different requirements and different software installed. The metering software permits an administrator to maintain a live and updated inventory of the software installed at different locations on the network. The logs show where installation has taken place, when the licenses expire, and when updates are necessary. Alerts can be set to notify system administrators when a license is about to expire or when an update has been accomplished.

42.2.2.2 Controlling Concurrent Usage. Software metering allows network administrators to identify and resolve cases of illegal installation of unauthorized copies of authorized software and also to catch people who install unauthorized software on the organization's computers. Metering software also allows a company to report and analyze logon and logout times, track software usage, and meter software licenses to keep those in the company legal. In addition to avoiding legal entanglements, monitoring can reduce the demand on system resources, network bandwidth, and technical support staff.

42.2.2.3 Examples and Implementation. Microsoft announced in 2000 that to combat piracy, new releases of the Office 2000 program would include a counting feature making the programs malfunction if the owner had not registered the software after launching it 50 times.⁴ Prior to this announcement, Microsoft published

antipiracy literature and provided a great deal of consumer education regarding the effects of software piracy on society; it established, as well, a piracy hotline (1-800-RU-LEGIT). Novell (1-800-PIRATES), Adobe, and Xerox are other companies that have vigorous antipiracy programs in place, although they have not yet announced that they are building metering into their products.

Metering software requires a bona fide license in order for it to be implemented. Typically, companies establish CD-ROM keys that are printed on legitimate copies of their product installation discs or jewel cases. The keys include checksums or message authentication codes that can be checked by the installation routines. The algorithms for the checksums are intended to cause difficulty for people trying to create counterfeit keys. The security of such measures depends on the cryptographic strength of the validation keys.

Software counters for controlling concurrent usage need to store information securely so that each load operation increments a counter and each unload operation decrements it. However, the security problem is to store this information in such a way that unauthorized people cannot modify it easily. Encrypting the data in a complex sequence of operations can stop most abuses of the system by making the effort required for circumventing the mechanisms more costly than buying a license.

More recently, starting with Vista, copies of the Windows operating system must be registered (Microsoft calls this *activating* a copy) soon after installation, or they will go into *reduced functionality mode*, in which basic functions are available for only an hour of operation before logging on again.⁵ For single-copy home use, Windows relies on a license key encoded on the installation medium. For enterprise deployments of Vista, an organization needs to run key servers to allow the registration to occur.⁶

42.3 HARDWARE-BASED ANTIPIRACY TECHNIQUES. Working on the theory that software is prone to misconfiguration and compromise, antipiracy groups and researchers have experimented with a variety of hardware-based approaches to preventing inappropriate use of protected content. These techniques include dongles and specialized readers attached to the reading hardware, evanescent media designed for viewing or playing only a limited number of times, and software keys incorporated into the media and the reading hardware.

42.3.1 Dongles. Dongles are hardware lock devices or modules that connect to a computer and communicate with software running on the computer. Without a dongle in place, the external device or regulated software does not work fully, or at all.

Initially, dongles controlled printing. With a dongle installed on the computer, no one could print data from the computer without authorization. However, there is now a necessity for protecting all types of devices. Now dongles are used to protect scanners; external drives (e.g., ZIP drives); CD-ROMs and rewritable CD-ROMs; DVDs and DVD-Rs; VHS recorders; PlayStation, Nintendo, and Sega video gaming systems; and even personal digital assistants (PDAs).

The most common type of dongle provides a pass-through port to connect a device cable. Generally, a dongle incorporates some type of algorithmic encryption in its on-board microelectronic circuitry. The sophistication of the encryption varies depending on the manufacturer and the device. Many dongles provide additional onboard non-volatile memory for the software to access. Some models even have real-time checks that keep track of date and time information, including when an application's license (temporary or leased) is set to expire.

42 · 6 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

Dongles provide some definite advantages:

- Because a dongle is an external device, it is fairly simple to install and uninstall. Early dongles used serial or parallel ports, but USB has become the norm in recent years. In most cases, since manufacturers support their devices, an ordinary user can install and use a dongle without help from an IT department.
- Dongles also require registration, which provides adequate control over the use of the dongle and thus provides legitimacy to both the device and the users. Registration (dependent on the contract in place) may provide support for both the software and the hardware.
- Dongles that support encryption provide an extra layer of protection by making transmitted data indecipherable until it reaches its destination, unless the hardware is in place.

There are also disadvantages to using dongles:

- Consumers resist the requirement for installation, maintenance, and additional cost. Most large corporations do not use dongles for their products.
- Dongles can be lost or stolen, and they also may fail.
- Sometimes a dongle will work well with a slow computer but cause errors when installed on a faster computer.
- Since not every manufacturer automatically replaces lost or stolen dongles without charge, there may be additional costs involved in getting replacements.
- Dongles can present a serious risk-management problem for critical applications where delays in obtaining replacements or registering them may be unacceptable.
- As with any device, there can be a serious problem if the dongle manufacturer ceases to support the model of dongle a company has installed or if the manufacturer goes out of business entirely.
- Laws regarding encryption usage differ in various countries. Specialized dongles that may be legal to use in the United States may be illegal in another country.

42.3.2 Specialized Readers. One of the impediments to illegal copying used to be the difficulty and cost of obtaining specialized hardware and software for reading and copying proprietary materials with fidelity. However, today such copying equipment is inexpensive and easy to find. In addition, the media for distributing illegal copies are less expensive than ever.

42.3.2.1 Audio. According to the Recording Industry Association of America (RIAA), the global audio industry loses in excess of \$4 billion every year to piracy worldwide.⁷ RIAA says that \$1 million a day, in just physical product, is lost in the United States alone. The loss of ancillary revenues drives the figures higher. But the RIAA claims that these figures are low, since it estimates that in some countries up to 98 percent of the music in use comes from illegal copies.

As part of an industry-wide, organized approach to highlighting and reducing the music piracy problem, the RIAA has taken a very active role in pursuing legal action against suspected pirates. Through the 1990s and continuing into the current decade, the biggest problem with audio piracy was illegally copied CDs. In 1998, for example, the RIAA confiscated 23,858 illegal CDs in the first half of the year. In that same year,

Operation Copycat—a joint investigation by RIAA, the Motion Picture Association of America (MPAA), and the New York Police Department—saw the arrest of 43 CD pirates and the shutdown of 15 illegal manufacturing locations. Many of the CDs seized in these types of operations apparently came from Asia and Eastern Europe, financed by organized crime operations with ties to drugs and prostitution.⁸ By 2002, even corner convenience stores were contributing to the problem, providing coin-operated CD copying machines akin to photocopiers, along with the familiar posted warning transferring liability to the user.⁹ Given the enormous profits involved, the problem has been simply too large and widespread for law enforcement to control. In 2005, the RIAA seized approximately 5 million illegal CDs.¹⁰

More recently, the RIAA has focused on the problem of music files illegally shared across the Internet. Using free software, sometimes already bundled into commercial operating systems, anyone can download music tracks and burn CDs. The MP3 music file format has become a ubiquitous way to share music with others. The RIAA originally protested against MP3 players, but the phenomenal success of personal digital music players, particularly the Apple iPod, has rendered such efforts futile. Some musicians and independent record labels have adopted the MP3 format to promote their records, showing that the technology itself has no inherent ties to piracy. These musicians and recording studios claim that they are happy with consumers downloading the music, and they are at odds with the RIAA.

Some musical groups have even experimented with severing ties with the traditional music industry altogether, using Websites and social networking services to advertise and distribute digital music files directly to their listeners.¹¹ As more musicians begin to use the Internet either in addition to or in lieu of traditional distribution models, the very model of music distribution is in flux.

Meanwhile, the music industry continues to face serious financial loss due to illegal downloading. The industry, through the RIAA, has been pursuing legal remedies. Some major lawsuits have achieved significant press coverage and have been instrumental in enforcing or changing existing laws or in helping develop new laws. For instance, deliberate copyright violations resulted in an award of \$50 million in statutory damages and \$3.4 million in legal fees to Universal Studios in a suit against the MyMP3.com music service. MyMP3 created a database of over 80,000 albums, which, when combined with the MyMP3 software, let users access and store music digitally, without paying a fee.

Perhaps the most recognizable name in the music field in regard to piracy at one time was Napster, a site that enabled individuals to share tracks of music via the Internet. The site provided free downloadable software for downloading and playing MP3 files. Essentially, Napster software turned a user's PC into part of a distributed server network that published available music files. It did not take long for the site to acquire a user group of millions of people who after "sampling" the music might then go to a store and buy the entire CD.

However, since the Napster site did not limit the length of the download, many users simply downloaded the entire track. Most never bought the commercial version of the music. Adding to successful piracy attempts was the development and ready availability of rewritable CD drives. More and more Napster users decided to download the music tracks they wanted and then burn their own CDs without ever purchasing the CDs made by the recording artists and music companies.

Creating a stir in the industry and ultimately a landmark judicial case, Napster was forced to radically alter operations in March 2000 after protracted court proceedings. Upon the verdict, Jack Valenti, president and chief executive officer of MPAA,

42 · 8 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

commented that the consumer would benefit most from the court's decision because "You cannot take for free what belongs to someone else."¹² But the subject of Napster and audio piracy remains highly controversial. Although some people argued that little-known artists received exposure that they may never have gotten without the free file-sharing service, others, especially large music companies and recording artists, argue that they were being denied the royalties they deserve.

Napster attempted to re-create itself as a pay-for-subscription music download service, but found record labels unwilling to work with it. In 2002, Napster folded; the name was eventually purchased by Roxio, Inc. to rebrand its own subscription service. In the meantime, other peer-to-peer (P2P) file-sharing protocols and applications appeared to fill the void left by Napster. By the time the iTunes Music Store emerged as a powerful contender with music company backing and with copyright protection, the world of free file sharing was reinvigorated by names such as Gnutella, FastTrack, Grokster, Limewire, and Kazaa.

Over the last few years, the music industry has identified universities as fertile ground for pursuing illegal downloading activities. In 2007, the RIAA launched a new round of attempts to bring music pirates to justice, sending letters offering to settle with students identified as probably sharing copyrighted files, in advance of any trial.¹³ The RIAA's tactics have been raising hackles in the higher education community, with opponents criticizing the letters as bordering on extortion. Some universities are refusing to forward the letters to students; one university agreed to forward the letters, but promised to bill the RIAA \$11 for every letter to pay for its staff time.¹⁴

42.3.2.2 Video. On the video side, Scour, Inc., provided free downloads of digital movies as well as software allowing users to share the downloaded files among themselves without the use of a central server. With an easy-to-use interface and quick response time, Scour.com became quite popular in a short period of time. Launched in 1997, with a Web search feature added in 1998 and a subsequent P2P tool, Scour eventually attracted negative attention from the movie and music industries. In July 2000, MPAA, RIAA, and the National Music Publishers Association (NMPA) sued Scour, accusing it of large-scale theft of copyrighted material and of trafficking in stolen works. By November 2000, the company was out of business.¹⁵

This case did not stop the counterfeiting of video media. Despite increasingly steep fines, judicial rulings, and even raids by various law enforcement agencies, counterfeit video is readily available. Along Fifth Avenue in New York City, for \$5 to \$10 anyone can buy the latest films and DVDs; in markets in Hong Kong, Southeast Asia, and India, the copies are even cheaper. It is true that some of the copies available may have been "legally produced," but it is more than likely that the counterfeit or bootleg copies were made illegally from a master copy that was either borrowed or stolen.

Advances in consumer electronics help the trend, as many PCs now come with a recordable/rewritable DVD player as a standard component. Arguments about legality of time-shifting and space-shifting that once defended the practice of making personal mixes on audiocassette have now moved to the realm of digital video.

42.3.2.3 Television (Analog). Broadcast television has been one of the most successful technologies in history, and financial interests are still huge, despite the growth of cable and satellite services. In January 2000, major television companies, the National Football League, and the National Basketball League all filed complaints against iCraveTV, a Canadian company that had been in existence for only a year.

According to the complaints, iCraveTV was illegally using broadcast television signals without authorization or payment and streaming the signals to the iCrave Internet site for viewing free of charge. Although this practice apparently did not violate Canadian copyright laws at the time, U.S. judges ruled in February 2000 that the unauthorized transmissions of broadcast signals into the United States via the Internet were a direct violation of U.S. copyright law, and iCraveTV was ordered to stop the practice. Shortly after iCraveTV agreed to an out-of-court settlement, the Web-site was shut down and iCraveTV went out of business.¹⁶

Hacking cable decoders is another technique for obtaining services without paying for them. Although it is not illegal to buy, install, or modify equipment for converting encoded cable TV signals from pay-per-view or other commercial suppliers, it is illegal to use such set-top decoders to obtain services without paying for them.

In the United States, Congress mandated that after February 17, 2008, all TV stations must transmit in digital format (DTV) only.

42.3.2.4 Television (HDTV). The first television image was created in 1884 when Paul Nipkow created a mechanical scanning disk. With only 18 lines of resolution, the picture was poor. Current National Television System Committee (NTSC) standard TV transmissions are done with bandwidth that does not exceed 6 MHz. The current analog system broadcasts 30 frames per second and 525 lines per frame.

High-definition television (HDTV) is a digital television system that offers twice the horizontal and vertical resolution of the current TV system. HDTV has the ability to deliver a video composed of approximately 1,125 lines per frames and 60 frames per second. Viewers then see a picture quality close to that of 35-mm film. Obviously, transmitting images containing that large amount of audio and video information requires wide bandwidth, actually about 18 MHz. Such bandwidth would permit the transmission of 1,050 lines of 600 pixels per line. However, the Federal Communications Commission (FCC) decided to limit HDTV to a 6-MHz maximum bandwidth. In order to meet that requirement, MPEG compression would be used.

MPEG compression applies algorithms to pixel groups and records information that changes within a frame, rather than all of the information in all of the frames. Audio is synchronized to the video. Using MPEG saves storage space and transmission requirements while retaining high image and sound quality. According to the Advanced Television Committee Standard (ATSC), the FCC will require that audio and video compression as well as the transmission of HDTV terrestrial signals follow this standard.

As with all other transmissions and media, there are serious concerns about piracy of HDTV transmissions and programs. At the present time, even though many TV transmissions are scrambled in order to thwart reception, it is fairly simple, although illegal, to purchase a descrambler and unscramble the transmissions. It is, however, legal for home viewers to record programs for their own personal use.

The HDTV market space has been evolving, and consumer demand for HD-capable devices has exploded over the past several years. Attempts by U.S. television producers to protect themselves and their content using a variety of scrambling and encryption schemes, including content scrambling systems (CSSs), have been made difficult by the frequent changes in hardware and signal formatting that have accompanied this rapid market expansion.

Encrypting terrestrial broadcast television programming would secure the transmissions, but according to the Home Recording Rights Coalition (HRRRC), such encryption will threaten established home recording rights. The HRRRC contends that Section 1202

(k) of the Digital Millennium Copyright Act provides a carefully balanced approach to analog home recording rights and stipulates that mandated technology may not be applied to interfere with consumer recording of free, over-the-air terrestrial broadcasts.

Furthermore, the HRRC contends that encrypting the free television broadcast content will create very little incentive for consumers to switch from regular analog to digital television. Instead of thwarting digital pirates, the HRRC contends that strong encryption will impose unfair and even illegal restrictions on consumers.

42.3.2.5 Consumer Acceptance of Specialized Readers. Illegal sharing of copyrighted content is common across the Internet. When the Software Publishing Association (SPA) was first formed, the group, together with law enforcement agencies, raided the physical premises of companies believed to be using pirated software. As a result of finding quantities of the pirated software, SPA won many legal actions and related settlements.

Some people see encryption as a challenge and work at breaking the algorithms so they can pirate the data—digital, video, or audio. In addition, the lack of standardization of laws throughout industries and countries has led to controversy and ongoing piracy.

Although average consumers do not think of themselves as intellectual property pirates, many otherwise honest citizens do get and use illegal programs, applications, games, audio tracks, CDs, DVDs, VHS tapes, and television signals. This situation might be attributed to a lack of ethical education, but many people like to save money and simply do not believe they will be caught and punished for such pilfering. A 2001 study by the Pew Internet & American Life Project, based on phone interviews with 4,205 adults 18 and over, some 2,299 of whom were Internet users, suggested that around 30 million U.S. residents had downloaded music from the Internet.¹⁷ At that time, the phrase “had downloaded music from the Internet” was basically equivalent to “had *illegally* downloaded music from the Internet,” since legal means of doing so had yet to evolve.

Since that report, Apple’s 2001 announcement of its iTunes and iPod products, and the 2003 launch of the iTunes Music Store, began a movement to provide consumer-friendly ways of downloading music that also give compensation to copyright owners. iTunes uses device authentication and proprietary encoding formats to limit redistribution of downloaded songs and videos. Despite—or perhaps because of—Apple’s attempts to comply with copyright laws, it is clear that Apple filled a perceived need in the market, as it has generated both a host of competitors and substantial sales. Consumers downloaded the first million songs from the iTunes Store in five days, and the overall market for digital music has grown to at least \$790 million per year. At \$0.99 per song, downloads from the iTunes Music Store passed the \$1 billion mark on January 23, 2006.¹⁸

42.3.3 Evanescent Media. There are many interpretations of the term *evanescent media*. The broad interpretation includes digital imaging, optics, multimedia and other electronic art, and data that are short-lived or transitory. When such media are original, creative works, society has an interest in protecting them against piracy.

Since most evanescent media involve some visual aspects as well as text, antipiracy techniques now being used or considered for other types of data may be applicable. Such techniques include previously discussed dongles, software keys, watermarks, encryption, and digital rights management. Part of the problem in electing and implementing a solution is the lack of existing standards that specifically deal with this new area of art and science.

42.3.4 Software Keys. Software keys of various kinds are used to secure data and equipment. A software key is generally a string of numbers that is used for identification purposes, either to allow access to the use of equipment or to permit authorized printing, processing, or copying of data. As described earlier in the discussion of dongles, most anticopying hardware devices are accompanied by software that works in tandem with the hardware. A software key activates or deactivates the hardware lock. When the software is working perfectly, there are generally no difficulties. However, all software can malfunction, and when that happens, there can be serious problems in getting equipment to work. Additional problems occur when the computer containing the software key malfunctions, and the software key cannot be made to work on a replacement machine.

42.3.4.1 Videocassettes versus Copy Machines. Watermarking is one of the techniques being seriously considered for protecting videocassettes and DVDs. In 1995, the ASTC formed a Copyright Protection Technical Working Group, which spun off a special Watermarking and Embedded Data Encoding subgroup. The group has broad representation, including representatives from the PC market, the Macintosh market, the MPAA, the Consumer Electronics Manufacturers Association (CEMA) and related manufacturers, technicians, and users. Their task is to look for technologies and services that might use hidden data clues as a means of inhibiting or barring digital piracy. Using a hidden watermark that can be embedded in the content would then prevent machines from making copies or would alert the operator that the videocassette is marked and that unauthorized copies would be considered pirated.

42.3.4.2 DVD Area Encoding. Digital video requires very large storage space—too large for a single CD to hold. However, by applying compression techniques, the digital video can be compressed to fit into the digital videodisc's maximum capacity of 17 gigabytes. Two different types of compression are used for encoding audio and video content for DVD: constant bit rate (CBR) and variable bit rate (VBR) compression.

In order to prevent piracy of the content of the DVD, many companies are turning to encryption. The compressed data are encapsulated through a mathematical algorithm that can be decrypted only through the use of a decryption key.

42.3.4.3 Implementation. For shorter programs, CBR is ideal. Based on MPEG-2 encoding, CBR compresses each frame of audio and video by a user-selected amount. This degree of compression is then applied to the entire program. Using VBR, it is possible to create a database of video content based on the amount of change in each frame or scene. This is particularly useful in programs with a long format. To construct the database, the encoding software does several analytical passes of the master footage and then makes a final digitizing pass. From the created database, the computer can encode the video with a variable data rate, allowing a higher bit rate for scenes with pans, zooms, and fast motion and giving scenes with little or no motion low data rates. By greatly compressing the areas of lower detail, areas of higher details can be allocated more space and use less compression.

42.3.4.4 Watermarks. Watermarking involves embedding one set of data inside a larger set of data. The embedded set of data identifies the origins or ownership of a specific work, just as a watermark does on paper.

42 · 12 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

Using digital watermarks can help copyright owners track the use of anything digital, including music, movies, photographs, and clip art. Digital watermarking is widely used for protecting images. For instance, photographers often post low-resolution (low-res) versions of their photos on public Websites and use visible digital watermarks to clearly label the low-res images as copyrighted. Upon payment of the appropriate fee, the customer receives the high-resolution version of the photo, presumably with at least any visible watermarks removed. The use of invisible watermarks to prevent undetected sharing after purchase of digital content is more controversial and more prone to questions about reliability of detection; for instance, how many false positives and false negatives will occur? Additionally, there is the question of survivability of the mark itself as it is run through various transformations.

The music industry flirted with digital watermarking to protect music files beginning in 1998 with the formation of the Secure Digital Media Initiative (SDMI), a consortium of technology, security, and music organizations. The SDMI developed several watermarking schemes, and in 2000, it offered a reward to anyone who could crack the code and remove the watermark from a song protected by SDMI's technologies. The Electronic Frontier Foundation asked the Internet community to boycott the contest, stressing that the use of DMAT (Digital Music Access Technology) would mean that manufacturers and users would be forced to adopt the DMAT format in equipment and would create additional costs for manufacturers and consumers. A team of researchers, led by Princeton professor Ed Felten, was able to remove the invisible watermarks. When Felten attempted to publish the results of his process, attorneys for SDMI threatened to sue him under the Digital Millennium Copyright Act (DMCA). SDMI never filed suit, but Felten himself sued for a declaratory judgment to clarify the matter. Felten's suit was dismissed by a federal judge, but not before the government and the RIAA agreed that researchers should not be punished under the DMCA for testing technologies to protect copyright.¹⁹ The SDMI has been inactive since 2001.²⁰

42.4 DIGITAL RIGHTS MANAGEMENT. Recognizing that piracy is a huge moral and financial problem, software developers have adopted and modified another type of system that can be applied to print, audio, video, and streaming media. Called *Digital Rights Management* (DRM), the system was originally devised to protect proprietary information and military information. The idea behind the system is to protect all types of intellectual digital content from anyone who would take it without the consent of the developer(s) or owners. Major companies like Microsoft, Adobe, and IBM are developing and marketing DRM systems, and dozens of smaller companies are springing up.

42.4.1 Purpose. The purpose of DRM is to protect all digital content that originators or owners want protected. DRM permits distributors of electronic content to control viewing access to that content. The content can be text, print, music, or images. Basically, DRM systems use a form of customized encryption. When an end user purchases viewing, listening, or printing rights, an individual "key" is provided. The system works on rules, meaning that although a key is provided, it generally comes with limitations regarding the copying, printing, and redistribution.

Unfortunately, there is no agreement on a DRM solution. Lack of standards is hampering businesses from moving forward with online business initiatives. Because there are so many companies promoting their own incompatible forms of DRM, customers will have to download megabytes of code for each version. Maintaining, upgrading, and managing all of those different versions are major headaches for customers. There

does not appear to be a simple solution; rather than being a technology issue, it is really a matter of business and politics.

42.4.2 Application. Typically, when users become prospective owners of digital rights, they download a content file. The DRM software does an identity check of users, contacts a financial clearinghouse to arrange for the payment to be made, and then decrypts the requested file and assigns users a key. The key is used for future access to the content.

Because the system works on rules, it is possible to impose restrictions. One user might pay just to view material, while another user might want to have printing privileges. A third user might want to download the content to his or her own machine, and, finally, a fourth user might want to have viewing privileges for a specified time. The four different authorized users would thus use the same content, and each would pay according to a rate scale established by the content distributor. Throughout all of the transactions, each user would need a mechanism that allows secure transmissions and identifies that user and the associated level of access privileges.

Although this approach to publishing may sound fairly simple, it is really quite complex. In addition to arranging for different users to access material according to the set rules and to pay according to a rate schedule, it is also necessary for content distributors to handle the back end of the application. Everyone involved in the creation, production, and distribution of the content has to be paid fairly for the use of the content.

Payment is especially important as more and more content providers digitize materials that they can show or print on demand. Many users will read books online, but some physical printing on paper will continue. However, publishers will be able to print precisely those volumes that are requested. This approach will provide customized printing (e.g., large-print editions) as well as saving paper and physical warehouse storage space.

42.4.3 Examples. Several different types of DRM systems exist. Experts agree that the best DRM systems combine both hardware and software access mechanisms. With the advent of the eBook, the digital pad, PDA modems, Internet access devices, and increasingly smaller laptop computers, tying access rights directly to storage media gives publishers and distributors control of where the content is being used as well as by whom.

With the passage of the *Electronic Signatures in Global and National Commerce Act*, referred to as the *E-Sign Bill* and the increasing use of digital signatures, original documents (e.g., legal, medical, or financial) will be stored digitally. President Clinton signed the E-Sign Bill on June 30, 2000, in Philadelphia's Congress Hall using a ceremonial pen and a digital smart card. The bill went into effect on October 1, 2000. The E-Sign Bill gives an online signature the same legal status as a signature etched on paper and makes the digital document the original. Any printout will be considered a copy, so the ability to view documents and videos (e.g., living wills) digitally will actually give the viewer access to the original. Eventually, records for medical treatment and documents for trials may be totally digital and may require submission and viewing digitally. When this becomes the norm rather than the exception, strict adherence to DRM in order to maintain privacy, as well as to provide restitution, will be paramount. In addition, such content-protection schemes will prevent unauthorized modifications of the digital data that would otherwise contribute to fraud.

For example, IBM has released antipiracy technology called the *Electronic Media Management System* that allows for downloading music tracks but puts controls on

how many copies can be made or allows for a copy length limitation to be inserted. Thus, a minute of music could be downloaded to give a listener a taste, but not a chance to pirate the entire music track. To obtain the entire track, the user would be required to pay a fee.

Microsoft distributes free software that embeds metatags in each audio file. The metatags refer back to a central server in which the business rules are stored. This approach requires that material be tagged as it is created; otherwise, if it is released without the embedded tags, it can be illegally copied.

Major companies like Xerox, Microsoft, IBM, and Adobe got heavily involved producing and using this software in the 1990s, and many smaller firms opened shop. As with other new technology launches, eventually many of the small entrants went out of business or were bought by larger firms. Some of the small companies, such as ContentGuard,²¹ continue to exist independently, as of this writing.

42.5 PRIVACY-ENHANCING TECHNOLOGIES. Although DRM may seem to be a valid solution for the piracy problem, dissenters feel that DRM and other antipiracy measures give producers and distributors too much control. The rationale is that excessively restrictive rights management may undermine the fair use rights of consumers and academics. Partly as a result of these conflicting viewpoints, many consumers are making increasing use of privacy-enhancing technologies (PET), a broad term for a range of technologies designed to hide the identity and activities of individual users and computers as their traffic traverses the Internet.

42.5.1 Network Proxy. One broad class of tactics and tools used to enhance privacy is based on the concept of a network proxy. In its most general form, a proxy takes a network connection request from a client and redirects it to the ultimate destination, changing the address headers to make it look like the original request came from the proxy itself. When the destination server responds, the proxy returns the results to the requesting client. Proxies have long been used within organizations, both to protect internal users as they make requests to untrusted networks and to track and sometimes block access to undesirable content. For more details on the use of proxies in Web content filtering and monitoring, see Chapter 31 in this *Handbook*.

More recently, proxies have been employed outside the bounds of corporate networks to allow anonymous connections across the Internet. These so-called anonymizing proxies sometimes use encryption to hide the traffic in transit and so also provide protection from traffic analysis. Anonymizing proxies are a serious threat to organizations that desire (or are required by law) to monitor and block users from accessing certain kinds of information. More advanced versions of this concept use multiple routers to hide the path that a request takes through the public network. As a general class, these are known as mixing networks. One example described as early as 1981 is the Chaum Mix.²² Recently, a concept known as onion routing has become popular in its incarnation as Tor (the onion router), which uses nested layers of traffic encryption as a session travels from one router to the next.²³ See Chapter 70 in this *Handbook* for further information about anonymity on the Internet.

42.5.2 Hidden Operating Systems. Rather than relying on network technologies, some users are choosing to make their actions on the network private by using hidden operating systems. Two basic approaches are common: the virtual machine and the bootable system.

A virtual machine is a system that runs within another operating system. Long used for cross-platform compatibility and the ability to run multiple systems on a single hardware platform, virtual machines, such as Java Virtual Machine, VirtualPC, and VMware, are also used to hide activity from those who would disapprove of it (system administrators, parents, law enforcement, etc.), since the activities of the virtual machine can be made invisible to the host machine.

The bootable system approach, however, stores an entire operating system on some sort of bootable medium, such as a CD or USB device. If a computer can boot from such media and store downloaded content to a peripheral device rather than the host operating system's hard drive, then no record of the usage will remain when the host is next booted up.²⁴

42.6 POLITICAL AND TECHNICAL OPPOSITION TO DRM. Vocal opponents of DRM have organized using the Web to exert pressure on vendors using the techniques; criminal hackers and others have developed and circulated software for disabling DRM.

42.6.1 Political Opposition. The *Electronic Frontier Foundation* (EFF) is a widely respected organization, which describes itself as follows:

From the Internet to the iPod, technologies are transforming our society and empowering us as speakers, citizens, creators, and consumers. When our freedoms in the networked world come under attack, the Electronic Frontier Foundation (EFF) is the first line of defense. EFF broke new ground when it was founded in 1990—well before the Internet was on most people's radar—and continues to confront cutting-edge issues defending free speech, privacy, innovation, and consumer rights today. From the beginning, EFF has championed the public interest in every critical battle affecting digital rights.

Blending the expertise of lawyers, policy analysts, activists, and technologists, EFF achieves significant victories on behalf of consumers and the general public. EFF fights for freedom primarily in the courts, bringing and defending lawsuits even when that means taking on the US government or large corporations. By mobilizing more than 140,000 concerned citizens through our Action Center, EFF beats back bad legislation. In addition to advising policymakers, EFF educates the press and public.²⁵

The EFF has steadfastly argued against DRM:

Digital Rights Management (DRM) technologies attempt to control what you can and can't do with the media and hardware you've purchased.

- Bought an ebook from Amazon but can't read it on your ebook reader of choice? That's DRM.
- Bought a DVD or Blu-Ray but can't copy the video onto your portable media player? That's DRM.
- Bought a video-game but can't play it today because the manufacturer's "authentication servers" are off-line? That's DRM.
- Bought a smart-phone but can't use the applications or the service provider you want on it? That's DRM.

Corporations claim that DRM is necessary to fight copyright infringement online and keep consumers safe from viruses. But there's no evidence that DRM helps fight either of those. Instead DRM helps big business stifle innovation and competition by making it easy to quash "unauthorized" uses of media and technology.

42 · 16 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

DRM has proliferated thanks to the Digital Millennium Copyright Act of 1998 (DMCA) which sought to outlaw any attempt to bypass DRM.

Fans shouldn't be treated like criminals and companies shouldn't get an automatic veto over user choice and innovation. EFF has led the effort to free the iPhone and other smart phones, is working to uncover and explain the restrictions around new hardware and software, has fought for the right to make copies of DVDs, and sued Sony-BMG for their "rootkit" CD copy protection scheme.²⁶

The Free Software Foundation created the *Defective by Design* campaign in May 2006 and organized the first International Day Against DRM. The eighth event took place on May 3, 2013. A recent campaign is *Stop DRM in HTML5*, which is described as follows:

The World Wide Web Consortium (W3C) is considering a proposal to weave Digital Restrictions Management (DRM) into HTML5—in other words, into the very fabric of the Web. Millions of Internet users came together to defeat SOPA/PIPA, but now Big Media moguls are going through non-governmental channels to try to sneak digital restrictions into every interaction we have online. Giants like Netflix, Google, Microsoft, and the BBC are all rallying behind this disastrous proposal, which flies in the face of the W3C's mission to "lead the World Wide Web to its full potential."²⁷

Defective by Design is

... [A] participatory and grassroots campaign exposing DRM-encumbered devices and media for what they really are: Defective by Design. We are working together to eliminate DRM as a threat to innovation in media, the privacy of readers, and freedom for computer users. Our actions involve identifying and targeting defective products, pressuring media retailers and hardware manufacturers to stop supporting DRM, exposing the immense concentration of power over media created by DRM, and raising awareness of DRM to libraries, schools, and individuals around the world.²⁸

Industry supporters of DRM refer to it as "digital rights management" as if they are the ultimate authority to grant us our rights, as if they are the ones who should have complete and total control over how we use and interact with our media. What they are really doing is managing the restrictions they impose on our media and devices that we would normally have control over in the absence of DRM. We should own our media, not be at the mercy of media companies. For that reason, we refer to it as "Digital Restrictions Management."²⁹

Defective by Design argues that DRM is grossly intrusive and unfair:

Amazon's new movie download service is called Unbox and it outlines what DRM implies. The user agreement requires that you allow Unbox DRM software to monitor your hard drive and to report activity to Amazon. These reports would thus include a list of: all the software installed; all the music and video you have; all your computer's interaction with other devices. You will surrender your freedom to such an extent that you will only be able to regain control by removing the software. But if you do remove the software you will also remove all your movies along with it. You are restricted even geographically, and you lose your movies if you ever move out of the USA. You of course have to agree that they can change these terms at any time. Microsoft's newly upgraded Windows Media Player 11 (WMP11) user agreement has a similar set of terms.²⁹

Stop DRM Now! argues along the same lines as Defective by Design:

DRM exists for the exclusive benefit of content producers and providers. Companies such as Disney, Sony, and Lion's Gate argue that DRM is needed to prevent people from pirating

music, movies, and other works on P2P networks or by other means. What they won't tell you is that they are really trying to control who, what, when, where, and how you access your music and videos. For instance, when you purchase a song from Apple's iTunes Music Store, you are purchasing a song that can only be played by media applications that support QuickTime or an Apple iPod. Suppose next year you want to buy a new portable music player? Instead of having choice, you must now buy another iPod if you expect to play music you've already purchased.³⁰

42.6.2 Technical Countermeasures

42.6.2.1 Reverse Engineering. Reverse engineering allows a programmer to work backward from the finished program or product. Encryption keys can be extracted by reverse engineering playback software. Reverse engineering can circumvent most anti-piracy solutions. As a result, manufacturers of anti-piracy software and hardware are strongly opposed to permitting reverse engineering. The DMCA does allow reverse engineering, but the provisions of DMCA were not intended to enable the circumvention of technical protection measures (TPMs) in order to gain unauthorized access to or to make unauthorized copies of copyrighted works.

42.6.2.2 Published Attacks. The most notable attack on a software key took place when a licensee of CSS neglected to encrypt a decryption key. Obtaining a key by reverse engineering the XingDVD from Xing Technologies, the hackers were then able to guess many other keys. This left the hackers with a collection of decryption keys; even if the XingDVD key was removed, they could still copy DVDs by using the other keys. Using the results of this compromise, a group of people including the Norwegian teenager Jon Lech Johansen developed a program called *DeCSS* to decrypt CSS-encrypted DVDs and play them on Linux machines.

A variety of groups, including the DVD CCA, sued Johansen for publishing tools to subvert copyright protection. Johansen was acquitted twice in Norwegian courts. As of 2007, all remaining lawsuits against him were dropped,³¹ and a number of programs like *DeCSS* are freely available across the Internet. The next section discusses the widespread availability of DRM-cracking tools.

42.6.2.3 Tools for Cracking DRM. Software for breaking DRM controls abounds on the Web. Methods exist to defeat restrictions on:

- CD copying
- DVD copying
- Blu-ray copying
- iTunes copying
- PDF content extraction
- Software activation

We decline to include specific links to such tools in this *Handbook*.

42.7 FUNDAMENTAL PROBLEMS. A number of experts have pointed out that there are fundamental flaws in all the methods for preventing illegal copying of digital materials as described in this chapter. Bruce Schneier, a respected cryptographer, has repeatedly explained that all digital information must be converted to a cleartext

(unencrypted) form before it is displayed or otherwise used. Schneier calls this “the Achilles’ heel of all content protection schemes based on encryption.”³² Because the cleartext version has to reside somewhere in volatile or nonvolatile memory for at least some period of time to be usable, it is theoretically possible to obtain a copy of the cleartext version regardless of the complexity of the methods that originally concealed or otherwise limited access to the data. For example, if a DVD movie using complex regional encoding is to be seen on a monitor, at some point the hardware and software that decoded the DVD have to send that data stream to a monitor driver. The decoded data stream is vulnerable to interception. By modifying the low-level routines in the monitor driver, it is possible to divert a copy of the raw data stream to a storage device for unauthorized replay or reconstitution. Similarly, a system may be devised to prevent more than one copy of a document from being printed directly on a printer; however, unless the system prevents screen snapshots, a user can circumvent the restrictions by copying the screen as a bit image and storing that image for later, unauthorized use. Although hardware devices such as dedicated DVD or CD players may successfully interfere with piracy for some time, the problem is exacerbated under the current popular operating systems that have no security kernel and thus allow any processes to access any region of memory without regard to security levels.

42.8 SUMMARY. Piracy is a rapidly growing societal problem affecting a multitude of people and industries. Although producers may suffer the greatest financial losses, there is a substantial impact on consumers. Pirated copies are generally inferior in quality and are sometimes defective. If anything goes wrong, pirated copies, being illegal, are unsupported. Additionally, producers’ financial losses due to pirated copies may push the cost of legitimate copies up. Retailers and distributors also suffer due to the loss of sales to pirates. Illegal copies generally are sold more inexpensively than legitimate copies, so retailers and distributors cannot compete on price.

Creative talent, whether software developers, writers, musicians, artists, or performers, plus all the people who helped create the book, magazine, record, performance, painting, concert, or other media, are cheated out of their royalties by pirates. Frequently, because of the amount of time and effort needed to create the end product, the creators depend on the royalties for their livelihood. In addition, poor quality of stolen concepts can irreparably damage the reputation of the creative talent.

Publishers, record companies, art dealers, and other individuals and companies that invest artistic and technical skill along with money and effort to create an original work also lose revenues when that work is pirated. Because of the expenses already laid out to create the original product, companies frequently have to recoup their losses by raising prices for the consumer.

Due to the sophistication of systems and the increased use of the Internet, piracy has become more widespread and has an even greater financial impact worldwide. Many different types of antipiracy systems and techniques have been developed and implemented in an effort to cut down on the ever-increasing instances of piracy. One drawback to all of the systems is the lack of standards applied to software, audio, video, and other media. One of the most promising antipiracy systems is digital rights management. However, even DRM systems are not yet standardized, thus creating even more confusion regarding which is best and what to use.

The media industry is still working out which DRM solution it likes best, or whether it likes DRM at all. In 2007, Apple’s Steve Jobs announced that a large portion of EMI’s song catalog will be available for DRM-free download from the iTunes Music Store, at a price per song just \$0.30 higher than the standard \$0.99. Previously downloaded songs,

with DRM, will be upgradeable to a DRM-free version for the difference in the two prices.³³ This move echoes Jobs's recent comments encouraging the music industry to move away from DRM. Apple's actions notwithstanding, some consumers and privacy organizations continue fighting what they see as serious threats to individual privacy in nascent DRM efforts. The use of network proxies and hidden operating systems is adding to the difficulty of discovering inappropriate use of content, much less preventing or prosecuting it. As the balance between content producers and consumers works itself out, it seems likely that many more technologies will come and go, and DRM may be the harbinger of things to come or an unfortunate choice on the way to a bold, new business model for the media industry.

42.9 GLOSSARY. Discussions of piracy and privacy often are riddled with a confusing array of terms and acronyms. Some of the most commonly used terms, organizations, and acronyms are listed in this glossary.

AAC—Advanced Audio Coding. A standardized, lossy compression and encoding scheme for digital audio. Most commonly used format for compressing audio CDs for Apple's iPod and iTunes.

ACATS. Advisory Committee on Advanced Television Service.

Anti-Bootleg Statute (Section 2319A). A U.S. federal statute that criminalizes the unauthorized manufacture, distribution, or trafficking in sound recordings and music videos of "live" musical performances.

ATSC. Advanced Television Systems Committee.

ATV. Advanced Television.

Bootleg recordings. The unauthorized recording of a musical broadcast on radio or television, or at a live concert or performance. These recordings are also known as *underground recordings*.

BSA—Business Software Alliance. A consortium of major software developers, including IBM, Microsoft, Novell, Apple, Dell, and Sun Microsystems, that is attempting to stem lost revenues from pirated computer software. BSA educates computer users on software copyrights and fights software piracy. Individual members, such as Microsoft and Adobe, have their own anti-piracy programs in addition to belonging to the BSA.

CEA. Consumer Electronics Association.

CEMA. Consumer Electronics Manufacturers Association.

CSS—Content Scrambling System. A form of data encryption used to discourage reading media files directly from the disc, without a decryption key. Descrambling the video and audio requires a 5-byte, 40-bit key.

DeCSS—Descrambling Content Scrambling System. A utility developed by Norwegian programmers via reverse engineering and posted on the Web. This utility decrypts CSS and allows individuals to make illegal copies of DVD movies.

DFAST. Dynamic Feedback Arrangement Scrambling Technique.

DMAT. Digital Music Access Technology.

DMCA. The Digital Millennium Copyright Act signed into law October 28, 1998. Designed to implement World Intellectual Property Organization (WIPO) treaties

(signed in Geneva in December 1996); the DMCA strengthens the protection of copyrighted materials in digital formats.

DivX. A brand name of products created by DivX, Inc. (formerly DivXNetworks, Inc.), including the DivX Codec. Known for its ability to compress lengthy video segments into small sizes, it has been the center of controversy because of its use in the replication and distribution of copyrighted DVDs. Many newer DVD players are able to play DivX movies.

DRM—Digital Rights Management. Refers to any of several technologies used by publishers or copyright owners to control access to, and usage of, digital data or hardware and to restrictions associated with a specific instance of a digital work or device.

DVD CCA—DVD Copy Control Association. A not-for-profit corporation that owns and licenses CSS. DVD CCA has filed numerous lawsuits against companies and individuals that make pirated copies of films.

EFF—Electronic Frontier Foundation. A nonprofit organization working in the public interest to protect fundamental civil liberties, including privacy where computers and the Internet are concerned. The organization frequently disagrees with the steps that other organizations and corporations want to take to protect copyrighted materials.

EPIC—Electronic Privacy Information Center. A public interest research group established in 1994 to focus public attention on emerging civil liberties issues and to protect privacy, the First Amendment, and constitutional values.

FairPlay. A digital rights management (DRM) technology created by Apple Inc. (formerly known as Apple Computer), built in to the QuickTime multimedia technology, and used by the iPod, iTunes, and the iTunes Store. Every file bought from the iTunes Store with iTunes is encoded with FairPlay. It digitally encrypts AAC audio files and prevents users from playing these files on unauthorized computers.

FAST—Federation against Software Theft. A group headquartered in Great Britain represents software manufacturers and works with law enforcement agencies in finding and stopping software pirates in Europe.

FCC. Federal Communications Commission.

grpff. A 7-line, 526-character program of Perl code developed by two students at the Massachusetts Institute of Technology. More compact than DeCSS, the program descrambles DVDs but does not contain a decryption key. The code is readily available on the MIT campus via hats, T-shirts, business cards, and bumper stickers.

Hard disk loading. PCs with unlicensed software preinstalled. Use of a single copy of a software program but installed illegally on many machines. The original disks and the documents that should come with the PC are often missing or incomplete.

HDTV—High-definition television. Digital television transmissions are mandated in the U.S. to be the standard.

HRRC—Home Recording Rights Coalition. A coalition representing consumers, retailers, and manufacturers of audio and audiovisual recording products and media. The HRRC dedicates itself to keeping products free of government-imposed charges or restraints on the products' distribution or operation.

- IFPI—International Federation of the Phonographic Industry.** An organization that promotes the interests of the international recording industry worldwide. Its mission is to fight music piracy; promote fair market access and good copyright laws; help develop the legal conditions and the technologies for the recording industry to prosper in the digital era; and promote the value of music.
- IIPA—International Intellectual Property Alliance.** A private-sector coalition formed in 1984. The organization represents the U.S. copyright-based industries in efforts to improve international protection of copyrighted materials.
- MP3.** A technology for downloading music files using the MPEG format via the Internet.
- MPAA—Motion Picture Association of America.** Composed of member companies that produce and distribute legitimate films and videos. This organization serves as the official voice and advocate of the American motion picture industry. MPAA also assists law enforcement in raids and seizure of pirated videocassettes and DVDs.
- MPEG—Moving Pictures Experts Group.** A generic means of compactly representing digital video and audio signals for consumer distribution. MPEG video syntax provides an efficient way to represent image sequences in the form of more compact-coded data.
- NMPA—National Music Publishers Association.** A trade association that represents 700 U.S. businesses that own, protect, and administer copyrights in musical works.
- NTSC.** National Television System Committee.
- PET—Privacy-Enhancing Technologies.** The general term for a variety of new technologies and Internet protocols designed to enhance online privacy; includes anonymizing proxies, mixing networks, and onion routing.
- Pirated recordings.** Unauthorized duplicates of the sounds of one or more legitimate recordings.
- RIAA—Recording Industry Association of America.** The group has an antipiracy unit that handles initial examination of product on behalf of the recording industry. Pirates can be turned in by calling RIAA at 1-800-BAD-BEAT.
- SAG—Screen Actors Guild.** The union for screen actors. Members do not get residuals from pirated films, as they do from authorized copies.
- SDMI—Secure Digital Music Initiative.** A forum of 200 companies from the electronics, music, telecommunications, and information technology industries and the RIAA. The group was active from 1998 to 2001.
- SIIA—Software & Information Industry Association.** A trade organization of the software and information content industries representing over 800 high-tech companies that develop and market software and electronic content. The organization provides policies and procedures for dealing with software and Internet use within businesses. SIIA also provides guidelines for telling if software is pirated or counterfeited. The SIIA Anti-Piracy Hotline is 1-800-388-7478.
- SPA—Software Publishers Association.** This association, a division of SIIA, assists in enforcement in dealing with software piracy and also provides education about software piracy. SPAudit Software is one of the first software audit and inventory

42 · 22 PROTECTING DIGITAL RIGHTS: TECHNICAL APPROACHES

tools made available for use by companies (in the 1980s). Improved versions of the software are now available.

Trademark Counterfeiting—Title 18 U.S.C. Section 2320. A federal statute that deals with sound recordings that contain the counterfeit trademark of the legitimate manufacturer or artists.

Trafficking in Counterfeit Labels—Title 18 U.S.C., Section 2318. A federal statute that covers counterfeit labels printed for use on a sound recording.

U.S. Copyright Law (Title 17 U.S.C.). A federal law that protects copyright owners from the unauthorized reproduction or distribution of their work.

WGA—Writers Guild of America. The union for writers of television, video, and film scripts.

WMA—Windows Media Audio. A proprietary compressed audio file format developed by Microsoft Corporation.

CONTENTS

PREFACE

ACKNOWLEDGMENTS

A NOTE TO THE INSTRUCTOR

PART I FOUNDATIONS OF COMPUTER SECURITY

- 1. Brief History and Mission of Information System Security**
Seymour Bosworth and Robert V. Jacobson
- 2. History of Computer Crime**
M. E. Kabay
- 3. Toward a New Framework for Information Security**
Donn B. Parker, CISSP
- 4. Hardware Elements of Security**
Sy Bosworth and Stephen Cobb
- 5. Data Communications and Information Security**
Raymond Panko and Eric Fisher
- 6. Local Area Network Topologies, Protocols, and Design**
Gary C. Kessler
- 7. Encryption**
Stephen Cobb and Corinne LeFrançois
- 8. Using a Common Language for Computer Security Incident Information**
John D. Howard
- 9. Mathematical Models of Computer Security**
Matt Bishop
- 10. Understanding Studies and Surveys of Computer Crime**
M. E. Kabay

vi CONTENTS

11. Fundamentals of Intellectual Property Law

William A. Zucker and Scott J. Nathan

PART II THREATS AND VULNERABILITIES

12. The Psychology of Computer Criminals

Q. Campbell and David M. Kennedy

13. The Insider Threat

Gary L. Tagg, CISSP

14. Information Warfare

Seymour Bosworth

15. Penetrating Computer Systems and Networks

Chey Cobb, Stephen Cobb, M. E. Kabay, and Tim Crothers

16. Malicious Code

Robert Guess and Eric Salveggio

17. Mobile Code

Robert Gezelter

18. Denial-of-Service Attacks

Gary C. Kessler

19. Social-Engineering and Low-Tech Attacks

Karthik Raman, Susan Baumes, Kevin Beets, and Carl Ness

20. Spam, Phishing, and Trojans: Attacks Meant to Fool

Stephen Cobb

21. Web-Based Vulnerabilities

Anup K. Ghosh, Kurt Baumgarten, Jennifer Hadley, and Steven Lovaas

22. Physical Threats to the Information Infrastructure

Franklin Platt

PART III PREVENTION: TECHNICAL DEFENSES

23. Protecting the Physical Information Infrastructure

Franklin Platt

24. Operating System Security

William Stallings

25. Local Area Networks

N. Todd Pritsky, Joseph R. Bumblis, and Gary C. Kessler

- 26. Gateway Security Devices**
Justin Opatrny
- 27. Intrusion Detection and Intrusion Prevention Devices**
Rebecca Gurley Bace
- 28. Identification and Authentication**
Ravi Sandhu, Jennifer Hadley, Steven Lovaas, and Nicholas Takacs
- 29. Biometric Authentication**
Eric Salveggio, Steven Lovaas, David R. Lease, and Robert Guess
- 30. E-Commerce and Web Server Safeguards**
Robert Gezelter
- 31. Web Monitoring and Content Filtering**
Steven Lovaas
- 32. Virtual Private Networks and Secure Remote Access**
Justin Opatrny and Carl Ness
- 33. 802.11 Wireless LAN Security**
Gary L. Tagg, CISSP and Jason Sinchak, CISSP
- 34. Securing VoIP**
Christopher Dantos and John Mason
- 35. Securing P2P, IM, SMS, and Collaboration Tools**
Carl Ness
- 36. Securing Stored Data**
David J. Johnson, Nicholas Takacs, Jennifer Hadley, and M. E. Kabay
- 37. PKI and Certificate Authorities**
Santosh Chokhani, Padgett Peterson, and Steven Lovaas
- 38. Writing Secure Code**
Lester E. Nichols, M. E. Kabay, and Timothy Braithwaite
- 39. Software Development and Quality Assurance**
Diane E. Levine, John Mason, and Jennifer Hadley
- 40. Managing Software Patches and Vulnerabilities**
Karen Scarfone, Peter Mell, and Murugiah Souppaya
- 41. Antivirus Technology**
Chey Cobb and Allysa Myers
- 42. Protecting Digital Rights: Technical Approaches**
Robert Guess, Jennifer Hadley, Steven Lovaas, and Diane E. Levine

viii CONTENTS

PART IV PREVENTION: HUMAN FACTORS

- 43. Ethical Decision Making and High Technology**
James Landon Linderman
- 44. Security Policy Guidelines**
M. E. Kabay and Bridgitt Robertson
- 45. Employment Practices and Policies**
M. E. Kabay and Bridgitt Robertson
- 46. Vulnerability Assessment**
Rebecca Gurley Bace and Jason Sinchak
- 47. Operations Security and Production Controls**
M. E. Kabay, Don Holden, and Myles Walsh
- 48. Email and Internet Use Policies**
M. E. Kabay and Nicholas Takacs
- 49. Implementing a Security-Awareness Program**
K. Rudolph
- 50. Using Social Psychology to Implement Security Policies**
M. E. Kabay, Bridgitt Robertson, Mani Akella, and D. T. Lang
- 51. Security Standards for Products**
Paul Brusil and Noel Zakin

PART V DETECTING SECURITY BREACHES

- 52. Application Controls**
Myles Walsh and Susan Baumes
- 53. Monitoring and Control Systems**
Caleb S. Coggins and Diane E. Levine
- 54. Security Audits**
Donald Glass, Richard O. Moore III, Chris Davis, John Mason,
David Gursky, James Thomas, Wendy Carr, M. E. Kabay, and Diane Levine
- 55. Cyber Investigation**
Peter Stephenson

PART VI RESPONSE AND REMEDIATION

- 56. Computer Security Incident Response Teams**
Michael Miora, M. E. Kabay, and Bernie Cowens

- 57. Data Backups and Archives**
M. E. Kabay and Don Holden

- 58. Business Continuity Planning**
Michael Miora

- 59. Disaster Recovery**
Michael Miora

- 60. Insurance Relief**
Robert A. Parisi, Jr., John F. Mullen, and Kevin Apollo

- 61. Working with Law Enforcement**
David A. Land

PART VII MANAGEMENT'S ROLE IN SECURITY

- 62. Quantitative Risk Assessment and Risk Management**
Robert V. Jacobson and Susan Baumes

- 63. Management Responsibilities and Liabilities**
Carl Hallberg, M. E. Kabay, Bridgitt Robertson, and Arthur E. Hutt

- 64. U.S. Legal and Regulatory Security Issues**
Timothy Virtue

- 65. The Role of the CISO**
Karen F. Worstell

- 66. Developing Security Policies**
M. E. Kabay and Sean Kelley

- 67. Developing Classification Policies for Data**
Karthik Raman, Kevin Beets, and M. E. Kabay

- 68. Outsourcing and Security**
Kip Boyle, Michael Buglewicz, and Steven Lovaas

PART VIII PUBLIC POLICY AND OTHER CONSIDERATIONS

- 69. Privacy in Cyberspace: U.S. and European Perspectives**
Henry L. Judy, Scott L. David, Benjamin S. Hayes, Jeffrey B. Ritter,
Marc Rotenberg, and M. E. Kabay

- 70. Anonymity and Identity in Cyberspace**
M. E. Kabay, Eric Salvaggio, Robert Guess, and Russell D. Rosco

- 71. Healthcare Security and Privacy**
Paul Brusil

x CONTENTS

72. Legal and Policy Issues of Censorship and Content Filtering

Lee Tien, Seth Finkelstein, and Steven Lovaas

73. Expert Witnesses and the *Daubert* Challenge

Chey Cobb

74. Professional Certification and Training in Information Assurance

M. E. Kabay, Christopher Christian, Kevin Henry, and Sondra Schneider

75. The Future of Information Assurance

Jeremy A. Hansen

INDEX

PREFACE

Computers are an integral part of our economic, social, professional, governmental, and military infrastructures. They have become necessities in virtually every area of modern life, but their vulnerability is of increasing concern. Computer-based systems are constantly under threats of inadvertent error and acts of nature, as well as those attributable to unethical, immoral, and criminal activities. It is the purpose of *The Computer Security Handbook* to provide guidance in recognizing these threats, eliminating them where possible and, if not, then reducing any losses attributable to them.

The Handbook will be most valuable to those directly responsible for computer, network, or information security, as well as those who must design, install, and maintain secure systems. It will be equally important to those managers whose operating functions can be affected by breaches in security and to those executives who are responsible for protecting the assets that have been entrusted to them.

With the advent of desktop, laptop, and handheld computers, and with the vast international networks that interconnect them, the nature and extent of threats to computer security have grown almost beyond measure. In order to encompass this unprecedented expansion, *The Computer Security Handbook* has grown apace.

When the first edition of the *Handbook* was published, its entire focus was on main-frame computers, the only type then in widespread use. The second edition recognized the advent of small computers, while the third edition placed increased emphasis on PCs and networks.

Edition	Publication Date	Chapters	Text Pages
First	1973	12	162
Second	1988	19	383
Third	1995	23	571
Fourth	2002	54	1,184
Fifth	2009	77	2,040
Sixth	2014	75	2224

The fourth edition of *The Computer Security Handbook* gave almost equal attention to mainframes and microcomputers, requiring more than twice the number of chapters and pages as the third.

xii PREFACE

The fifth edition was as great a step forward as the fourth. With 77 chapters and the work of 86 authors, we increased coverage in both breadth and depth. In this sixth edition, we updated all chapters while continuing to cover all 10 domains of the Common Body of Knowledge, as defined by the International Information Systems Security Certification Consortium (ISC)²:

1. Security Management Practices: Chapters 10, 12, 13, 14, 15, 19, 31, 43, 44, 45, 46, 47, 48, 49, 50, 51, 54, 55, 62, 63, 64, 65, 66, 67, 68, 74, 75
2. Security Architecture and Models: Chapters 1, 2, 3, 8, 9, 24, 26, 27, 51
3. Access Control Systems and Methodology: Chapters 15, 19, 28, 29, 32
4. Application Development Security: Chapters 13, 19, 21, 30, 38, 39, 52, 53
5. Operations Security: Chapters 13, 14, 15, 19, 21, 24, 36, 40, 47, 53, 57
6. Physical Security: Chapters 4, 13, 15, 19, 22, 23, 28, 29
7. Cryptography: Chapters 7, 32, 37, 42
8. Telecomm, Networks, and Internet Security: Chapters 4, 5, 6, 13, 14, 15, 16, 17, 18, 20, 21, 24, 25, 26, 27, 30, 31, 32, 33, 34, 35, 41, 48
9. Business Continuity Planning: Chapters 22, 23, 56, 57, 58, 59, 60
10. Law, Investigations, and Ethics: Chapters 11, 12, 13, 31, 42, 61

We have continued our practice from the fourth and fifth editions of inviting a security luminary to write the final chapter, “The Future of Information Assurance.” We are pleased to include this stellar contribution from Jeremy A. Hansen.

SEYMOUR BOSWORTH
Editor-in-Chief
February 2014

ACKNOWLEDGMENTS

Seymour Bosworth, Editor-in-Chief. I would like to give grateful recognition to Arthur Hutt and Douglas Hoyt, my coeditors of the first, second, and third editions of this *Handbook*. Although both Art and Doug are deceased, their commitment and their competence remain as constant reminders that nothing less than excellence is acceptable. Mich Kabay, my coeditor from the fourth and fifth editions, and Eric Whyne, our fellow editor from the fifth and now sixth editions, continue in that tradition. I would not have wanted to undertake this project without them.

Thanks are also due to our colleagues at John Wiley & Sons: Tim Burgard as former Acquisitions Editor, Helen Cho as Editorial Program Coordinator, Sheck Cho as Executive Editor, Kimberly Kappmeyer as Production Editor, Natasha Andrews as Senior Production Editor, and Darice Moore as Copyeditor. All have performed their duties in an exemplary manner and with unfailing kindness, courtesy, and professionalism.

M. E. Kabay, Technical Editor. I want to thank my beloved wife, Deborah Black, light of my life, for her support and understanding over the years that this project has taken away from our time together. I am also grateful to the authors who have selflessly contributed so much to updating the material presented in this text.

Eric Whyne, Administrative Editor. An undertaking as big as pulling together this handbook would not be possible without my wife Lindsay and the love and support she gives to me and to our son Colton. I'd also like to thank the friends and mentors that have helped me most in my career: Mich and Sy, Tom Aldrich, Tom Payne, Frank Vanecek, and my parents Len and Terri. Any successful undertakings I've had, including this book, have been from listening to the advice they've given and aspiring to internalize the virtues that they exemplify. The authors who have contributed to this book also deserve many thanks for sharing their experience and wisdom. It is something for which I, myself, and the readers are extremely grateful.

A NOTE TO THE INSTRUCTOR

This two-volume text will serve the interests of practitioners and teachers of information assurance. The fourth edition and fifth editions of the *Handbook* were well received in academia; at least one-quarter of all copies were bought by university and college bookstores. The design of this sixth edition continues in the same vein and includes many updates to the material.

University professors looking for texts appropriate for a two-semester sequence of undergraduate courses in information assurance will find the *Handbook* most suitable. In my own work at Norwich University in Vermont, Volume I is the text for our *IS340 Introduction to Information Assurance* and Volume II is the basis for our *IS342 Management of Information Assurance* courses.

The text will also be useful as a resource in graduate courses. In the School of Graduate and Continuing Studies at Norwich University, both volumes have been used as required and supplementary reading for the 18-month, 36-credit Master's of Science in Information Security and Assurance program (MISA).

I will continue to create, update, and post PowerPoint lecture slides based on the chapters of the *Handbook* on my Website for free access by anyone applying them to noncommercial use (e.g., for self-study, for courses in academic institutions, and for unpaid industry training); the materials will be available in the IS340 and IS342 sections:

www.mekabay.com/courses/academic/norwich/is340/index.htm

www.mekabay.com/courses/academic/norwich/is342/index.htm

M. E. KABAY
Technical Editor
October 2013

INTRODUCTION TO PART IV

PREVENTION: HUMAN FACTORS

Human factors underlie all the mechanisms invented by technical experts. Without human awareness, training, education, and motivation, technical defenses inevitably fail. This part details a number of valuable areas of knowledge for security practitioners, including these chapters and topics:

- 43. Ethical Decision Making and High Technology.** A strategy for setting a high priority on ethical behavior and a framework for making ethical decisions
- 44. Security Policy Guidelines.** Guidelines for how to express security policies effectively
- 45. Employment Practices and Policies.** Policy guidelines on hiring, managing, and firing employees
- 46. Vulnerability Assessment.** Methods for smoothly integrating vulnerability assessments into the corporate culture
- 47. Operations Security and Production Controls.** Running computer operations securely, and controlling production for service levels and quality
- 48. E-Mail and Internet Use Policies.** Guidelines for setting expectations about employee use of the Web and e-mail at work
- 49. Implementing a Security-Awareness Program.** Methods for ensuring that all employees are aware of security requirements and policies
- 50. Using Social Psychology to Implement Security Policies.** Drawing on the science of social psychology for effective implementation of security policies
- 51. Security Standards for Products.** Established standards for evaluating the trustworthiness and effectiveness of security products

43.1 INTRODUCTION: THE ABCs OF COMPUTER ETHICS

43.1.1 Why an Ethics Chapter in a Computer Security Handbook? In an information age, many potential misuses and abuses of information create privacy and security problems. In addition to possible legal issues, ethical issues affect many groups and individuals—including employees and customers, vendors, consultants, bankers, and stockholders—who have enough at stake in the matter to confront and

43 · 2 ETHICAL DECISION MAKING AND HIGH TECHNOLOGY

even destroy an organization over ethical lapses. As is so often the case, consciousness raising is at the heart of maintaining control.

In this chapter, the term “ethics” refers to a system of moral principles that relate to the benefits and harms of particular actions and to the rightness and wrongness of motives and ends of these actions. The major sections cover principles of ethics, tests to help recognize ethical and unethical behavior, and approaches to help ensure good ethical conduct.

43.1.2 How Much Time Do You Have for This Chapter? Section 43.2 requires only one minute to read, but it forms the foundation of this chapter and of a lifelong concern for one of the most important requisites of a valued career and of a civilized society. Ethics matters, and here are the ABCs:

Section 43.2 Awareness (a one-minute primer)

Section 43.3 Basics (a 10-minute summary)

Section 43.4 Considerations (a 100-minute study)

Section 43.5 Details (a lifetime of ongoing commitment)

43.2 AWARENESS. The sections that follow distill some of the most important issues.

43.2.1 Principle 1: Ethics Counts. Increasingly, society is holding individuals and organizations to higher ethical standards than in the past; for example, in recent years, many countries have passed privacy legislation, conflict-of-interest restrictions for public officials, and full-disclosure laws for candidates for a variety of public offices. People, individually and collectively, really want to trust others. Two corollaries to the principle that ethics counts are:

1. Good ethical standards are usually good for business.
2. Violations of ethics are almost always bad for business.

In other words, good ethical behavior usually is appreciated by society, and bad ethical behavior almost always is frowned on and punished—sooner or later.

43.2.2 Principle 2: Ethics Is Everybody's Business. A second important principle is that good ethics flourishes best when everyone works at it, both in practicing good ethics and in holding others to do so. The reverse of this is also true: Those who practice bad ethics, or choose to ignore the bad ethics of others, are truly part of the problem. Ethics is inescapably everybody's business.

43.2.3 A Test: Put Yourself in Another's Shoes. One of the best evaluators of whether certain behavior is ethical or not invites you to put yourself in the other person's shoes and ask the role-reversal question: “What if I were on the receiving end of the behavior in question?” This variant of the time-honored golden rule translates to “If I wouldn't like it done to me, I probably shouldn't do it to others.”

43.2.4 An Approach: Disclose! One of the best guidelines to help ensure good ethical behavior is to let your stakeholders in on what you are doing or are about to do. Good ethics flourishes in the light of day; bad ethics ultimately relies on concealment.

Disclosure buys you two forms of peace of mind: First, you're being openly honest; second, if others do not like it, you have at least given them the opportunity to express their concerns.

For example, consider organizational policy about managers reading employee email. Almost any policy (anywhere from aggressive intervention to complete hands off) is likely to be ethical if and only if employees are made aware of it.

43.3 BASICS. The expansion of Section 43.2 that follows elaborates on the basic principles enunciated there.

43.3.1 Principle 3: Stakeholders Dictate Ethics. Stakeholders are defined as any individuals or groups with something at stake in the outcome of a decision. In the world of business, stockholders are almost always stakeholders; employees, customers, suppliers, and even competitors are often stakeholders too. How a decision harms or benefits stakeholders is a major ethical consideration. Effects on stakeholders are so important that the best place to start looking at the ethics of a decision is to identify stakeholders and just what it is they have at stake. Decisions will invariably affect individuals and groups, often in opposite ways: Some may stand to gain, others to lose or suffer. The effects and trade-offs raise the principal ethics concerns.

43.3.2 Principle 4: Traditional Principles Still Apply. Recent generations are not the first to raise questions and develop ideas about ethics, although the concept of business ethics has been mocked as an oxymoron and only recently promoted in academia as a valuable area of study. High technology has complicated some issues, but these fundamental principles still apply:

- The Golden Rule (“Do unto others as you would have them do unto you”) and its variants have already been mentioned. These principles remain timeless and fundamental.
- Consideration of the interplay of duties, rights, and responsibilities remains important. When making ethical decisions, we normally examine the legal, professional, and customary constraints on behavior that apply to our situation.
- Traditional reasons for good ethical behavior, such as religious principles, egoism, utilitarianism, and altruism, still provide us with a useful taxonomy for discussions about ethics.

The point is that even though modern technology has created new opportunities for unethical behavior and new motivations for good ethical behavior, it has not been necessary to develop new principles to deal with ethics. For example, many of the principles (including politeness) governing the behavior of door-to-door sales still apply to Internet push technology.

43.3.3 More Tests. In Section 43.2.3, we suggested the “other’s shoes test” as an excellent evaluator of whether certain behavior is ethical or not. Here we introduce three other tests. The first two are negative in the sense of suggesting that behavior is inappropriate; the third is positive and suggests that the behavior in question is ethical.

43 · 4 ETHICAL DECISION MAKING AND HIGH TECHNOLOGY

1. The “mom test” asks how your mom (spouse, children, best friend, etc.) would react if aware of your actions. If you would be embarrassed having someone close to you know what is going on, the odds are pretty good it is unethical.
2. The “eye-team test” takes this a step further and considers the results of exposing your actions to the whole world as part of an investigative team broadcast. Again, the more embarrassment, the more likely the unethical nature of the actions.
3. The “market test” asks you to think about openly publicizing your actions as a competitive customer relations strategy. Never mind whether such a marketing strategy is actually feasible; if such exposure could impress others favorably, chances are you are on solid ethical ground.

43.3.4 A Guideline Approach: Ask! Section 43.2.4 endorsed disclosure as one of the best guidelines to help ensure good ethical behavior. This simply means letting your stakeholders in on what you are doing, or about to do. Having done so, it then becomes an appropriate guideline to ask those stakeholders for their permission (or acquiescence, or at least acknowledgment) before you proceed. This can be in the form of allowing stakeholders to opt out of certain policies. Many stakeholders prefer an opt-in approach rather than a default assumption of acceptability, particularly if that assumption is nonintuitive or otherwise obscure.

An example of this approach to ethical behavior is the legally enforced requirement in many countries to ask customers for permission to use their personally identifiable information for purposes other than the original defined functions. Typically, customers have either to opt out of information sharing or opt in to such use of their information.

In other cases, stakeholders such as employees or shareholders may disagree with the ethical implications of proposed actions. They can then argue against the proposals to the extent possible. The ultimate option for such stakeholders is to withdraw; employees can resign and shareholders can sell their shares. If the proposed actions are perceived as illegal, critics can become whistle-blowers and report the suspected illegality to law enforcement and regulatory officials.

43.3.5 Another Guideline Approach: An Ethics Officer. Designating an individual to serve as a full- or part-time ethics officer in an enterprise is a powerful, proactive way to help ensure good ethical behavior. Many large organizations now consider this a position on the top management team. But even small organizations can formally delegate such responsibilities on a part-time basis; they need not require much time and energy of the individual involved. In all cases, the common objectives include:

- Clear management commitment to good business ethics, including adequate resources to support this position
- Organizational recognition that this individual has appropriate authority and responsibility, and is a conduit of information into and within the organization
- Hassle-free avenues of access to this person

43.4 CONSIDERATIONS. This section discusses some issues of management style in promulgating and enforcing ethics.

43.4.1 Principle 5: Ethics Need Not and Should Not Be a Hassle. The last thing one wants with business ethics is hassle. An organization’s ethics policies

should not be obscure, complicated, onerous, or an obstacle to getting things done. The keys to avoiding hassles include:

- Clear and straightforward articulation of ethics policies
- Consciousness raising as a prime objective of ethics policies
- Clear, comfortable, and safe access to interpretation, for example, by an ethics officer
- Consistency in promulgation, education, application, and enforcement

Employees should not have to guess what constitutes acceptable behavior, nor should they be encumbered by anxiety, guilt, or fear. Individuals should be able to gain clarification on matters before, during, or after events without delay and without fear of being considered a nuisance. Questions about ethics issues deserve unbiased answers, without the presumption that there has been a breach of ethical conduct or that ulterior motives are involved.

Whenever an individual is uncomfortable with a situation or a potential situation, whether he or she is directly involved or not, and particularly if “whistle-blowing” implicates others or even organizational policy, that discomfort needs to be addressed. Even if the individual is wrong and should not be concerned, the discomfort should be dispelled. If the individual is right and there is a legitimate concern, the organization should resolve the issue in a way that does not put the whistle-blower on the spot but rather indicates support for such disclosure.

43.4.2 Principle 6: Ethics Policies Deserve Formality. Like other important policies, an organization’s ethics policies deserve formality:

- Clear documentation
- Clear motivation
- Clear sanctions
- Clear management support at every level, including the top

Anything less than the foregoing suggests confusion at best and lip service at worst. Formality should not mean bureaucracy or piles of manuals. Consistent with the fifth principle of avoiding hassles, documentation should be brief and clear, and directed at simplifying matters rather than complicating them. The preparation and presentation of policies should reflect a process of thoughtful, high-priority consideration.

A corollary of this principle is peer participation. Policies that ultimately rely on organizational support are best developed and disseminated with peer involvement.

43.4.3 Principle 7: Ethics Policies Deserve Review. Perhaps the only thing as dangerous as ignorance when it comes to policy is complacency. This is as true of ethics policies as it is of any other organizational policy. In particular, to assume everyone in an organization is on board with policy is naïve at best. Review offers a type of preventive maintenance whereby policies and their promulgation are reconsidered with an eye to improvement.

Any organizational policy requires subscription on the part of the members of the organization. Understanding of and compliance with any policy suffers a dangerous tendency to lapse when a policy simply gathers dust. Even an occasional mention and

43 · 6 ETHICAL DECISION MAKING AND HIGH TECHNOLOGY

discussion of ethical issues or principles during meetings can breathe new life into old policy.

Just as a corollary of Principle 6 was peer participation in the formalization of policy, so is peer involvement a corollary of policy review. Such peer review not only facilitates fresh insights into policy, but the process itself represents a powerful educational opportunity.

43.4.4 Principle 8: Anticipate. Few people relish the prospect of a serious breach of organizational ethics, particularly if matters reach the point of embarrassing publicity or even legal action. It is better to contemplate the worst scenarios in advance rather than to deal with them without preparation and after the fact. Wishful thinking often deters an organization from including appropriate issues in formal policy. This must not be permitted to happen.

It is better to address tough issues head on than to take anything for granted. The two best ways of doing so are to:

1. Have comprehensive policies that cover any foreseeable eventuality.
2. Have a full- or part-time ethics officer in place to stay on top of things.

43.4.5 The Smell Test. Sometimes the other tests discussed (other's shoes, mom, eye-team, market) can result in fuzzy or ambiguous analysis. It may be hard to put yourself in someone else's shoes, especially if different individuals would have widely different reactions to your behavior. And sometimes your family and friends, the general public, or your customers could be neutral or divided in their reactions. The so-called smell test does not require quantitative or even qualitative estimations; it simply relies on your intuition as to whether the behavior in question "smells fishy." In other words, if you catch yourself seeking justifications, or feel a bit uncomfortable even thinking about the implications, the ethics may be as bad or poor as they smell.

43.4.6 An Approach: Stocktaking. Where can an organization start with all this if it has not already done so? Things usually start with a concerned individual (you?) doing some stocktaking and consciousness raising. Questions for you and others in your organization to consider follow. If you like the answers, then your organization is ethically aware. If you do not like the answers, your organization must deal with the issues you have uncovered.

- If you felt that a fellow employee was misusing company resources or harassing someone, is it obvious what you should do? Is there someone in the organization you could comfortably talk with?
- Do you have the sense that top management in your organization is aware of ethics issues? Do you have the sense that they care?
- Do you know if your organization monitors employee email or computer usage? How much personal business, such as email and net surfing, is permissible on company time?
- How important is quality to your company's products and services? Are marketing claims consistent with quality?
- What, if any, information does your company capture about customers, suppliers, or employees without their permission? Without even their knowledge? What, if

any, information does your company provide to entities outside the organization about customers, suppliers, or employees without their permission? Without even their knowledge?

- Does your organization fully comply with license arrangements and payments for software and hardware?
- Are customers, suppliers, and employees always treated with dignity and respect? How would a stakeholder (e.g., a new employee) become aware of organizational ethics policies?

For each of these questions, the issue of how one knows must be raised. Ambiguous, confusing, or unreliable knowledge of what is or is not going on should raise red flags of concern. Discomfort with such knowledge may be symptomatic of underlying problems with ethics.

The stocktaking just suggested should translate into action steps for your organization. Here are a few suggested actions to get started.

- Ask some of your peers to consider the same stock-taking questions, and compare their thoughts with yours.
- Itemize and prioritize any concerns.
- Make an appointment with someone fairly high up in management to discuss those concerns. If you are that someone, make an appointment with two or three peers and with subordinates who represent the staff.
- Examine the feasibility of appointing a full- or part-time ethics officer while considering the downside of not having one.
- Ask your internal or external auditors to consider an audit of your ethics policies the next time they do a financial or operational audit.

43.5 CONCLUDING REMARKS. As with security awareness, ethical awareness needs freshness and repetition.

43.5.1 How to Keep Up. One of the best ways for individuals and organizations to keep up with matters of good ethics is to spread the job around. Do not try to shoulder the effort alone; it will likely overwhelm any one individual, and collective thinking is valuable in these matters. Without abrogating individual responsibilities, charging the right person with the job of ethics officer will certainly help to keep the enterprise on an appropriate ethical course. A growing number of periodicals, both professional and of general interest, include articles involving ethics. Reading and then discussing them with your peers can be invaluable. Additionally, there has been an increase in the number of Websites addressing ethical issues. See Section 43.6.

43.5.2 Why to Keep Up. Keeping on top of organizational ethics is important because it is the right thing to do. Contemporary business practice embraces the idea of an extended value chain where entities such as customers and suppliers, traditionally seen as outside organizational boundaries, are now viewed as partners. Strategic alliances are being formed with these entities, and keeping business partners satisfied and confident is now a strategic necessity. Souring the relationship by a breach of ethics is completely inconsistent with sound business practices. Even if customers and suppliers are not formally viewed as business partners, they are still essential to doing

43 · 8 ETHICAL DECISION MAKING AND HIGH TECHNOLOGY

business and are not to be taken for granted. At the very least, given the range of alternative choices available today, unfair exploitation and other forms of unethical practice expose an organization to outright abandonment.

Finally, in the spirit of total quality management, whereby everyone in the enterprise is seen to contribute to its success or failure, your enterprise can be said to be counting on you. The converse may also be true: Your job and your future career may well depend on the success of your enterprise. The good ethics of your organization reflect favorably on you and your colleagues, but bad ethics will have an opposite effect.

44.1 INTRODUCTION. This chapter reviews principles, topics, and resources for creating effective security policies. It does not propose specific guidelines except as examples. Many of the chapters in this *Handbook* discuss policy; examples include:

- Chapter 23 provides an extensive overview of physical security policies
- Chapter 25 discusses local area network security issues and policies
- Chapter 38 reviews software development policies
- Chapter 39 surveys quality assurance policies
- Chapter 43 discusses ethics
- Chapter 45 provides guidance on employment policies from a security standpoint

44 · 2 SECURITY POLICY GUIDELINES

- Chapter 47 includes policies for improving operations security and production
- Chapter 48 reviews specific recommendations for email and Internet usage
- Chapter 49 looks at methods for enhancing security awareness
- Chapter 52 offers policies for secure application design
- Chapters 56 through 59 deal with policies for emergency response, backup, and recovery
- Chapter 61 presents policies for working effectively with law enforcement
- Chapter 66 discusses effective methods for developing security policies in specific organizations

44.2 TERMINOLOGY. One of the preeminent leaders in security policy development, Charles Cresson Wood, has emphasized that when developing policy, it helps to segregate information that has different purposes. Specifically, one should create different documents for policy, standards, and procedures.¹

44.2.1 Policy. The term “policy” is defined as the rules and regulations set by the organization. Policies are laid down by management in compliance with applicable law, industry regulations, and the decisions of enterprise leaders. Policies are mandatory; they are expressed in definite language and require compliance. Failure to conform to policy can result in disciplinary action, termination of employment, and even legal action. Familiar examples of policy include requirements for background checks when hiring employees, the obligation to follow laws governing the duplication of proprietary software, and restrictions on the use of corporate vehicles for private purposes.

Security policy governs how an organization’s information is to be protected against breaches of security; examples include policies on identification and authentication, authorization for specific kinds of access to specific data, responsibilities for data protection, limitations on the use of corporate resources for email and Internet access, and restrictions on installation of programs on corporate systems. Policies are the basis for security awareness, training, and education; they are a necessary underpinning for security audits. Without policies, it is impossible to demonstrate due diligence in the protection of corporate assets.

Policies are focused on the desired results, not on the means for achieving those results. The methods for achieving policies are defined in the next sections on controls, standards, and procedures.

44.2.2 Controls. When developing a framework for implementing security policies, controls are the measures used to protect systems against specific threats. For example, a policy might stipulate that all production systems must be protected against unauthorized modification of data by programmers; a specific control that could be named in the policy might be that test data extracted by programmers from the production databases must be anonymized to protect confidential data.

44.2.3 Standards. A standard in computing can be an accepted specification for hardware, software, or human actions. An example of a technical standard is the Transmission Control Protocol/Internet Protocol (TCP/IP) that governs how systems can be interconnected into the Internet.

Standards can be de facto when they are so widely used that new applications routinely respect their conventions; an example is the Hewlett-Packard interface bus

(HP-IB), which became so popular that it was eventually turned into a *de jure* standard when the Institute of Electrical and Electronics Engineers (IEEE) based its formal IEEE-488 standard on the HP-IB. In contrast, the Centronix parallel interface, although equally popular and universally used, remained proprietary.

In a corporate environment, the term “standard” refers to specific technical choices for implementing particular policies. For example, a corporate policy might stipulate that strong identification and authentication, selected by the technical staff, must be used when gaining access to restricted data; the corresponding standard might specify that a particular brand and model of a microprocessor-equipped smart card should be used in satisfying access control restrictions. Typically, standards are of concern to those who must implement policies; not all standards need be made known to all personnel. Standards also must change in response to a changing technical environment; typically standards change much more rapidly than policies.

44.2.4 Procedures. Procedures prescribe how people are to behave in implementing policies. For example, a policy might stipulate that all confidential communications from employees traveling outside the enterprise must be encrypted; the corresponding standard might define the proprietary virtual private network (VPN) software and hardware needed to implement that policy; and the corresponding procedure would explain in detail each step required to initiate a secure connection using that particular VPN.

44.3 RESOURCES FOR POLICY WRITERS. If one is setting out to create policy *de novo* (i.e., without a preexisting policy document), it is critically important to use an existing policy template. Creating policies without guidance from experienced policy writers is a time-consuming, frustrating job that can consume thousands of hours of time, cause dissension within the enterprise, and leave everyone so disgusted that the policies end up turning into *shelfware*: stored, but never used. There are several well-recognized resources for helping policy writers structure their work, avoid pitfalls, and save enormous amounts of time. In the review that follows, readers will find information about these resources:

- ISO 17799
- COBIT®
- CERT-CC documentation
- NSA Security Guidelines
- U.S. Federal Best Security Practices
- RFC 2196
- IT Baseline Protection Manual
- Commercial policy guides

44.3.1 ISO/IEC 27002:2005. An increasingly popular standard for writing and implementing security policies, especially in Europe, is ISO/IEC 27002:2005, which is the current version of ISO/IEC 17799:2005, in turn based on the old BS7799.

The British Standard 7799 (BS7799) originated in the U.K. Department of Trade and Industry as a code of practice; it was formally renamed the BS7799 in February 1995. BS7799 was not adopted quickly in Great Britain because it was not flexible enough, it used a simplistic security model, and there were more pressing issues, such

44 · 4 SECURITY POLICY GUIDELINES

as the imminent arrival of the Y2K problem.² In addition, BS7799 was a proprietary standard for which users had to pay the equivalent of several hundred dollars before accessing the full documentation.

Version 2 of BS7799 was published in May 1999, and that year also saw the establishment of formal certification and accreditation methods. At that point, the International Organization for Standardization (ISO) began the process of defining BS7799 as an international standard; ISO 17799 was published in 1999. In 2005, the standard was renamed as ISO/IEC 17799:2005 in collaboration with the International Electrochemical Commission (IEC). It was then renamed in 2007.³

With the increasing interest in security, ISO/IEC 27002:2005 certification has been established as a goal for many organizations throughout the world. Major consultancies have trained their auditing staff for compliance with ISO/IEC 27002:2005; e-commerce is also a driving force behind the push for certification. One possible motivation is the experience of the ISO 9000 (quality) certification process in the 1980s; certification soon became a competitive edge and then a competitive requirement to maintain and develop market share.

In the context of policy development, ISO/IEC 27002:2005 offers a convenient framework to help policy writers structure their project in accordance with an international standard. The abstract from the ISO follows.

ISO/IEC 27002:2005 comprises ISO/IEC 17799:2005 and ISO/IEC 17799:2005/Cor.1:2007. Its technical content is identical to that of ISO/IEC 17799:2005. ISO/IEC 17799:2005/Cor.1:2007 changes the reference number of the standard from 17799 to 27002.

ISO/IEC 27002:2005 establishes guidelines and general principles for initiating, implementing, maintaining, and improving information security management in an organization. The objectives outlined provide general guidance on the commonly accepted goals of information security management. ISO/IEC 27002:2005 contains best practices of control objectives and controls in the following areas of information security management:

- security policy;
- organization of information security;
- asset management;
- human resources security;
- physical and environmental security;
- communications and operations management;
- access control;
- information systems acquisition, development and maintenance;
- information security incident management;
- business continuity management;
- compliance.

The control objectives and controls in ISO/IEC 27002:2005 are intended to be implemented to meet the requirements identified by a risk assessment. ISO/IEC 27002:2005 is intended as a common basis and practical guideline for developing organizational security standards and effective security management practices, and to help build confidence in inter-organizational activities.

The full text of ISO/IEC 27002:2005 is available in electronic format or on paper from the ISO. In addition, a variety of guides are available to help organizations to develop ISO/IEC 27002:2005-compliant policies with minimal rewriting.⁴

44.3.2 COBIT. The *Control Objectives for Information and related Technology* (COBIT) provide a business-oriented set of standards for guiding management in the sound use of information technology.⁵ COBIT was developed by volunteers working under the aegis of the IT Governance Institute (ITGI), which was itself founded by the Information Systems Audit and Control Association (ISACA).

COBIT is an information technology (IT) governance framework and supporting tool set that allows managers to bridge the gap between control requirements, technical issues, and business risks. COBIT enables clear policy development and good practice for IT control throughout organizations. COBIT was first published by ITGI in April 1996. ITGI's latest update—COBIT 5, published in 2012—emphasizes regulatory compliance, helps organizations to increase the value attained from IT, highlights links between business and IT goals, and simplifies implementation of the COBIT framework. COBIT 5 is a fine-tuning of the COBIT framework and can be used to enhance work already done based on earlier versions of COBIT. When major activities are planned for IT governance initiatives, or when an overhaul of the enterprise control framework is anticipated, it is recommended to start fresh with COBIT 5. COBIT 5 presents activities in a more streamlined and practical manner so continuous improvement in IT governance is easier than ever to achieve.⁶

COBIT Case Studies provide specific examples of how the framework has been applied.⁷ The extensive *Frequently Asked Questions* provide detailed guidance for managers beginning their study of the standard.⁸ ISACA also provides an interactive, Web-enabled version of COBIT that allows registered users to “construct and download [their] own, personalized version of COBIT for use on the desktop in MS Word or Access format.”⁹ Different levels of detail are available for visitors, ISACA members, and purchasers. ISACA also offers training courses¹⁰ as shown:

- COBIT 5 Foundation
- COBIT 5 Implementation
- COBIT 5 Assessor Course

44.3.3 Informal Security Standards. In addition to the formal standards just discussed, several sets of guidelines have garnered a degree of acceptance as the basis for exercising due diligence in the protection of information systems. These informal standards include:

- CERT-CC security improvement modules
- Security guidelines handbook from the U.S. National Security Agency (NSA)
- RFC 2196 from the Internet Engineering Task Force
- IT baseline protection manual from the German Information Security Department

44.3.3.1 CERT-CC® Documentation. The Computer Emergency Response Team Coordination Center (CERT-CC)® at the Software Engineering Institute (SEI) of Carnegie Mellon University (CMU) has compiled a series of security improvement modules (www.cert.org/certcc.html) on these topics:

Vulnerability Remediation

- Current Vulnerability Work
- Vulnerability Notes Database

44 · 6 SECURITY POLICY GUIDELINES

CSIRT Community

- CSIRT Development
- National CSIRTs

Secure Coding

- Secure Coding Project Page
- Secure Coding Standards

Artifact Analysis

In addition, CERT expert Julia H. Allen published an excellent guide in 2001 that has retained its value.¹¹ Chapter headings for this 480-page text are listed next.

1. The CERT Guide to System and Network Security Practices
2. Securing Network Servers and User Workstations
3. Securing Public Web Servers
4. Deploying Firewalls
5. Setting Up Intrusion Detection and Response Preparation
6. Detecting Signs of Intrusion
7. Responding to Intrusions
8. Appendix A: Security Implementations
9. Appendix B: Practice-Level Policy Considerations

44.3.3.2 NSA Security Guidelines. The National Security Agency (NSA) of the United States has published a freely available *Security Guidelines Handbook*.¹² The preface describes it in this way:

This handbook is designed to introduce you to some of the basic security principles and procedures with which all NSA employees must comply. It highlights some of your security responsibilities, and provides guidelines for answering questions you may be asked concerning your association with this Agency. Although you will be busy during the forthcoming weeks learning your job, meeting co-workers, and becoming accustomed to a new work environment, you are urged to become familiar with the security information contained in this handbook.

This set of employee policies is tailored to the needs of the high-security NSA, but it provides useful information that all organizations can adapt to their own requirements. According to the table of contents, these topics are included:

Initial Security Responsibilities

- Anonymity
- Answering Questions about Your Employment
- Answering Questions about Your Agency Training
- Verifying Your Employment
- The Agency and Public News Media

General Responsibilities

- Espionage and Terrorism
- Classification

- Need-to-Know
- For Official Use Only
- Prepublication Review
- Personnel Security Responsibilities
- Association with Foreign Nationals
- Correspondence with Foreign Nationals
- Embassy Visits
- Amateur Radio Activities
- Unofficial Foreign Travel
- Membership in Organizations
- Changes in Marital Status/Cohabitation/Names
- Use and Abuse of Drugs
- Physical Security Policies
- The NSA Badge
- Area Control
- Items Treated as Classified
- Prohibited Items
- Exit Inspection
- Removal of Material from NSA Spaces
- External Protection of Classified Information
- Reporting Loss or Disclosure of Classified Information
- Use of Secure and Nonsecure Telephones

Helpful Information

- Security Resources

44.3.3.3 U.S. Federal Best Security Practices. The United States Federal Chief Information Officers (CIO) Council has created a Best Practices Committee that provides extensive free documentation for policy makers.¹³ The committee is defined in this way:

The Best Practices Committee (BPC) is established by the CIO Council Charter to serve as a focal point for promoting information management/information technology (IM/IT) best practices within the federal government. The BPC brings together a team of IT professionals committed to identifying the most successful of IM/IT practices being implemented in industry, government, and academia, and sharing them with agency CIOs as best practices, to be considered for emulation throughout the Federal government. It is about sharing the successes of others, and *not reinventing the wheel*. It is about constantly learning and applying working models to reduce complexity and achieve results. It is also about cost avoidance and sound stewardship of the taxpayers' dollars.

There is an extensive collection of documents freely available in PDF format for downloading.¹⁴ Some of the topics in the collection of particular interest for this chapter's context include:

- Best Practices
- Enterprise Architecture

44 · 8 SECURITY POLICY GUIDELINES

- IT Security/Privacy
- GAO Reports
- IT-Related Laws and Regulations

44.3.3.4 RFC 2196 (*Site Security Handbook*). The Internet Engineering Task Force (IETF) has an extensive list of informational documents called Requests for Comments (RFCs) governing all aspects of the Internet.¹⁵ One document of particular value to any organization trying to improve its security practices is the classic *Site Security Handbook*, RFC 2196, edited by B. Fraser of the Software Engineering Institute at Carnegie Mellon University, the same body that hosts the CERT-CC.¹⁶ The *Handbook* has this structure:

Introduction

- Purpose of this Work
- Audience
- Definitions
- Related Work
- Basic Approach
- Risk Assessment

Security Policies

- What Is a Security Policy and Why Have One?
- What Makes a Good Security Policy?
- Keeping the Policy Flexible

Architecture

- Objectives
- Network and Service Configuration
- Firewalls

Security Services and Procedures

- Authentication
- Confidentiality
- Integrity
- Authorization
- Access
- Auditing
- Securing Backups

Security Incident Handling

- Preparing and Planning for Incident Handling
- Notification and Points of Contact
- Identifying an Incident

- Handling an Incident
- Aftermath of an Incident
- Responsibilities

Ongoing Activities

Tools and Locations

Mailing Lists and Other Resources

References

44.3.3.5 IT-Grundschrift Catalogues. The German government's computer security arm, the *Bundesamt für Sicherheit in der Informationstechnik*, has published a useful set of guidelines since 1997, the *IT-Grundschrifthandbuch*. Originally known in English as the *IT Baseline Protection Manual*, the most recent version as of this writing was published in 2005 and is available free in English as the *IT-Grundschrift Catalogues*.¹⁷ The work is freely available in PDF in German, English, Swedish, and Estonian.

In general, each module presents concepts, threats and vulnerabilities, and countermeasures. This work is easy to understand and provides a sound basis for effective information security protection.

44.3.4 Commercially Available Policy Guides. There are several commercially available policy templates that save time when developing new policies or improving existing policies. Three of the particular values are discussed next.

44.3.4.1 Charles Cresson Wood's ISPME. The most widely used commercially available collection of security standards is the work by Charles Cresson Wood, *Information Security Policies Made Easy (ISPME)*. The text includes a CD-ROM for easy access to the text so that users can avoid tedious retyping of existing materials.

Wood integrates the perspectives of both management and technical staff when making recommendations. He was one of the original promoters of information security as a way to achieve a competitive advantage and a coauthor of the first computer crime investigation manual. He was one of the first to advocate and document integration of information resource management concepts with information security activities, use of head-count ratio analysis to determine appropriate levels of information security staffing, an information security document life cycle for planning and budgeting purposes, and network management tools to achieve consistent and centralized systems security. He has also developed and successfully marketed two unique software packages that automate information security administration activities. In addition, he evaluated and recommended U.S. Government policies on open versus classified cryptographic research for Frank Press, President Carter's technology advisor.

One of the outstanding features of *ISPME* is that Wood explains every policy and sometimes provides opposing policies for use in different environments. His text is not only a set of templates but an excellent basis for teaching security principles by looking at the practice of security.

44.3.4.2 Tom Peltier's Practitioner's Reference. Tom Peltier is the Year 2001 Hall of Fame Award Recipient from the Information Systems Security Association

44 · 10 SECURITY POLICY GUIDELINES

(www.issa.org). The citation provides the background that explains why Peltier is so highly regarded in the field of security:

Tom Peltier is in his fifth decade working with computer technology. During this time he has garnered numerous industry honors for sharing his experiences with fellow professionals. Because of his work he was given the 1993 Computer Security Institute's (CSI) Lifetime Achievement Award. In 1999, the Information Systems Security Association (ISSA) bestowed on him its Individual Contribution to the Profession Award, and in 2001 he was inducted into the ISSA Hall of Fame. Tom was also awarded the CSI Lifetime Emeritus Membership Award.

Peltier's policy text is *Information Security Policies and Procedures*. He provides you with the tools you need to develop policies, procedures, and standards. He demonstrates the importance of a clear, concise, and well-written security program. His examination of recommended industry best practices illustrates how they can be customized to fit any organization's needs.

44.3.4.3 SANS Resources. The System Administration and Network Security (SANS) Institute is well known for the excellent security resources it makes available to members and the general public.

44.3.4.3.1 Security Essentials Courses. The SANS Security Essentials Courses (www.sans.org) provide a solid foundation for understanding the issues underlying security policies. Level 524, *Security Policy & Awareness* (www.sans.org), highlights this objective:

This course is designed to offer an individual a comprehensive approach to understanding security awareness and developing security policy. Business needs change, the business environment changes, and critical systems are continually exposed to new and developing vulnerabilities. Security awareness training is an effective business strategy that reduces the overall risk to an organization, therefore minimizing user-related faults and errors that lead to destructive and costly security incidents. Security awareness and policy development and assessment are a never-ending process.

44.3.4.3.2 Free Resources. The SANS Institute offers many free resources. For details, see www.sans.org/free_resources.php?utm_source=web-sans&utm_medium=ImageReplace&utm_content=Main_resource_button_green&utm_campaign=HomePage&ref=3601. Topics include:

- Reading Room: Over 1,600 computer security white papers in over 70 categories
- Top 20: The Twenty Most Critical Internet Security Vulnerabilities
- Newsletters: Latest Security News

44.4 WRITING THE POLICIES. How should one write security policies? Should they be suggestions? Orders? Positive? Negative? This section affirms that policies should be definite, unambiguous, and directive. In addition, all policies should have (preferably optional) explanations for the reasons behind them.

44.4.1 Orientation: Prescriptive and Proscriptive. Security policies should be written with clear indications that all employees are expected to conform to them. Language should be definite and unambiguous (e.g., "All employees must..." or "No employees shall..."). Some policies require people to do something—these

are *prescriptive* (e.g., “Employees must follow the password procedures defined by the Information Protection Group at all times.”). Other policies prohibit certain actions—these are *proscriptive* (e.g., “No employee shall make or order illegal copies of proprietary software under any circumstances.”).

44.4.2 Writing Style. Each policy should be short. Simple declarative sentences are best; writers should avoid long compound sentences with multiple clauses. Details of implementation are appropriate for standards and procedures, not for policies. Policies can refer users to the appropriate documents for implementation details; for example, “Passwords shall be changed on a schedule defined in the *Security Procedures* from the Information Protection Group.”

For more details on developing policy, see Chapter 45 in this *Handbook*.

44.4.3 Reasons. Few people like to be ordered about with arbitrary rules. Trying to impose what appear to be senseless injunctions can generate a tide of rebellion among employees. It is far better to provide explanations of why policies make sense for the particular enterprise; however, such explanations can make the policies tedious to read for more experienced users. A solution is to provide optional explanations. One approach is to summarize policies in one part of the document and then to provide an extensive expansion of all the policies in a separate section or a separate document. Another approach is to use hypertext, as explained in Section 44.6.3 of this chapter.

44.5 ORGANIZING THE POLICIES. Policies are distinct from the sequence in which they are presented. It is useful to have two distinct presentation sequences for policies: topical and organizational.

44.5.1 Topical Organization. Security involves a multitude of details; how one organizes these details depends on the purpose of the policy document. The most common format puts policies in a sequence that corresponds to some reasonable model of how people perceive security. For example, employees can look at security with a rough correspondence to the physical world. Under this model, one might have a policy document with a table of contents that looks like this:

Principles

Organizational Reporting Structure

Physical Security

- Servers
- Workstations
- Portable computers

Hiring, Management, and Firing Data Protection

- Classifying information
- Data access controls
- Encryption
- Countering industrial espionage

44 · 12 SECURITY POLICY GUIDELINES

Communications Security

- Perimeter controls
- Web usage and content filtering
- Email usage and privacy
- Telephone and fax usage

Software

- Authorized products only
- Proprietary (purchased) software
- Development standards
- Quality assurance and testing

Operating Systems

- Access controls
- Logging

Technical Support

- Service-level agreements
- Helpdesk functions

44.5.2 Organizational. The complete set of policies may be comprehensive, concise, and well written, but they will still likely be a daunting document, especially for nontechnical staff. To avoid distressing employees with huge tomes of incomprehensible materials, it makes sense to create special-purpose documents aimed at particular groups. For example, one could have guides like these:

- General Guide for Protecting Corporate Information Assets
- Guide for Users of Portable Computers
- A Manager's Guide to Security Policies
- Human Resources and Security
- Network Administration Security Policies
- Programmer's Guide to Security and Quality Assurance
- The Operator's Security Responsibilities
- Security and the Helpdesk

Each of these volumes or files can present just enough information to be useful and interesting to the readers without overwhelming them with detail. Each can make reference to the full policy document.

44.6 PRESENTING THE POLICIES. What options do policy makers have for publishing their policies? This section discusses printing them on paper versus publishing them electronically.

44.6.1 Printed Text. Policies are not inherently interesting. Large volumes full of policies quickly become shelfware. Short paper documents, however, are familiar

to people; they can be carried around, or placed at hand for easy reference anywhere. Reference cards, summary sheets, stickers, and posters are some of the printed media that can be useful in security awareness, training, and education programs. Printed text, like its electronic versions, provides the opportunity for typeface and color to be used in clarifying and emphasizing specific ideas. However, printed copies of policies share a universal disadvantage: They are difficult to update.

Updating dozens, hundreds, or thousands of individual copies of policy documents can be such a headache that organizations simply reprint the entire document rather than struggle with updates. Updates on individual sheets require the cooperation of every user to insert the new sheets and remove the old ones; experience teaches that many people simply defer such a task, sometimes indefinitely, and that others have an apparently limited understanding of the sequential nature of page numbers. Badly updated policy guides may be worse than none at all, especially from a legal standpoint. If an employee violates a new policy that has been promulgated verbally, but available manuals fail to reflect that new policy, it may be difficult to justify dismissal for wrongdoing.

44.6.2 Electronic One-Dimensional Text. Despite the familiarity and ubiquity of paper, in today's world of near-universal access to computers in the work environment, there is a place for electronic documentation of policies. Such publication has enormous advantages from an administrative standpoint. All access to the policies can be controlled centrally, at least in theory. Making the current version of the policies (and subsets of the policies, as explained in Section 44.5.2) available for reference on a server obviates the problem of updating countless independent copies and avoids the normal situation when using paper: chaotic differences among copies of different ages.

How can one cope with employees stubbornly determined to have their own local copies of the policies on their workstations? One solution to this problem of enforcing a single version is to alert every user to changes in the central copy, or to send every user copies of the appropriate documents by email, with a request to replace their copies of lower version number. Although this solution is not perfect, it does help to keep most people up to date.

44.6.3 Hypertext. Perhaps the most valuable contribution from electronic publication of policies is the availability of hypertext. Hypertext allows a reader to jump to a different section of text and then come back to the original place easily. On paper, forward and backward references are cumbersome, and most readers do not follow such links unless they are particularly keen on the extra information promised in the reference. In electronic files, however, additional information may be as easy to obtain as placing the cursor over a link and clicking.

The most important function of hypertext for policy documents is to provide definitions of technical terms and explanations of the reasons for specific policies.

Some users are more comfortable with printed policies. Hypertext, like other formats of text, generally permits users to print out their own copies of all or part of their policy documentation. Many of the tools also allow annotations by users on their own copy of a file.

44.6.3.1 HTML and XML. The most widely used hypertext format today is Hypertext Markup Language (HTML). Its variant Extensible Markup Language (XML), provides additional functionality for programmers, but from the user's perspective, the

44 · 14 SECURITY POLICY GUIDELINES

hyperlinks are the same. A simple click of the mouse in a Web browser (e.g., Microsoft Internet Explorer, Netscape Communicator, or Firefox) branches to a different page. More sophisticated programming allows the use of frames and, with Java or ActiveX, pop-up windows. Navigation buttons allow the user to move backward to a previous page or forward to another page. Links also can be used to open new windows so that several pages are visible at once. All of these techniques allow users to move freely through a text with full control over the degree of detail they wish to pursue.

44.6.3.2 Rich Text Format and Proprietary Word Processor Files.

Some people prefer to use word processor files for hypertext. As long as everyone uses the same word processing software, this approach can work acceptably. For example, it is usually possible to insert a hyperlink to a section of a single document, to a location in a different file on disk, or to a page on the Web. Some word processors, such as Microsoft Word and Corel WordPerfect, allow one to insert pop-up comments; floating the cursor over highlighted text brings up a text box that can provide definitions and commentary.

In addition to explicit links, Microsoft Word and other modern word processing programs can display a table of headings that allows instant movement to any section of the document.

Rich text format (RTF) is a general format for interchanging documents among word processors, but the results are not always comparable. For example, a comment created using Microsoft Word shows up as a pop-up box with a word or phrase highlighted in the text; the same comment and marker read from an RTF file by Corel WordPerfect shows up as a balloon symbol in the left margin of the document.

44.6.3.3 Portable Document Format. Adobe Acrobat's portable document format (PDF) provides all the hyperlinking that HTML offers, but it does so in a form that is universally readable and that can be controlled more easily. The free Acrobat reader is available for multiple operating systems from www.adobe.com. PDF documents can be locked easily, for example, so that no unauthorized changes can be made. In addition, unlike HTML and word processor documents, PDF files can be constructed to provide near-perfect reproduction of their original appearance, even if not all the fonts used by the author are present on the target computer system.

44.6.3.4 Help Files. Help files also provide hypertext capability. In the Windows environment, one can create help files using utilities such as *Help & Manual* from EC Software GmbH. Entering the search string "create help files" into an Internet search engine brings up many pages of such tools. Windows Help files can be distributed easily to any Windows user because they are relatively small, and they are loaded almost instantly by the Help subsystem. In addition, users are permitted to add their own notes to such documents and can easily print out sections if they wish.

44.7 MAINTAINING POLICIES. No fixed policy document can cover all eventualities. The information security field changes constantly and so must policies. Information security is a process much like total quality management: For success, both require a thoroughgoing integration into corporate culture.

Above all, some named individuals must see maintaining security policies as an explicit part of their job descriptions. Hoping that someone will spontaneously maintain security policies is like hoping that someone will spontaneously maintain financial records. However, as explained in Chapter 45 of this *Handbook*, security policies

should represent the best efforts of people from throughout the organization, not the arbitrary dictates of just one person.

44.7.1 Review Process. An information protection working group can meet regularly—quarterly is a good frequency to try—to review all or part of the policies. Employees can be encouraged to suggest improvements in policies or to propose new policies. The working group can identify key areas of greatest change and work on those first, leaving minor policy changes to subcommittees. Members of the working group should discuss ideas with their colleagues from throughout the enterprise, not just with each other. Every effort should contribute to increasing the legitimate sense of involvement in security policy by all employees, including managers and executives.

44.7.2 Announcing Changes. Drafts of the new versions can be circulated to the people principally affected by changes, so that their responses can improve the new edition. Truly respectful inquiry will result in a greater sense of ownership of the policies by employees, although few of them will rejoice in the new policies. Some employees will see new security policies merely as a mild irritant, while others may view them as a tremendous obstacle to productivity and a general nuisance.

Ideally, major changes in policy should be described and explained in several ways. For example, a letter or email (digitally signed, for security) from the president, chair of the board of directors, chief officers, or chief information security officer can announce important changes in policy and the reasons for the changes. A brief article in the organization's internal newsletter, or a spot on the intranet, can also provide channels for communicating the policy decisions to everyone involved.

Finally, the updated policies can be made available or distributed to all employees using some of the channels discussed in Section 44.6.

44.8 SUMMARY. These 10 recommendations will help in preparing to create and implement security policies:

1. Distinguish among policies, controls, standards, and procedures.
2. Use all resources from government, industry bodies, and commercial organizations in preparing to create policies.
3. Use unambiguous prose when defining policies: Tell people what to *do* and what *not* to do.
4. Use short sentences.
5. Give reasons for policies.
6. Provide different views of policies—topical and organizational.
7. Provide several ways of reading the policies, including printed text, electronic text, and hypertext.
8. Review and improve or adapt policies regularly.
9. Circulate drafts showing changes in policies to interested participants before publishing them.
10. Announce major changes using high-level authorities within the enterprise.

45.1 INTRODUCTION. Crime is a human issue, not merely a technological one. True, technology can reduce the incidence of computer crimes, but the fundamental problem is that people can be tempted to take advantage of flaws in our information systems. The most spectacular biometric access control in the world will not stop someone from getting into the computer room if the janitor believes it is “just to pick up a listing.”

People are the key to effective information security, and disaffected employees and angry ex-employees are important threats according to many current studies. Chapter 13 in this *Handbook* provides detailed information about insider crime.

This chapter presents principles for integrating human resources (HR) management and information security into corporate culture.¹

45.2 HIRING. The quality of employees is the foundation of success for all enterprises; it is also the basis for effective information security.

45 · 2 EMPLOYMENT PRACTICES AND POLICIES

45.2.1 Checking Candidate's Background. Hiring new employees poses a particular problem; growing evidence suggests that many people inflate their résumés with unfounded claims. According to Edward Andler, author of *The Complete Reference Checking Handbook*, “cheating on résumés has become distressingly common. And many people are getting by with it, which appears to be making others follow suit.” His research shows that up to 10 percent “seriously misrepresent” their background or work histories. A research project run by the Port Authority of New York and New Jersey used an advertisement asking for electricians who were expert at using “Sontag Connectors.” They received 170 responses claiming such expertise, even though there was no such device.²

Reviewers should be especially careful of vague words such as “monitored” and “initiated.” During interviews or background checking, HR staff should find out what the candidate did in specific detail, if possible. All references should be followed up, at least to verify that the candidates really worked where the résumé claims they did.

Unfortunately, there is a civil liberties problem when considering someone's criminal record. Once people have suffered the legally mandated punishment for a crime, whether fines, community service, or imprisonment, discriminating against them in hiring may be a violation of their civil rights. Can one exclude convicted felons from any job openings? From job openings similar to areas in which they abused their former employers' trust? Are employers permitted in law to require that prospective employees approve background checks? Can one legally require polygraph tests? Drug tests? Personality tests?

In some jurisdictions, “negligent hiring” that results in harm to third parties is being punished in civil litigation. Imagine, for example, that a firm were to hire an active criminal hacker as a system administrator without adequate background checking and interviews; if the hacker were then to use his position and corporate resources to break into or sabotage another organization's systems, it is reasonable to suppose that the victim could claim damages from the criminal's employer on the basis of negligent hiring. In addition, “negligent retention” could hold an employer liable when an employee, who may pose a risk to coworkers or the public, is not terminated immediately.

Employers should consult their corporate legal staffs to ensure that they know, and exercise, their rights and obligations in the specific legal context of their work.

Even checking references from previous employers is fraught with uncertainty. Employers may hesitate to give bad references for incompetent or unethical employees for fear of lawsuits if their comments become known, or if the employee fails to get a new job. Today, one cannot rely on getting an answer to the simple question “Would you rehire this employee?”

Ex-employers must also be careful not to inflate their evaluation of an ex-employee. Sterling praise for a scoundrel could lead to a lawsuit from the disgruntled new employer.

For these reasons, a growing number of employers have corporate policies that forbid discussing a former employee's performance in any way, positive or negative. All one gets from a contact in such cases is “Your candidate did work as an Engineer Class 3 from 1991 to 1992. I am forbidden to provide any further information.”

It is commonplace in the security field that some people who have successfully committed crimes have been rewarded by a “golden handshake” (a special payment in return for leaving), sometimes even with positive references. The criminals can then move on to victimize a new employer. However, no one knows how often this takes place.

To work around such distortions, interviewers should question candidates closely about details of their education and work experience. The answers can then be checked for internal consistency and compared with the candidate's written submissions. Liars hate details: It is so much harder to remember which lie to repeat to which person than it is to tell the truth.

There are commercial services specializing in background checking (e.g., Achievement Tec). They provide the necessary forms to allow employers to query credit records and other background information. Companies such as Kroll and Securitas Security Services also conduct extensive background checks.

Another way to conduct an employee background check can be done for free or at modest cost via Internet search engines. By entering someone's name into one of these search engines, there is a good possibility that some aspect of the applicant's life will be retrieved. Of particular interest might be a search of messages from a particular blog to see what information is being disseminated.

Experienced employees should interview the candidate and compare notes in meetings to spot inconsistencies. A director of technical support at a large computer service bureau questioned a new employee who claimed to have worked on a particular platform for several years—but did not know how to log on. Had he chatted with any of the programmers on staff before being hired, his deception would have been discovered quickly enough. Ironically, had he told the truth, he might have been hired anyway.

45.2.2 Employment Agreements. Before allowing new employees to start work, they should sign an employment agreement stipulating that they will not disclose confidential information or trade secrets of their previous employers. Another clause must state that they understand that the new employer is explicitly *not* requesting access to information misappropriated from their previous employer, or from any other source. The Uniform Trade Secrets Act, which is enforced in many jurisdictions in the United States, provides penalties that are up to triple the demonstrated financial damages, plus attorney's fees, caused by such data leakage. One high-profile case involved three employees who were found guilty of stealing and trying to sell Coca-Cola secrets to its rival Pepsi.³

45.3 MANAGEMENT. Security is the result of corporate culture; therefore, management practices are critically important for successful information protection. External attacks through Internet connections and damage from malicious software are certainly important threats; nonetheless, insider damage due to errors and omissions as well as through dishonesty or a desire for revenge are still major problems for information security.⁴ These problems are compounded when there are collaborative threats involving insiders working with those outside the enterprise.

45.3.1 Identify Opportunities for Abuse. Security managers do not have to be paranoid, they just have to act as if they are paranoid. Managers must treat people with scrupulously fair attention to written policies and procedures. Selective or capricious enforcement of procedures may constitute harassment. If some individuals are permitted to be alone in the printer room as salary checks are printed, while other employees of equivalent rank must be accompanied, the latter can justifiably interpret the inconsistency as an implicit indication of distrust. Such treatment may move certain employees to initiate grievances and civil lawsuits, to lay complaints under criminal statutes for discrimination, or even to commit vengeful acts.

45 · 4 EMPLOYMENT PRACTICES AND POLICIES

45.3.2 Access Is Neither a Privilege Nor a Right. When management removes access rights to the network server room from a system analyst who has no reason to enter that area, the response may be resentment, sulking, and abuse. People sometimes treat access controls as status symbols; why else would a CEO who has no technical training demand that his access code include the tape library and the wiring closet? Managers can overcome these psychological barriers to better security by introducing a different way of looking at vulnerabilities and access. After identifying an opportunity for a particular employee to use the system in unauthorized ways, one should turn the discussion into a question of protecting the person who has unnecessary access against undue suspicion. For example, an employee having more access to secured files than is required is put at risk. If anything ever did go wrong with the secured files, that employee would be a suspect. There is no need to frame the problem in terms of suspicion and distrust.

With these principles in mind, managers should be alert to such dangers as permitting an employee to remain alone in a sensitive area, allowing unsupervised access to unencrypted backups, or having only one programmer who knows anything about the internals of the accounting package.

As for language, it would be better to stop referring to access *privileges*. The very word connotes superiority and status—the last things management should imply. Access is a function and a responsibility, not a privilege or a right; it should be referred to simply as *access functions* or *access authorizations*.

45.3.3 The Indispensable Employee. In many areas of information processing, redundancy is generally viewed as either a bad thing or an unavoidable but regrettable cost paid for specific advantages. For example, in a database, indexing may require identical fields (items, columns) to be placed in separate files (data sets, tables) for links (views, joins) to be established. However, in managing personnel for better security, redundancy is a requirement. Without shared knowledge, an organization is at constant risk of a breach of availability.

Redundancy in this context means having more than one person who can accomplish a given task. Another way of looking at it is that no knowledge should belong to only one person in an organization. Putting the keys to the kingdom in the hands of one employee invites disaster.

Unique resources always put systems at risk; that is why companies such as Tandem, Stratus, and others have so successfully provided redundant and fault-tolerant computer systems for critical task functions, such as stock exchanges and banking networks. These computer systems and networks have twin processors, channels, memory arrays, disk drives, and controllers. Similarly, a fault-tolerant organization will invest in cross-training of all its personnel. Every task should have at least one other person who knows how to do it—even if less well than the primary resource. This principle does not imply that managers have to create clones of all their employees; it is in fact preferable to have several people who can accomplish various parts of any one person's job. Spreading knowledge throughout the organization makes it possible to reduce the damage caused by absence or unavailability of key people.

It is dangerous to allow a single employee to be the only person who knows about a critical function in the enterprise. Operations will suffer if the key person is away, and the enterprise will certainly suffer if this unique resource person decides to behave in unauthorized and harmful ways. Managers should ask themselves if there is anyone in their department whose absence they dread. Are there any critical yet undocumented procedures for which everyone has to ask a particular person?

A client in a data center operations management class volunteered the following story. There was a programming wizard responsible for maintaining a key production program; unfortunately, he had poor communication skills and preferred to solve problems himself rather than to train and involve his colleagues. "It'll be faster for me to do it myself," he used to say. During one of his rare vacations, something went wrong with "his" production program, shutting down the company's operations. The wizard was in the north woods, out of reach of all communications; the disaster lasted until he returned.

Not only does the organization suffer, but also the indispensable persons suffer from the imbalance of knowledge and skill when no one else knows what they know. Some indispensable employees are dedicated to the welfare of their employer and of their colleagues. They may hesitate to take holidays. If their skills are needed from hour to hour, it becomes more difficult for them to participate in committee meetings. These are the people who wear beepers and cannot sit undisturbed even in a two-hour class. If the indispensable employees' skills affect day-to-day operations, they may find it hard to go to offsite training courses, conferences, and conventions. Despite their suitability for promotion, indispensable people may be delayed in their career change because the organization finds it difficult or expensive to train their replacements. In extreme cases, newly promoted managers may find themselves continuing to perform specialized duties that ought to be done by their staff. Sometimes even a VP of Operations is the only person who can make the changes to a production system that should be performed by a programmer three or four levels down.

A particular kind of indispensability occurs when an employee becomes the *de facto* technical support resource for a particular software package or system. Without authorization from their managers, these employees can find themselves in difficulty. They may be fired because their productivity drops too low according to their job descriptions, which do not include providing undocumented technical support to other people. They may burn out and quit because of overwork and criticism. Or they may cause resentment among their colleagues and neighbors by declining to help them, or by complaining about overwork. Alternatively, they may enjoy the situation, and manage to meet all the demands on their time quite successfully, until others in the information technology department begin to feel threatened, and someone either complains to the higher-ups or begins spreading nasty comments about these unauthorized support technicians.

Looking at this situation from a management point of view, there are problems for the recipients of all this free aid. The longer they persist in getting apparently free help from their unofficial benefactor, the longer they can avoid letting upper management know they need help. Then when the bubble bursts and the expert becomes unavailable, managers are confronted with a sudden demand for unplanned resources. In most organizations, unexpected staffing requirements are difficult to satisfy. Managers have a hard time explaining how it is that they were unable to predict the need and to budget for it.

Sometimes persons continue to be indispensable because of fear that their value to their employers resides in their private knowledge. Such employees resent training others. The best way to change their counterproductive attitude is to set a good example; managers should share knowledge with them and with everyone else in their group. Education should be a normal part of the way everyone in the enterprise works. Managers can encourage cross-training by allocating time for it. Cross-training can be a factor in employee evaluations. Current topics from the trade press and academic journals, for example, can be discussed in a journal club, or at informal, scheduled

45 · 6 EMPLOYMENT PRACTICES AND POLICIES

meetings, where people take turns presenting the findings from recent research in areas of interest.

Reluctance to explain their jobs to someone else may also mask unauthorized or illegal activity. Take, for example, the case of Lloyd Benjamin Lewis, assistant operations officer at Wells Fargo Bank in Beverly Hills, California. He arranged with a confederate outside the bank to cash fraudulent checks for up to \$250,000 each on selected legitimate accounts at Lewis's branch. Using a secret code stolen from another branch, Lewis would scrupulously encode a credit for the exact amount of the theft, thus giving the illusion of correcting a transaction error. Lewis stole \$21.3 million from his employer between September 1978 and January 1981, when he was caught by accident. For unknown reasons, a computer program flagged one of his fraudulent transactions so that another employee was notified of an irregularity. It did not take long to discover the fraud, and Lewis was convicted of embezzlement. He was sentenced to five years in a federal prison.⁵

Because Lewis was obliged to be physically present to trap the fraudulent checks as they came through the system, he could not afford to have anyone with him watching what he did. Lewis would have been less than enthusiastic about having to train a backup to do his job. If anyone had been cross-trained, the embezzlement would probably not have continued so long, or have become so serious.

45.3.4 Career Advancement. In a topic related to avoiding indispensability, managers can improve the security climate through accepted principles of good human resources management, such as career advancement for all employees. By promoting individuals to new responsibilities, managers can also increase the number of people with expertise in critical functions. As managers carry out their regular employee performance reviews, they should include discussions of each person's career goals. Here, based on a summary by employment expert Lee Kushner, are some practical questions to discuss with employees as part of their interviews.⁶⁷

1. What are your long-term plans?
2. What are your strengths and weaknesses?
3. What skills do you need to develop?
4. Have you acquired a new skill in the past year?
5. What are your most significant career accomplishments, and will you soon achieve another one?
6. Have you been promoted over the past three years?
7. What investments have you made in your own career?

When managers support individuals' interests and aspirations, they foster a climate of respect and appreciation and concurrently support positive feelings about the organization.

45.3.5 Vacation Time. In the example presented in Section 45.3.3, Lloyd Benjamin Lewis took his unauthorized duties (stealing money from his bank) so seriously that during the entire period of his embezzlement, about 850 days, he was never late, never absent, and never took a single vacation day in over two years. Any data center manager should have been quite alarmed at having an employee who had failed to be absent or late a single day in more than two years. The usual rule in companies is that

unused vacation days can be carried over for only a limited time, and then they expire. This is intended to be an incentive to take vacation time; for normal, honest employees, it probably works fine. For dishonest employees who have to be present to control a scam, losing vacation days is intolerable.

Every employee should be required to take scheduled vacations within a definite—and short—time limit. No exceptions should be permitted. Excessive resistance to taking vacations should be investigated to find out why the employee insists on being at work all the time.

Unfortunately, this suspicious attitude toward perfect attendance can cause problems for the devoted, dedicated, and honest employee. An innocent person can get caught up in a web of suspicion precisely because of exceptional commitment. One may be able to avoid difficulties of this kind by:

1. Making the reasons for the policy well known to all employees so no one feels singled out;
2. Relying on the judgment, discretion, and goodwill of the investigating manager to avoid hurt feelings in their most loyal employees; and
3. Switching such an employee's functions temporarily to see if anything breaks.

45.3.6 Responding to Changes in Behavior. Any kind of unusual behavior can pique the curiosity of a manager. Even more important from a security management standpoint, any consistent change in behavior should stimulate interest. Is a normally punctual person suddenly late, day after day? Did an employee start showing up regularly in hand-tailored suits? Why is a usually charming person snarling obscenities at subordinates these days? What accounts for someone's suddenly working overtime every day, in the absence of any known special project? Is a competent person now producing obvious errors in simple reports? How is it that a formerly complacent staffer is now a demanding and bitter complainer?

With so much of the enterprise's financial affairs controlled by information systems, it is not surprising that sudden wealth may be a clue that someone is committing a computer crime. A participant in an information systems security course reported that an accounting clerk at a government agency in Washington, DC, was arrested for massive embezzlement. The tip-off? He arrived at work one day in a Porsche sports car and boasted of the expensive real estate he was buying in a wealthy area of the capital region—all completely beyond any reasonable estimate of his income.

Not all thieves are that stupid. A healthy curiosity is perfectly justified if you see an employee sporting unusually expensive clothes, driving a sleek car after years with a rust bucket, and chatting pleasantly about the latest trip to Acapulco when that person's salary does not appear to explain such expenditures. Unsolicited inquiries into people's private lives, however, will usually win no friends. There is a delicate line to walk, but ignoring the issue does not make it disappear.

The other kind of change—toward the negative—also may indicate trouble. Why is the system manager looking both dejected and threadbare these days? Is he in the throes of a personal debt crisis? In the grip of a blackmailer? Beset with a family medical emergency? A compulsive gambler on a losing streak? On humane grounds alone, one would want to know what is up in order to help; however, a manager concerned with security would be compelled to investigate. In these days of explosive rage and ready access to weapons, ignoring employees with a dark cloud hovering over their heads may be irresponsible and dangerous.

45 · 8 EMPLOYMENT PRACTICES AND POLICIES

Any radical change in personality should elicit concern. If the normally relaxed head accountant now has beads of sweat on her forehead whenever you discuss the audit trails, perhaps it is time to look into her work more closely. Why does a good family man begin returning from long lunches with whiskey on his breath? A formerly grim manager now waltzes through the office with a perpetual smile on his face. What happened? Or what is happening?

All of these changes should alert managers to the possibility of changes in the lives of their employees. Although these changes do indeed affect the security of an organization, they also concern managers as human beings who can help other human beings. Mood swings, irritability, depression, euphoria—these can be signs of psychological stress. Is an employee becoming alcoholic? A drug addict? Abused at home? Going through financial difficulties? Having trouble with teenagers? Falling in love with a colleague? Of course managers cannot help everyone, and in some cases, help should involve qualified mental health professionals; but at least everyone can express concern and support in a sensitive and gentle way. Such discussions should take place in private, and without alarming the subject or exciting other employees. At any time, a manager should feel free to involve the HR or personnel department. They will either have a psychologist or trained counselor on staff or be able to provide appropriate help in some other way, such as an employee crisis line.

There are sad cases in which employees have shown signs of stress but have been ignored, with disastrous consequences: suicides, murders, theft, and sabotage. Be alert to the indicators and take action quickly.

Australian human resources expert Laura Stack offers this analysis of signs of extreme stress:

People don't normally all of a sudden flip out; they give off early warning signals. Luckily, managers can observe signs of stress in employee behaviour, beginning with milder signs and culminating in desk rage. Be observant for the following stress stages:

- Physical stage: Headaches, illness, fatigue.
- Social stage: Negativity, blaming things on others, missed deadlines, working through lunch.
- Cerebral stage: Clock-watching, errors in assignments, minor accidents, absentmindedness and indecisiveness.
- Emotional stage: Anger, sadness, crying, yelling, feelings of being overwhelmed, depression.
- Spiritual stage: Brooding, crying, wanting to make drastic changes in life, not relating well with people, distancing themselves from personal relationships.⁷

The manager's job in probing behavioral changes is difficult; one must walk the thin and possibly invisible line between laissez-faire uninvolvedness, risking lifelong regrets or even prosecution for dereliction of duty, and overt interference in the private affairs of the staff, risking embarrassment and possible prosecution for harassment.

Written policies will help; so will a strong and ongoing working relationship with the HR staff. Making it clear to all employees that managers are available for support, but are also expected to investigate unusual behavior, will also help avoid misunderstandings.

45.3.7 Separation of Duties. The same principles that apply to the control of money should apply to control of data. Tellers at a bank, when someone deposits a large check, will always go to a supervisor and have that person look the check over and

initial the transaction. When bank tellers empty the automatic teller machines at night and fill the cash hoppers, there are always two people present. In most organizations, the person who creates a check is not the person who signs it.

In well-run information systems departments, with good operations security, data entry is distinct from validation and verification.⁸ For example, a data entry supervisor can check on the accuracy of data entry but should not be allowed to enter a new transaction without having a direct supervisor check the work. There is no excuse for allowing the data entry supervisor to enter a transaction and then, effectively, to authorize it. What if the entry were in error—or fraudulent? Where would the control be?

In quality assurance for program development, the principles of separation of duty are well established. For example, the person who designs or codes a program must not be the only one to test the design or the code.⁹ Test systems are separate from production systems; programmers must not have access to confidential and critical data that are controlled by the production staff. Programmers must not enter the computer room if they have no authorized business there; operators must not modify production programs and batch jobs without authorization.¹⁰

Managers should consider giving up access to functions that have been delegated to two or more subordinates. Maintaining such access could cause more problems than it solves, but in an emergency, access and control could easily be restored. This attitude exemplifies the concept of separation of duties.

In early 1995, the financial world was rocked by the collapse of the Barings PLC investment banking firm. The Singapore office chief, Nicholas Leeson, was accused of having played the futures market with disastrous consequences.¹¹ The significant point is that he managed to carry out all the orders without independent overview. Had there been effective separation of duties, the collapse would not have occurred.

Another shocking example occurred when a system administrator at UBS PaineWebber, upset about the poor salary bonus he received, deployed malicious code on the company's network. But before quitting his job, he wrote a program that would delete files and wreak havoc on the company's network. By creating a logic bomb, he was able to impact over 1,000 servers and 17,000 individual workstations. Additionally, buying puts against UBS, he would profit from that attack.

A related approach is called dual control. As an example of dual control, consider the perennial problem of having secret passwords not known to managers who sometimes need emergency access to those passwords. This problem does not generally apply to ordinary users' passwords, which normally can be reset by a security administrator without having to know the old password. This temporary password should be changed to a truly secret string by the user, after a single logon. However, to guard against the absence of the only person who has the root password for a system, possibly because the others are on vacation, it is advisable to arrange for dual-access to backup copies of the password. The principle of dual control dictates that such a copy of the root password should be accessible only if two officers of the organization simultaneously sign for it when taking it out of the secure storage:

- One can store a written copy of the root password in a truly opaque envelope, seal it, sign the seal, tape over the seal with nonremovable tape, and then store the envelope in a corporate safe or strongbox
- The password can be encrypted twice using the public keys of two officers; the dual encryption requires the officers to decrypt the ciphertext in the reverse order of encryption (see Chapter 7 in this *Handbook*).

45 · 10 EMPLOYMENT PRACTICES AND POLICIES

In conclusion, managers should think about the structure of control over information as they design security policies, so that the safeguards afforded by separation of duties or dual control are present throughout all systems.

45.3.8 The Capability and Responsibility Matrices. One of the tools that can help evaluate and improve the resilience of organizations is the capabilities matrix.¹² One starts by listing (or brainstorming, perhaps using Computer-Aided Consensus™)¹³ all the critical functions that the organization requires and all the people in the team. The group then has to decide on a way of rating the capabilities of each person; the figure suggests one way to do it, but in no sense is this suggestion meant to constrain users. The group can come to a consensus on which of the team members can do which tasks at which level of competence and then examine the overall pattern of skills. Exhibit 45.1 shows such a matrix with made-up information.

Problems may be highlighted when no one has high-level capabilities or when too few people can effectively carry out those tasks. Another problem is that some people

EXHIBIT 45.1 Capabilities Matrix For Untelecom Corporation

may have so much knowledge compared with others that the organization is in danger were they to be absent; such cases should lead to training efforts to bring others up to an appropriate level of knowledge and skill. Individuals may also be noticeably lacking in skills; again, training may help solve such problems.

A similar matrix should be developed showing the responsibilities of every team member, with indicators of who has primary responsibility and the names of two or more members who can serve as backups (in prioritized order). It is important that every team member fill out their matrix by themselves, because conflicts may be discovered that way.¹⁴

The responsibility matrix can identify problems in the management structure. For example

- Some tasks may have no one assigned formally or have nobody assigned primary responsibility, leading to breakdowns in response, especially in emergencies.
- There may be tasks where two or more people believe that they are primary decision makers or leaders for a task, leading to conflicts.
- Some people may be identified with far too many assigned tasks; others may have too few.

45.3.9 No Unauthorized Security Probes. In general, all managers—not just security officers—should always be looking for vulnerabilities and opportunities for improving security. However, no one should ever *test* production systems for vulnerabilities without the full cooperation of the corporate information protection group, and only with authorization of the right executives. Written approval for explicit tests of security are informally known as *get-out-of-jail cards*, because without them, employees can go to jail for unauthorized probes of system security.

The case of Randal Schwartz, a consultant to Intel Corporation in Beaverton, Oregon, is a salutary example for employees of the dangers of unauthorized security probes. He was convicted of hacking his way into Intel Corporation computer networks in what he claimed was an effort to point out security flaws while he was working there as a consultant. The would-be security expert failed to notify his employers of his intentions and forgot to get authorization for stealing passwords and making unauthorized changes in system software. He was convicted of three felony counts in July 1995 and was fined \$68,000 in restitution as well as being put under five years of probation and having to perform 480 hours of community service.¹⁵

A counterexample to warn managers of misplaced zeal in suppressing cooperation with law enforcement is the case of Shawn Carpenter, a network intrusion detection security analyst at Sandia National Laboratories. He was fired by publicity-shy administrators when he worked with law enforcement officials to track down extensive penetrations of U.S. national security assets. An investigation code-named TITAN RAIN began in late 2003.¹⁶ Carpenter noted a flood of expert hacker activity focusing on data theft from a wide range of national security interests. Carpenter discovered that “the attacks emanated from just three Chinese routers that acted as the first connection point from a local network to the Internet.”¹⁷ Carpenter worked with U.S. Army Counterintelligence and FBI investigators to learn more about the attacks and the attackers. Carpenter never used Sandia’s or government-owned equipment or network resources in his investigations. Administrators applied Sandia Internal Directive 12 ISNL ID012, which “specifically prohibits employees from speaking with local,

45 · 12 EMPLOYMENT PRACTICES AND POLICIES

state, or Federally elected officials.” In 2007, Carpenter was awarded \$4.3 million for wrongful termination.¹⁸

In February 2012, police and courthouse managers in Vienna, Austria, staged a theatrically convincing terrorist attack as a training exercise. The staging included “one simulated death, apparently by a gunshot to the head. Makeup was used to simulate injuries, and several officers were placed in the building as if they were injured persons. The supposed death was staged in front of courthouse staff who were evacuating offices.” Because none of the ordinary staff members was informed (and nothing was announced to the public), “By the next day 40 staff members were in treatment for severe trauma and an undisclosed number had taken sick leave. We must assume that some will suffer from post-traumatic stress disorder (PTSD) in the weeks and months to come.”¹⁹ See Chapter 46 in this *Handbook* for more discussion of how to prepare for tests of this sort.

45.4 TERMINATION OF EMPLOYMENT. Taking our security mandate in the widest sense, we have to protect our employer and ourselves against potential damage from unethical, disgruntled, or incompetent employees, and against the legal consequences of improper firing procedures. Common sense and common decency argue for humane and sensitive treatment of people being fired and those who are resigning. Firing people is a stressful time for everyone concerned, and it usually leads to increased security risks.²⁰ Managers should do everything in their power to ensure a courteous, respectful, and supportive experience when terminating employment.

45.4.1 Resignations. Potentially the most dangerous form of employment termination is a resignation. The problem is summed up in the caption of a cartoon where a savage attack is in progress against a medieval town that is in flames; a clan war chieftain confronts a singed and dirty warrior. “No, no, Thor! Pillage, THEN burn!” Like the war chieftain, employees rarely resign without planning. An employee may have an indefinite period during which the action is imminent, while the employer may remain unaware of the situation. If the employee has bad feelings toward, or evil designs on, the current employer, there is a period of vulnerability frequently unknown to management. Dishonest or unbalanced employees could steal information or equipment, cause immediate or delayed damage using programmatic techniques, or introduce faulty data into the system.

The policies discussed in previous sections of this chapter should reduce the risks associated with resignations. The manager’s goal should be to make resignations rare and reasonable. By staying in touch with employees’ feelings, moods, and morale, managers can identify sources of strain and perhaps resolve problems before they lead to resignations and their associated security risks.

45.4.2 Firings. Firings appear to give the advantage to employers, but there may be complications.

45.4.2.1 Timing. One advantage is that the time of notification to a fired employee can be controlled to minimize effects on the organization and its business. For example, employers might find it best to fire an incompetent, or no longer acceptable, employee before beginning an important new project or after a particular project has finished.

Some people argue that to reduce the psychological impact on other employees, they should fire people at the end of the day, perhaps even before a long weekend.

The theory is that the practice gives everyone a cooling-off period outside working hours. These managers say they do not want the buzz of conversation and speculation that often follow a firing to intrude on the workday. This policy fails to regard the psychological stress to employees who have a ruined weekend and no way of responding constructively to their potentially catastrophic loss of a regular income.

A better approach to this stressful task is to fire people early on Monday morning in order to provide an unrushed exit interview and, if appropriate, job counseling to help the employee prepare for job hunting. In this scenario, the regrettable necessity (from the manager's point of view) of terminating employment is buffered by professionals in the HR department, who can give the departing employee a sense of hope and some practical as well as emotional support in this difficult time. A humane attitude is particularly important during downsizing, or when plants are closed, and many people are being fired—one of the worst experiences possible for both employees and managers, and an event that has serious security implications.

In one large company, the personnel department asked their information security staff to suspend the access codes for more than 100 people who were to be fired at 6:00 PM on Tuesday. On Wednesday at 8:00 AM, the security staff began receiving phone calls asking why the callers' logon IDs no longer worked. It turned out that the personnel staff had failed to inform the terminated employees on time. The psychological trauma to both the employees who were fired and to the security staff was severe. Several security staff members were sent home in tears to recuperate from their unfortunate experience. The harm done to the fired employees was even more serious, and the effect on morale of the remaining employees was a disaster. There could well have been violence in that situation.

45.4.2.2 Procedures upon Termination. In both resignations and firings, security consultants unanimously advise instant action. Not for them the leisurely grace period during which employees wind down their projects, or hand them off to other staff members. Security officers are a hard lot, and they usually advise this scenario: In a formal exit interview, and in the presence of at least two managers, an officer of the employer informs the employee politely that his or her employment is at an end. During the exit interview, the officer explains the reasons for termination of employment. The officer gives the employee a check for the period of notification required by law or by contract, plus any severance pay due. Under supervision, preferably in the presence of at least one security guard, the employee is escorted to the accustomed work area and invited to remove all personal belongings and place them in a container provided by the employer. The employee returns all company badges, IDs, business cards, credit cards, and keys, and is then ushered politely outside the building.

At the same time all this is happening, all security arrangements must be changed to exclude the ex-employee from access to the building and to all information systems. Such restrictions can include:

- Striking the person's name from all security post lists of authorized access
- Explicitly informing guards that the ex-employee may not be allowed into the building, whether unaccompanied or accompanied by an employee, without special authorization by named authorities
- Changing the combinations, reprogramming access card systems, and replacing physical keys if necessary for all secure areas to which the individual used to have authorized access

45 · 14 EMPLOYMENT PRACTICES AND POLICIES

- Removing or changing all personal access codes known to have been used by the ex-employee on all secured computer systems, including microcomputers, networks, and mainframes
- Informing all outside agencies (e.g., tape storage facilities and outsourced functions) that the ex-employee is no longer authorized to access any of the employer's information or to initiate security or disaster recovery procedures
- Requesting cooperation from outside agencies in informing the employer if ex-employees attempt to exercise unauthorized functions on behalf of their former employer

The task is made more difficult by seniority, or if the ex-employee played an important role in disaster recovery or security. The employer should be assiduous in searching out all possible avenues of entry resulting from the person's position of responsibility and familiarity with security procedures.

In one story circulating in the security literature, an employee was fired without the safeguards just suggested. He returned to the workplace the next Saturday with his station wagon and greeted the security guard with the usual friendliness and confidence. The guard, who had known him for years, was unaware that the man had been fired. The ex-employee still had access codes and copies of keys to secure areas. He entered the unattended computer room, destroyed all the files on the system, and then opened the tape vault. He engaged the guard's help in loading all the company's backup tapes into his station wagon. The thief even complained about how he had to work on weekends. This criminal then tried to extort money from the company by threatening to destroy the backup tapes, but he was found by police and arrested in time to prevent a disaster for his ex-employer.

This story emphasizes the importance of reaching *everyone* who needs to know that an employee no longer works for the enterprise.

45.4.2.3 Support in Involuntary Terminations. Security does sometimes prevent a farewell party, one obvious sign of friendliness. The problem with a farewell party at work is that employees leaving under a cloud may feel humiliated when other people get a party but they do not. Generally, it makes sense to treat all departing employees the same, even if the termination is involuntary.

However, nothing stops a humane and sensitive employer from encouraging employees to arrange an after-hours party even for people who have been fired. If a *resignation* is on good terms, however, the employer may even arrange a celebration, possibly during working hours and perhaps at company cost, without having to worry about possible negative repercussions.

A firing, or a resignation on poor terms, has two psychological dangers: effects on the individual concerned of embarrassment, shame, and anger, and effects on the remaining staff of rumors, resentment, and fear. Both kinds of problems can be minimized by publishing termination procedures in organization documents provided to all employees; by requiring all employees to sign a statement confirming that they have read and agreed to the termination procedures; and by consistent application of the termination procedures.

The personal shock of being fired can be reduced by politeness and consideration consistent with the nature of the reasons for being fired, although even nasty people should not be subject to verbal or physical abuse, no matter how bad their behavior. Their treatment should be consistent with that meted out to other fired employees, and there should be generous severance arrangements, if possible.

Organizational turmoil can be reduced by convening organization-wide or departmental meetings to brief remaining employees on the details of a significant termination. Open discussions, including how people feel about the rupture of relationships, can be helpful. The remaining employees may have to suffer grief, as a process, not a state. Grief is a normal and healthy response to disruption of relationships (e.g., death of a loved one, divorce, and even the loss of a coworker). Some people value social relationships more than other aspects of their work, and they may be especially affected by firings. Grief involves stages of denial, anger, mourning, and recovery. Trying to forestall such responses by denying that people legitimately have feelings is foolish and counterproductive. It is far better to encourage those who are upset to voice their feelings, and to engage in constructive discussion, than to clamp down in a futile attempt to suppress discussion.

45.4.2.4 Style of Termination. The way an organization handles job termination affects more than internal relations; it also influences its image in the outside world. Prospective employees will think twice about accepting job offers from an organization that mistreats departing employees. Clients may form a negative impression of a company's stability if it abuses its own people. Investors also may look askance at a firm that gets a reputation for shoddy treatment of employees. Bad relations among managers and employees are a warning sign of long-term difficulties.

45.4.2.5 Legal Issues. There is another dimension to employment termination that depends on local laws and the litigation environment. The United States, for example, is said to be one of the most litigious nations on the planet, perhaps because of the high number of lawyers compared with the total population.

The list that follows is not legal advice; for legal advice, consult an attorney. However, simple experience does teach some principles, even without going to law school. Here are some pragmatic guidelines for preventing legal problems related to firings for cause:

- Build a solid, documented case for firing someone before acting.
- Keep good records, be objective, and get the opinions of several trustworthy people on record.
- Offer the delinquent employee all reasonable chances to correct his or her behavior.
- Give the employee clear feedback long before considering firing.

Timing is important in employee relations, as it is in almost everything else we do. In particular, if an employee is found to be behaving improperly or illegally, there must be no marked delay in dealing with the problem. Such persons could sue the employer and individual managers. They could argue in court that the very fact that there was a delay in firing them was proof that the firing was due to other factors such as personality conflicts, racism, or sexism. A well-defined procedure for progressing through the decision will minimize such problems.

The critical legal issue is consistency. If rules such as those just described for the day of the firing are applied haphazardly, there could easily be grounds for complaining of unfairness. Those to whom the rules were strictly applied would justifiably feel implicitly criticized. How would we feel if we were singled out by having guards check what we took home from our desk—if everyone else got a party and two weeks' notice? Such inconsistency would be grounds for legal proceedings for defamation of character. The company might lose and it might win, but what nonlawyer wants to spend time in court?

45 · 16 EMPLOYMENT PRACTICES AND POLICIES

Another issue that arises in connection with firings and resignations involves nondisclosure agreements. All such agreements must be included in a contract signed before the prospective employee begins work; it is almost impossible to force an existing employee to sign such an agreement.

Managers, the legal department, and the personnel department should study the necessity and feasibility of instituting a legally binding contractual obligation to protect their company's confidential information for a specified period of time after leaving. One typically does not impose indefinite gags on people, as one year seems to be normal. (However, there are exceptions. Oprah Winfrey insists that all employees who work at Harpo sign a lifelong confidentiality agreement, which an Illinois appeals court upheld when a former employee tried to write a book about the media mogul.) For this measure to be meaningful, the initial employment contract should stipulate that departing employees must reveal their new employer, if there is one at that time.

Noncompetition agreements require the employee to refrain from working for direct competitors for perhaps a year after termination of employment. The key to a successful clause here is that there be a strict, operational definition of "direct competitors." Because this limitation can be an onerous impediment to earning a living, many jurisdictions forbid such clauses.

45.5 SUMMARY. Some of the key recommendations from this chapter follow:

Hiring

- Investigate the accuracy of every likely job candidate's résumé.
- Perform background investigations when hiring for sensitive positions.
- Arrange for experienced staff members to interview candidates and discuss inconsistencies.
- Require signing of a legally appropriate employment contract.

Ongoing Management

- Identify and resolve opportunities for abuse.
- Assign access functions on the basis of need, not social status.
- Identify indispensable employees, and arrange for cross-training of other staff.
- Require employees to take their vacations, or to rotate their job functions periodically, so as to assure operational continuity and as a possible indication of fraud.
- Note and respond to sudden changes in behavior and mood; involve human resources as appropriate.
- Enforce separation of duties and dual control for sensitive functions.
- Do not engage in, or tolerate, unauthorized probes of system security.

Termination of Employment

- Provide an opportunity for fired employees to receive counseling and support.
- Ensure that the HR department collaborates with the information technology group to take all appropriate security measures when anyone leaves the employment of the enterprise.

- Ensure that firings do not cause long-term morale problems.
- Follow the guidance of corporate counsel to avoid wrongful dismissal suits.
- Use legally appropriate nondisclosure and noncompetition clauses in employment contracts.

In summary, information security depends on coordination with HR personnel to ensure consistent policies for hiring, ongoing management, and termination of employment.

46.1 THE SCOREKEEPER OF SECURITY MANAGEMENT. Information security has, over time, evolved from a collection of esoteric security issues and technical remedies to its current state, in which it is more tightly integrated with the area of enterprise risk management. One hallmark of this evolution from technology to management discipline is the emphasis placed on the deployment and use of vulnerability management practices. Vulnerability management has three complementary functional components, *vulnerability assessment* (VA), *penetration testing*, and *remediation*. Vulnerability management is considered fundamental to modern information security practice, and its components have adapted in architecture, features, and interfaces to accommodate the changing landscape of modern enterprises.

46.1.1 What Is Vulnerability Management? Vulnerability management is the process of assessing deployed IT systems in order to determine the security state of those systems. It includes the automated scanning of system attributes (vulnerability assessment), the manual testing and exploitation of systems in search of illicit

46 · 2 VULNERABILITY ASSESSMENT

authorization or access (penetration testing), and the determination of corrective measures to mitigate issues identified that represent exposures for the enterprise, as well as managing the application of those measures (remediation). Vulnerability assessment is considered by many the key technology component of vulnerability management. However, there is a synergy between VA and the other elements of vulnerability management such that these elements drive what features are supported by VA technology (i.e., vulnerabilities that arise in the course of penetration testing may be reflected in future versions of VA scanners). Although early vulnerability management systems focused on vulnerabilities in operating systems and network configuration of IT enterprise systems, over time, the scope of VM coverage has grown to include applications as well.

The vulnerability management process is often defined in terms of four key functions. They are as follows:

- **Inventory.** Before an examiner can determine the extent of testing, she must identify all systems that are resident within the domain of interest. At this time, the operating system platforms and functions associated with each system are articulated and documented; furthermore any unauthorized or unmanaged systems are identified.
- **Focus.** Once an examiner has an idea of the systems that reside within the network, he must determine what information he (or his assessment tools) needs to see in order to find those vulnerabilities that are relevant to him and the enterprise. Some include the tuning of VA tools as a part of this step. When VA is driven by compliance requirements, such information is often specified in the regulations or policies in question.
- **Assess.** The examiner performs any testing (both automated and manual) necessary to identify vulnerabilities resident on the systems. She then assesses the results of these tests. Finally, she evaluates (and ranks) the actual risk to her organization's systems security, making that judgment guided by security policy and current risk management criteria.
- **Respond.** Finally, the examiner must execute procedures that act on the results of the assessment in order to address the problems identified. As much of current vulnerability management is performed as part of regulatory compliance, formal reporting of the results of VA, including remediation status, is an important part of this step.

Now that we've laid the cornerstones of the vulnerability management process, let's proceed to the technology particulars of VA.

46.1.2 What Is Vulnerability Assessment? VA is the analysis of the security state of a system on the basis of system information collected on demand. The four-step strategy for VA is as follows:

1. A predetermined set of target system attributes (for example, specific parameters for particular firewalls), are sampled.
2. The sampled information is placed in a data store.
3. The data store is organized and compared to a reference set of attributes.
4. The differences between the data store and the reference set are documented and reported.

46.1.3 Where Does Vulnerability Assessment Fit in Security Management? Vulnerability assessment and its parent function, vulnerability management are key elements of virtually all modern system security management strategies. There are many reasons for the popularity and acceptance of these functions, including:

- When systems are first deployed, VA allows you to baseline the security state of those systems.
- When security breaches are suspected, VA may allow you to quickly identify likely paths of attack and furthermore, determine whether they have been exercised.
- When new vulnerabilities are reported, VA can allow you to identify systems that are subject to the vulnerabilities so that you can patch or otherwise address the exposures.
- The results of individual VAs can be archived and used to document the security state of systems at a specific time. This is often used to satisfy regulatory audit or other oversight requirements.

Although VA and vulnerability management are accepted as important system security functions, they are not sufficient to protect systems from all security threats. Such measures should be included in a more comprehensive security strategy that includes security policy and procedural controls (see Chapters 44, 47, 50, 51, 52, and 53 in this *Handbook*), network firewalls and other perimeter defenses (Chapters 26 and 27), strong identification and authentication mechanisms (Chapters 28 and 29), access control mechanisms (Chapter 32), file and link encryption (Chapters 7, 32, and 33), file integrity checking (Chapters 7, 24, and 37), physical security measures (Chapters 22 and 23), and security training and education (Chapters 43, 45, 48, and 49). There are references and insight into building the rest of a comprehensive security strategy throughout this *Handbook*.

46.1.4 Brief History of Vulnerability Assessment. Early vulnerability assessment systems (VASSs) include the COPS system, developed in the late 1980s by Eugene H. Spafford and Daniel Farmer at Purdue University.¹ COPS was a UNIX-targeted credentialed VA product that gained wide acceptance in security circles. The initial freeware version of the Internet Security Scanner (ISS) was also released in the early 1990s, as was Farmer's and Wietse Venema's VA software, SATAN.²

Subsequent trends of note include the advent of open-source tools for performing various forms of VA (e.g., NESSUS,³ which provides vulnerability scanning capabilities, and NMAP,⁴ which provides an inventory of the systems on a specific network, along with the network services resident on those systems).

Also of note is the move of VA from individual systems to the network infrastructure (i.e., dedicated network-connected appliances) and to the cloud (i.e., the VA is actually performed over the network, controlled by the security administrator over a Web interface, with results stored offsite).

Finally, as endpoints have become more mobile and application-centric than classic workstations, VA coverage has grown to cover software applications. The solution provider market for VA has adapted to these trends, and modern VA practice usually involves a mix of application software, dedicated appliances, managed services, and expert professional services (especially in areas such as penetration testing.)

46 · 4 VULNERABILITY ASSESSMENT

46.2 A TAXONOMY OF VULNERABILITY ASSESSMENT TECHNOLOGIES. VA products snapshot the security state of systems, diagnosing problems that indicate that the system is vulnerable to specific attacks.

VA performs an examination of key indicators within systems that are known to correspond to security vulnerabilities. Some consider some types of VAs a special case of a host-based, interval-based intrusion detection process and describe it in terms of the intrusion detection process model outlined in Chapter 27 in this *Handbook*.

46.2.1 Vulnerability Assessment Strategy and Techniques. As noted above, there is a four-stage high-level strategy for conducting VA: Sample, Store, Compare, and Report. This four-stage process becomes quite complex when fleshed out to cover the full range of vulnerabilities that are commonly exploited by modern adversaries. A standard VA process may involve the use of any or all of the following techniques:

- **Network Scanning.** Maps network nodes and associated services by use of a “port scanner.” This articulates issues at a network and network services layer of abstraction.
- **Vulnerability Scanning.** Takes the port scanning functions of network scanners to the next level by testing for operating system and application software system vulnerabilities resident on hosts connected to the network.
- **Password Cracking.** Identifies weak passwords.
- **Log Review.** A feature rooted in the earliest production computing platforms, log review remains one of the most powerful means of identifying weaknesses in systems.
- **Integrity Checking.** Uses checksums, hash totals, and digital signatures to allow quick and reliable detection of tampered files and system objects.
- **Virus Detection.** Scans for known viruses infecting systems.
- **War Dialing.** Scans enterprise systems for unauthorized modems.
- **War Driving.** Scans enterprise systems for unauthorized wireless LAN connections.
- **Penetration Testing.** Reenacts attackers’ behavior in order to gain access and thereby test technical and procedural security measures.⁵

As many of these techniques are complex enough to merit a full chapter of their own (and are covered in specific chapters in this *Handbook*), we focus on only three of them in this chapter: network scanning, vulnerability scanning, and penetration testing.

46.2.2 Network Scanning. Network scanners run a function called a *port scanner*, which uses a feature of ICMP, part of TCP/IP, in order to identify hosts available in a specified network address range. The port scanner then scans identified systems for open network ports and associated services.

Some network scanners use inference and other techniques to make intelligent guesses about the operating systems being run on open systems. These inferences are based on the combinations of active ports observed on a specific host (e.g., if Port 80 is open on a given host, it is likely running a Web server). Some scanners listen to ports for traffic that provides additional information about the system connected to that port.

One example of this type of surveillance is called *banner grabbing*, and can provide a great deal of detail about the connected system. The scanner collects information that is routinely sent to any process on connection; this *banner* often includes details of the name and version of the application.⁶

As a primary security policy decision involves specifying what systems are allowed on an enterprise network, network scanners provide a vital piece of information for VA. They also provide collateral information regarding the connected systems on a network, which is critical for tuning and refining the VA process. It is important, however, to understand that although the operation of a network scanner is automated, the identification of vulnerabilities discovered by network scanning is not. There is minimal, if any, decision support in network scanning products—some will identify certain port numbers as associated with a known Trojan attack. Therefore, it is important that the results from a network scanner be evaluated by someone familiar with the assessed network and associated security policy.

Increasingly, VA products include passive network scanning in addition to active network scanning. This involves placing passive network monitors to sniff traffic between target systems, inferring vulnerabilities from the traffic patterns observed between the target systems. This is useful in certain enterprise situations when protective mechanisms interfere with more classic active scanning (e.g., personal firewall agents on endpoints) but provides insights versus actionable results.

46.2.3 Vulnerability Scanning. Vulnerability scanning is the heart of traditional VA systems. In some ways vulnerability scanning appears to be the same as port scanning, but it differs in a critical way—it takes the additional step of not only collecting data regarding traffic, connections, and system attributes, but also analyzes the data to determine whether it matches a known vulnerability. Many systems (credentialled; see below) also attempt to correct the vulnerabilities identified in the scan, either automatically or overseen by human operators.

As vulnerability scanning usually targets specific hosts, it often conducts a deeper inspection than network scanners, identifying software versions, specific software applications, and configuration attributes of systems. The policy checks available to host-based vulnerability scanners can include usage patterns for software.

Perhaps the most valuable feature of vulnerability scanners is the current database of known vulnerabilities. Virtually all commercial offerings in this area include updates to these vulnerability databases as a core feature of the product. Many products offer features that assist security managers in configuring scanners to fit their environments, including a wide variety of configuration, reporting, and support features.

Vulnerability scanners can perform extremely fine-grained security assessment, in far more detail than network port scanners. However, this degree of detail comes at a price. Vulnerability scanners are typically slower and more resource greedy than network port scanners. The range of available assessment techniques is usually richer for vulnerability scanners; some (e.g., DDoS testing) can disrupt the normal operation of an enterprise network. False-positive rates (i.e., vulnerabilities spotted where none exist), can be high for many vulnerability scanners, requiring more human intervention. Finally as the value of the vulnerability scanner resides in its vulnerability database, it is critical that the database be updated frequently. A vulnerability scanner with a noncurrent database leaves users open to compromise.

46.2.4 Assessment Strategies. As in intrusion detection systems, VASs have features that allow differentiation between individual systems. The primary descriptors

46 · 6 VULNERABILITY ASSESSMENT

for VASs involve the information sources and how those information sources are generated.

46.2.4.1 Credentialed Monitoring. Credentialed monitoring approaches for VAs are those that utilize system data sources such as file contents, installed applications, configuration information, and status information. This information is gained from nonintrusive sources; that is, it is gained by performing standard system status queries and inspection of system attributes. These sources are accessible only when the entity gathering them has legitimate access to the system (i.e., the entity possesses access credentials). In UNIX systems, this information is gathered at the host or device level; therefore, *credentialed approaches* are also *host-based* approaches. As many modern operating systems (e.g., Windows) handle status information differently, often providing it in the form of Application Programming Interfaces (APIs), the *credentialed* = *host-based* equivalence does not always apply in those environments.

46.2.4.2 Noncredentialed Monitors. Noncredentialed monitoring approaches are those approaches that stage system attacks and record target system responses to the attacks. These approaches are much more intrusive than credentialed attacks and do not assume (nor do they require) any legitimate access to the target system; they are launched from an attacker's perspective. Noncredentialed approaches are often called *active* approaches and have detection and monitoring features that complement those of credentialed approaches. In particular, noncredentialed approaches are usually superior for diagnosing vulnerabilities associated with network services. As noted, in UNIX systems, noncredentialed assessments are usually considered *network-based* assessments. For instance, network scanning is a noncredentialed monitoring process. It bears repeating that here, as in credentialed approached, the equivalence relationship does not necessarily apply in Windows and other modern operating system environments that provide status information in API form.⁷

46.2.5 Strengths and Weaknesses of VASs. Knowing that security point products (e.g., firewalls, NIDS, and access-control systems) that defend particular features of a security perimeter cannot be perfect in the dynamic world of network and system attack, VASs serve an important function in the overall strategy for protecting information assets.

The benefits associated with vulnerability analysis are as follows:

- VASs conserve time and resources, as they allow even nonexpert personnel to check systems automatically for literally thousands of problems, any one of each might result in an intrusion.
- VASs can be extremely helpful in training security novices to make systems more secure.
- VASs can be updated to reflect new knowledge of vulnerabilities found by vendors and researchers.
- VASs can be configured to address specific vulnerabilities and configurations affected by regulatory requirements. They are a critical component in IT security regulatory compliance.

As VASs are used in more environments as a part of a risk-management regime, they are helpful for benchmarking the security state of systems in order to document progress toward a protection goal.

As security problems have become an item of broad interest to customer and regulatory communities, the capabilities of VASs may be a fundamental requirement for operating in certain IT markets. This inclusion of VA as a requirement for doing business is likely to not only remain stable over time, but grow at an appreciable rate.

VASs are systematic and therefore consistent. These attributes allow them to be used as quality assurance measures for network or security managers. Many security professionals routinely recommend that operational security policies include provisions for using VASs to check systems for problems after major changes have occurred (as might be the case whenever software is updated or system recovery is required).

Weaknesses in VA include the following:

- Although VA is necessary for system security, it is not in and of itself sufficient to secure a system.
- Many VASs serve only to diagnose problems, not to correct them. They are part of a more comprehensive vulnerability management process. User follow-through is still required.
- If the VASs are not kept up to date, they may mislead users into underestimating the risk of penetration.
- VAS can negatively impact the performance of an operational network. It is critical to balance demand for the network with the performance hits associated with running some types of VAS.

As in many other knowledge-based security tools, VA can be used for either productive or malicious purposes. In the hands of a security manager, VA is a valuable diagnostic technique. In the hands of an attacker, VA may optimize efforts to identify targets of attack and provide insight as to exactly how those targets might be compromised.

46.2.6 Roles for Vulnerability Assessment in System Security Management. VA products can be used at several points in the system security management life cycle.

First, when a new program is put into place, a VA can baseline the security state of the system. This application is particularly valuable in establishing the case for a security program, as it provides hard evidence that security problems exist.

Next, when an operational system changes (as might be the case when software updates are installed or new equipment is connected), a VA can help. It can find specific security vulnerabilities that occur as side effects of such changes.

Finally, when security incidents occur or are suspected, VA results can assist investigators in diagnosing possible paths of entry for attackers, locating artifacts of attacks (such as back doors or Trojan horses), and identifying the system resources affected by an attack so that they may be restored to their original states.

46.3 PENETRATION TESTING. A penetration assessment is used to augment the vulnerability management program's reoccurring and baseline VA by iteratively exploiting known and unknown vulnerabilities with the intent of demonstrating business impact and risk across technical, physical, and personnel environments. The goal of a VA and underlying automated vulnerability scanning activities is to identify and prioritize *known* technical vulnerabilities. A penetration assessment will test the effectiveness of the VA through the objective identification of vulnerabilities in the environment and the ensuing exploitation of them. The exploitation of known vulnerabilities

46 · 8 VULNERABILITY ASSESSMENT

demonstrates the real-life impact and business risk associated with the VA's ability to effectively identify known vulnerabilities and remediate them in the environment. The exploitation of *unknown* vulnerabilities or "stacked" known vulnerabilities will assess the organization's ability to respond to an incident or mitigate the impact caused by unforeseen vulnerabilities. Exploitation is performed in a manner that closely simulates actions that a real-life attacker is capable of performing outside and within the targeted environment.

Penetration assessments are performed by professional, ethical hackers using automated and manual techniques in conventional and unconventional ways. A penetration assessment should be leveraged to augment a VA and not as a replacement for the vulnerability scanning component. Assessments are performed by a *team* of qualified practitioners, ensuring well-rounded subject matter expertise in diverse areas.

Human penetration ("pen") testers have several advantages over purely automated methods:

- Automated VA tools, such as vulnerability scanners, are incapable of leveraging a vulnerability, component, or specification through a sequence of iterative and adaptive actions which may produce a high-impact outcome.
- A VA is only capable of testing and assessing the organization's susceptibility to known vulnerabilities; a penetration test is inclusive of unknown vulnerabilities and the exploitation of both.
- Pen testers possess an out-of-the-box mentality combined with a continuous strive to adapt circumvention efforts and pivot around preventative controls.
- Penetration tester activities are very difficult to mirror through automated means primarily due to human intuition.
- A pen tester thinks very differently than a traditional system or network administrator, making a large effort to solve problems in an *untraditional* way using *traditional* tools or methods.

46.3.1 Testing Goals

46.3.1.1 Demonstration of Impact and Risk. As penetration testers, our hearts thrive on the ability to compromise a target and received the coveted command level access. Although this may appear successful in the short term, the ultimate goal of a penetration test is to determine, demonstrate, and explain the risk as it applies to the organization, with accompanying steps to mitigate it or adequately manage it in the future.

Management should discuss with the penetration team what the assessment's end goal should be. *Goal-oriented* penetration testing aims to maximize value by demonstrating impact and risk appropriately for the organization's unique business. Goals include things that are important to the organization outside of security controls, such as the theft of intellectual property, theft of client base information, or a reduction in availability for core business processes thereby affecting an organization's bottom line.

46.3.1.2 Attestation and Compliance. The result of the penetration assessment can be provided to management, business partners, or regulators as an attestation to organizations point-in-time level of susceptibility to impact as a result of the current effectiveness of the vulnerability management program and underlying assessment capabilities.

A penetration assessment is a point-in-time assessment. Due to the fluid nature of information security advancement, a penetration testing team can never provide any level of assurance relating to the audit of vulnerabilities currently present in the environment. The primary goal of a penetration assessment is to demonstrate business impact and risk to management and business partners for the threats they face at a specific point in time.

46.3.2 Testing Perspectives. Penetration assessments provide a vehicle for evaluating the security of technical, physical, personnel, and procedural controls at a holistic level through the objective perspective of a third party mimicking the actions of an external attacker or malicious internal user. A VA is typically managed by an internal office and is therefore subject to bias during the assessment phase and compounded by resistance to the advancement in skillsets required to align with an advancing security field.

A malicious user and external attacker are different perspectives and approaches to the assessment which result in different perceived levels of impact and risk. It is important to understand the difference in order to properly develop the scope of the assessment to cover VA and management's objective for the assessment.

External Attacker

- An external attacker mimics the capabilities of an outsider with no internal knowledge of the target environment.
- The capabilities of an external attacker are greatly limited to publicly available resources.
- This type of test typically involves attacks against perimeter network devices and applications, which may result in internal connectivity.

Malicious User

- A malicious user mimics the capabilities of an authenticated or authorized user who possesses knowledge of internal operations.
- The capabilities of a malicious user are only afforded to trusted employees or contractors inside the network perimeter or within an application's authenticated or authorized zone.
- This type of test typically poses a greater risk of impact than an external attack, primarily due to the intricate knowledge pertaining to the location of and adequacy of preventive controls around sensitive data.

46.3.3 Testing Types. Penetration testing can be utilized to expand the scope of a technical VA to include the physical, personnel, and procedural controls that may be targeted by an adversary in an attack. Additionally, penetration tests can be used to increase focus on a particularly weak technical area within the over-arching assessment.

External Assessment: Penetration efforts originate from the Internet and target Internet-facing devices with the primary goal of gaining internal access to systems and acquiring business trophies such as client information or intellectual property.

46 · 10 VULNERABILITY ASSESSMENT

Application Assessment: Application level assessments are increasingly common as organizations continue to remove Internet-accessible external services and heavily leverage Web services. Application assessments involve user-based attacks such as manipulating user input or client-controlled parameters. Goals include accessing administrative panels, extracting sensitive database information, masquerading as authorized users, or compromising the underlying Web or backend database server.

Internal Assessment: Internal penetration assessments target vulnerabilities within the organization. This assessment assumes the role of an attacker or malicious users who has been provided access to a network port within the facility. Goals of this assessment mirror those of an external or application assessment with the inclusion of a reduced level of accessibility controls.

Wireless Assessment: Wireless penetration assessments involve internally and externally surveying the organization's physical facilities for authorized and unauthorized wireless communications (e.g., 802.11) and attempting to circumvent or exploit controls to gain access. The primary goal of this assessment is to gain internal access to resources. Secondary goals of a wireless assessment include those of an internal assessment on achieving connectivity.

Physical Assessment: Physical security assessments focus testing activities on bypassing controls designed to prevent access to the facility and access to physical electronic data such as computing areas or telecommunication closet.

Personnel and Social Engineering: Personnel and social engineering assessments aim to test an organization's security awareness training and ability of personnel to follow procedures designed to safeguard their interactions with external parties.

46.3.4 Social Engineering. Security depends on people; therefore, people are the single weakest link in any penetration assessment and overarching VA. People possess the power to assist an attacker in covertly bypassing any security control in the environment with a minimal amount of resources. Social engineering is defined as the use of persuasive techniques to abuse an inherent trust relationship and induce personnel to divulge information or perform an action used to gain illicit access to systems or data. Social engineering attacks can be performed through multiple mediums of communication, such as telephone conversations, convincing emails, or spoofed Websites.

Social engineering attacks have historically been leveraged in many high-profile security breaches involving Advanced Persistent Threats (APTs). This is primarily due to the level of effectiveness, covert nature, high impact of return, and ease of execution. Including social engineering as a component of a penetration assessment should be considered to evaluate policies, procedures, and security awareness programs designed to protect the business and inform personnel of this particular threat.

Practical recommendations

- The decision to include Social Engineering as part of the assessment should align with objectives and goals.
- Precautionary measures should be taken to protect the testing team from unnecessary harm if they are identified; this can be provided through a "get-out-of-jail-free" document provided by upper management.

Common assessment scenarios

The following are example scenarios commonly executed during penetration assessments inclusive of Social Engineering tests:

- *USB/CD Drops*: The testing team stages a series of USB thumb drives or CDs with an auto-run or convincing “click me” executable. This executable “calls home” to an Internet rendezvous point once executed. This test is benign and rudimentary but a valuable determination of the susceptibility of authorized personnel to executing attacker provided code on internal systems.
- *Email Phishing/Pharming*: Hoaxes or scams are sent to a subset of targeted personal groups by an attacker masquerading as an internal employee or department with the intent of coercing them into responding, visiting a malicious Web page, or executing an attachment.
- *Call Masquerading*: The testing team contacts a provided list of phone numbers for a subset of personal groups within the organization to elicit information or perform an action by posing as an employee or contractor.

46.3.5 Managing a Penetration Assessment. Varying testing models can be used to fine-tune the impact of the penetration assessment and align it with the vulnerability management and assessment goals.

46.3.5.1 Announced versus Unannounced Testing. Announced testing introduces awareness to internal IT staff prior to the beginning of the assessment. The primary motivation behind announced testing is to reduce any perceived impact from testing activities.

- Due to heightened awareness, announced testing reduces the effectiveness of the assessment to accurately evaluate security monitoring and incident response processes.
- Announced testing can provide educational value by presenting a learning opportunity to internal security staff through the real-time observation of controls, which are attacked or circumvented.

Unannounced testing involves the covert performance of testing activities under the sole knowledge and authorization from upper management to perform the agreed-upon assessment. Unannounced testing will deliver the most accurate assessment of all tested security controls.

Due to the covert nature of unannounced testing, activities are commonly focused on demonstrating impact through only exploiting vulnerabilities, which will quickly and covertly lead to a desired trophy.

46.3.5.2 Testing Scope. The penetration testing scope should be developed so that it aligns with the objectives of the assessment and its purpose within the vulnerability management program. It should be noted that regulatory requirements may dictate the scope to include specific network segments or applications (e.g., the Payment Card Industry Data Security Standard, or PCI DSS).

Penetration assessments can be scoped to allow social engineering attacks and specify to what degree these attacks will proceed, such as targets for phishing campaigns or locations for USB/CD drive drops.

46 · 12 VULNERABILITY ASSESSMENT

Scope should ensure the assessment covers all intended areas within the VA, such as physical, personnel, and procedural controls.

- Scope should be reduced to a manageable number of targets within the environment for the allocated time period to ensure proper assessment of critical components.
- Scope reduction may eliminate a subset of vulnerabilities but may be necessary to ensure adequate time is available to test the environment and important assets using the provided methodology.

46.3.5.3 Testing Methodology. A penetration assessment should be performed under a consistent and repeatable methodology to ensure it can be operated in a repeatable manner for each VA.

Penetration testing activities involve a large variety of techniques and tools. The best way to harness and document the range of activities is through a vetted and documented methodology.

A structured methodology is crucial to accurately document the scope and depth for which testing activities should be performed.

- The assessment must be performed under a proven and structured methodology to be accepted by many third-party auditors or regulatory agencies.
- A structured methodology enables the ability to transition testing resources into and out of the assessment and provides results in a comparative manner between testing periods.

47 · 2 OPERATIONS SECURITY AND PRODUCTION CONTROLS

47.1 INTRODUCTION. Despite the enormous increase in individual computing on personal computers and workstations in the years since the first edition of this *Handbook* was published in 1975, centralized arrays of dozens, hundreds, or thousands of computers used in computational arrays and cloud services are still used for enterprise computing in applications devoted to the core business of the enterprise. This chapter focuses on how to run vital computers and networks safely and effectively.

Readers with a military background will note that operations security in the civilian sector is different from the OPSEC (a military acronym for “operational security”) designation used in military discourse. As defined by the Joint Chiefs of Staff of the United States military, “OPSEC seeks to deny real information to an adversary, and prevent correct deduction of friendly plans.”¹

In determining what operations security and production controls are required for any system, a thorough risk analysis should be conducted; you will find references throughout this *Handbook*. For a quick analysis, it may be helpful to use a few other common military acronyms and list the threats from their perspectives.

EMPCOA—enemy’s most probable course of action. What is the most likely course of action an attacker will take against your systems?

EMDCOA—enemy’s most dangerous course of action. What is the worst possible thing an attacker could accomplish?

Weighing these as part of a risk analysis can help tremendously to decide how to employ limited resources. The acronym *METT-TC*, which is essentially a larger version of the engineering triad of cost, time, and quality, may help. There are various versions of the *METT-TC* acronym, but perhaps the most useful stands for

- Mission (what we need to do),
- Equipment (what we have),
- Time (by when we need to do it),
- Troops (whom we have to do it),
- Terrain (where are we doing it), and
- Culture (the possible cultural considerations).

Each part of our *METT-TC* analysis should be self-evident, except for perhaps culture. Ignoring the management, political, and community cultures of the locations in which to install security controls is a frequent mistake, usually with dire consequences for both security and the careers of security professionals.

It is critical to be able to define precisely the terms associated with operations security and production controls before engaging in a discourse about them.

47.1.1 What Are Production Systems? A *production system* is one on which an enterprise depends for critically important functions. Examples include systems for handling accounts receivable, accounts payable, payroll, inventory, manufacturing systems, real-time process control, data-entry systems, Web-based client interfaces for e-commerce, critical information systems, portable data-handling systems, and management information systems. What is defined as critical is a function of the mission, not a uniform prescription. Thus, the accounts receivable may be a critically important function for a manufacturing company working on a tight profit

margin, with receivables needed to pay immediately for crucial supplies, but it may be less critical for a small group of successful partners running a consulting firm.

47.1.2 What Are Operations? *Operations* consist of the requirements for control, maintenance, and support of production systems. Operations staff are responsible for such functions as:

- Integrating new software systems into an existing configuration
- Running programs and batch jobs to update databases and create reports
- Installing new versions of production programs
- Maintaining production databases for maximal efficiency
- Managing backups (creation, labeling, storage, and disposal)
- Responding to emergencies and recovering functionality
- Mounting storage volumes of tapes, cartridges, or disks in response to user or program requests
- Handling special forms for particular printouts (e.g., check blanks)
- Managing all aspects of production networks, such as configuring routers, bridges, gateways, wireless propagation, and firewalls

47.1.3 What Are Computer Programs? A *computer program* is a set of instructions that tells a computer what to do to perform a task. Computer programs may be acquired, or they may be internally developed.

Internally developed programs are stored in computer systems in two basic forms. *Source* programs are in the form in which they were written (coded) by computer programmers. The statements in source programs are in languages such as COBOL, Visual BASIC, C++, and Java. Source language programs are kept in files and stored on disk folders called *source libraries* or *program libraries*.

Executable programs have been converted from source code, by *compilation* or *interpretation*, into a program that the computer can execute. Executable programs may be maintained in two separate forms: *object* and *load*.

An object program is a partially executable module that must be linked to other executable modules, such as input/output modules, to become a load module. As load modules, the programs are said to be in executable form. Executable programs are kept in *production libraries*, from which they are called when needed. Acquired programs are generally in object and load form. The source code is proprietary to the organization that developed it and is rarely given to the acquiring enterprise.

When internally developed programs have to be changed, programmers work with copies of the source programs. The copies are stored in another type of library, referred to as *programmer libraries*. The programmers make changes to their copy of the source programs, and go through a process of recompiling and testing until the modified program is working properly. When acquired programs require changes, often a contract to make the modifications is issued to the organization from which the programs were acquired. In some situations, internal programmers generate new programs and interfaces to the original acquired programs. The same libraries are used: source libraries for source code, production libraries for executable modules, and programmer libraries for work in progress. These libraries need to be protected. Loss or damage can entail huge costs and considerable inconvenience; recovering them can require a long time and great expense.

47 · 4 OPERATIONS SECURITY AND PRODUCTION CONTROLS

47.1.4 What Are Procedures? *Procedures* are sets of statements that tell a computer what to do in certain situations. They are unlike programs in that they are not compiled. Stored in files or databases, they are invoked and interpreted as needed. Procedural statements are made up of operational commands and parameters. The operational commands tell the computer what to do, and the parameters tell the computer which entity to act upon. *Job Control Language* (JCL) is an example of a procedural language. Procedural language statements often are used in database management systems and in security software products. On personal computers, *batch files* (.BAT) are a form of simple procedure.

47.1.5 What Are Data Files? Almost everything stored and maintained in a computer system takes the form of a *file*.² Programs, procedures, information, all are stored in files, using the concept of a file in its broadest sense; that is, a collection of related items. This usage has become most apparent with the ubiquitous personal computer (PC). Data files, as distinguished from program files and other types, are those that store information. In a PC environment, data files may be called documents. Documents are created by word processors, spreadsheet programs, graphics generators, and other application programs. In mainframe and midsize computer environments, data files are those created and maintained by applications such as payroll, accounting, inventory, order entry, and sales.

Some data files are transient; that is, they are created, used, and deleted within a short period of time. If lost or damaged, they can be reconstructed quickly, with little difficulty. There is usually no need to protect transient files. Other files, such as *master files* or organizational *databases* (groups of files that are linked to one another using a database management system or DBMS), contain information that is vital, confidential, or virtually irreplaceable. These files, generated by PCs, mainframes, and midsize computer systems, must be protected by security software and backup procedures to ensure against loss, destruction, theft, interference, and unauthorized disclosure.

47.2 OPERATIONS MANAGEMENT. The processes for effective and efficient management of operations have direct benefits on information assurance. In particular, these aspects of operations management are of special value for improving and maintaining security:

- Separation of duties
- Defining the role of the security officer or security administrator
- Limiting access to the operations center
- Defining secure change-control processes
- Careful controls over externally supplied software
- Managing quality assurance and quality control

47.2.1 Separation of Duties. *Separation of duties* (also discussed in Chapter 45 in this *Handbook*) is a key control that should be applied to development and modification of programs. In enterprises where there are systems and programming departments that create and maintain custom programs, each individual programmer is assigned a user ID and a password. In these enterprises, where programs are developed and maintained internally, changes are constantly made to programs in order to meet

changing business requirements. Modified executable programs, after recompilation and testing by programmers, are moved from their libraries into production libraries. Modified source programs are moved into source libraries. The programmers are responsible for keeping the source libraries current, while computer operations, or some other functional group separated from programming, may be responsible for maintaining the production libraries. When an updated executable program is transferred from the programmer's library to the production library, a transmittal is included, signed off by a manager in the programming department.

A particular consequence of the separation of duties is that a member of the operations staff should always be involved in the functional analysis and requirements definition phases for changes to production programs. The operations perspective is not always clear to programmers, and such issues as logging, backout, and recovery, as discussed later in this chapter, need to be brought to their attention early in the development and maintenance cycles.

It is critically important that programmers and operations staff understand that under no circumstances are programmers to install changes into production systems without adequate testing and authorization. Patch management is discussed in detail in Chapter 40 in this *Handbook*.

47.2.2 Security Officer or Security Administrator. Contemporary enterprises typically include a mix of external cloud-computing services, mainframes, mid-size computers, and local area networks (LANs) comprising hundreds or thousands of workstations, PCs, terminals, and other devices, all interconnected with one another, and often connected with the same mix in other enterprises throughout the world via the Internet.

A department, or an individual or small group in smaller enterprises, has the responsibility for providing and maintaining the security of files, databases, and programs. The title that is often associated with this function is *information security officer* (ISO) or *information systems security officer* (ISSO). This individual or department has the mandate to carry out the security policy as set down by the senior management of the enterprise. The security officer is empowered to allow or to disallow access to files, databases, and programs. In the language of the security officer, procedures are set up and maintained that establish relationships among individuals, programs, and files. Users, programmers, and technicians are granted privileges for full access, update only, or even read only. The security officer has the power to change or to revoke privileges (see Chapter 24 in this *Handbook* for details of operating-system security mechanisms; see Chapters 28 and 29 for discussions of identification and authentication).

47.2.3 Limit Access to Operations Center. Physical access to the operations center grants a person enormous power to disrupt production systems. Such access must be tightly controlled.

47.2.3.1 Need, Not Status, Determines Access. A fundamental principle for effective security is that access to restricted areas is granted on the basis of roles. Employees whose roles do not justify access should be excluded from autonomous access to production systems. In particular, high-placed executives, such as the president, chief executive officer, chief financial officer, chief operating officer, chief technical officer, and all vice presidents, should examine their own roles and determine if they should be able to enter the operations center unaccompanied; in most cases, such access is unjustified. Limiting their own access sets an important model for other aspects

47 · 6 OPERATIONS SECURITY AND PRODUCTION CONTROLS

of security policy and demonstrates that need, not social status or position within the corporate hierarchy, determines access to restricted areas. This issue is also discussed in Chapter 45 on employment practices and policies in this *Handbook*.

47.2.3.2 Basic Methods of Access Control. As explained in Chapters 28 and 29 in this *Handbook*, access control depends on identification and authentication (I&A). I&A can be based on:

- What one has that others lack (tokens such as physical keys or smart cards)
- What one knows that others don't know (user IDs and passwords or passphrases)
- What one is that differs from what others are (static biometric attributes, such as fingerprints, iris patterns, retinal patterns, and facial features)
- What one does differently from how others do it (dynamic biometrics, such as voice patterns, typing patterns, and signature dynamics)

A typical arrangement for secure access to an operations center may involve keypads for entry of a particular code or card readers programmed to admit the holders of specific magnetic-stripe cards, smart cards, or radio-frequency identification (RFID) tokens. If the operations center is a 24-hour operation with full-time staffing, the presence of operators provides an additional layer of security to preclude unauthorized access. Remote monitoring of sensitive areas increases security by discouraging unauthorized access or unauthorized behavior and speeds up the response to possible sabotage. For extensive discussion of physical and facilities security, see Chapters 22 and 23 in this *Handbook*.

47.2.3.3 Log In and Badge Visitors. Visitors to a facility that houses sensitive systems should be logged in (that is, their identification checked and recorded in writing) at a controlled entrance and provided with visitor badges.

In high-security applications, an additional login may be required when entering the operations center itself. To encourage return of visitor badges, some security policies require the visitor to deposit a valuable document, such as a driver's license, with the security guards at the main entrance.

The effectiveness of visitor badges as a means of identifying nonemployees depends entirely on the use of badges by all personnel at all times; if *not* wearing a badge is acceptable and common, a malicious visitor could simply hide a visitor badge to pass as an authorized employee.

The time of login and of logout can be valuable forensic evidence if malfeasance is detected. However, such records can be shown to be reliable only if the guards responsible for keeping the logs consistently verify the completeness and correctness of all information written into the logs. Video recordings of the entrance to capture the face of each visitor as well as the exact time of arrival and departure can be of great value both for identifying imposters and also for verifying that the security guards are doing their job properly.

47.2.3.4 Accompany Visitors. No unaccompanied visitors should be permitted to circulate in the operations center or in the facility housing such a center. In high-security facilities, someone must even accompany the visitor to the washroom and wait for the visitor outside the door.

If a consultant or temporary employee is to work on a project for longer than a day, it may be acceptable to grant that person a restricted pass for low-security areas; however, high-security areas, such as the operations center, would still require such a person to be accompanied.

When one of the authors (Kabay) was director of technical services for a large service bureau in Montreal in the mid-1980s, the president of the company arrived unannounced on a Saturday evening at the door of the operations center with a visitor to show him around the computer center. The young operator explained with some trepidation that the president's name was not on the list of approved solo visitors, and so he would not grant entry (although he offered to call his boss for authorization). To his credit, the president accepted the restriction gracefully—and wrote a letter of commendation for the operator on Monday morning.

47.2.4 Change-Control Procedures from the Operations Perspective.

When programmers have made changes to production programs and all documentation and testing procedures are complete, the new versions are formally turned over to the operations staff for integration into production.

47.2.4.1 Moving New Versions of Software into Production. Operations managers and staff must meet these demands when moving new versions of software into production:

- Identification—tracking which software is in use
- Authorization—controlling changes
- Scheduling—minimizing disruptions to production
- Backups—ensuring that all requisite information is available to restore a prior state
- Logging—keeping track of data input for recovery, and of errors for diagnosis of problems
- Backout—returning to a prior production version in case of catastrophic errors

47.2.4.1.1 Identification. Knowing precisely which versions of all production software are in use is the basis of production controls. Every module must have a unique identification that allows immediate tracking between executable code and source code; all changes to a particular module must be fully documented by the programming group. Unique identifiers allow the quality assurance process to ensure that the only modules that go into production are those that have been properly tested.

Most production shops use a three-level numbering scheme to track versions. Typically, version *a.b.c* (e.g., 7.13.201) is defined in this way:

- *c* changes every time anything at all—even a spelling mistake—is changed.
- *b* changes when program managers decide to group a number of fixes to errors into a new version for release to production.
- *a* changes when significant new functions are added; often the source code is completely renumbered if the changes are great enough.

The version number of object code must match the number of its source code. All object code should include internal documentation of its version number so that

47 · 8 OPERATIONS SECURITY AND PRODUCTION CONTROLS

the version can be ascertained instantly, without having to consult possibly inaccurate external documentation.

47.2.4.1.2 Authorization. Strict procedures must be in place to preclude rogue programmers from introducing modified code into the production suite. In addition to the dangers of introducing untested or undocumented changes, allowing any individual to modify production processes without verification and authorization by an appropriate chain of responsibility can allow hostile code, such as Trojan horses and backdoors (see Chapters 13, 16, and 20 in this *Handbook*), to be introduced into the systems.

47.2.4.1.3 Scheduling. Implementing any new version of a production system requires careful planning and scheduling. Operations staff must prepare for changes in all aspects of production that depend on the system in question; for example, there may be requirements for new printer forms, additional magnetic tapes, and other supplies that must be ordered in advance. New requests for operator intervention, or changes in status and error messages during production, necessitate appropriate documentation and training. Effects on other programs may require special preparations that must take into account the scheduling requirements of the other systems that are affected. In addition, new versions of software often are implemented immediately after major production jobs, such as end-of-year or quarterly processing, to maintain consistency within an accounting period. For all these reasons, scheduling is critically important for trouble-free operations.

47.2.4.1.4 Backups. When modifying production systems, operations staffs usually take one or more complete backups (see Chapter 57 in this *Handbook*) of the software and data to be modified. This procedure is essential to allow complete restoration of the previous working environment should there be catastrophic failure of the new software and data structures.

System managers and operators should be aware that if their proposed changes require reformatting disk drives on the production system, they must make at least *two* full backups to ensure that an error in one of the backups won't cause a catastrophe when the entire system has to be restored.

47.2.4.1.5 Logging. To allow recovery or backout without losing the new data and changes to existing data that may have been carried out using new software and data structures, all production programs should include a logging facility. Logging keeps a journal of all information required to track changes in data and to regenerate a valid version of the data by applying all changes to an initial starting condition. Logging requires synchronization with backups to avoid data loss or data corruption. Special requirements may exist when a new version of the production system involves changes to data structures; in such cases, applying the information about changes to the older data structures may require special-purpose application programs. Since programmers sometimes forget about such possibilities, operations staff should be prepared to remind the programming staff about such requirements during the design phases for all changes.

47.2.4.1.6 Backout and Recovery. Sometimes a new version of production software is unacceptable and must be removed from the production environment. This decision may be made immediately, or it may occur after a significant amount of data entry and data manipulation has taken place. In either case, operations should be able

to return to the previous version of a production system without data loss. This process involves restoring the earlier complete operating environment, with software and data in synchrony, and then using log files to repeat the data input and data modifications from the moment of changeover to the moment of fallback (see Chapter 52 in this *Handbook*).

Not all of the changes that were made using a new version will necessarily be applicable to the previous data; for example, if new fields were added to a database, the data stored in those fields would not be usable for an older, simpler data structure. Similarly, if fields were removed in the newer database, recovery will involve providing values for those fields in the older database. All of these functions must be available in the recovery programs and backups that should accompany any version change in production systems.

47.2.4.2 Using Digital Signatures to Validate Production Programs.

If an unauthorized intruder or a disgruntled employee were discovered to have gained access to the production libraries, it would be necessary to determine if there had been unauthorized modifications to the production programs.

Date and time stamps on programs can record the timing of changes, but many operating environments allow such information to be modified using system utilities that read and write directly to disk without passing through normal system calls. In those instances, there would be no time stamp or log entry.

One approach that has been used successfully is to apply checksums to all production components. Checksum software applies computations to programs as if the codes were simply numbers; the results can be sensitive to changes as small as a single bit. However, if the checksums are computed the same way for all programs, access to the checksum utility could allow a malefactor to change a module and then run the checksum utility to create the appropriate new checksum, thus concealing the evidence of change. To make such subterfuge harder, the checksums can be stored in a database. Naturally, this database of checksums itself must be protected against unauthorized changes, for example, using encryption. Storing checksums may make unauthorized changes more difficult to disguise, but it also extends the chain of vulnerabilities.

A better way of determining whether object code or source code has been modified is to use digital signatures. Digital signatures are similar to checksums, but they require input of a *private key* that can, and must, be protected against disclosure. Verifying the digital signature may be done using a corresponding *public key* that can be made available without compromising the secrecy of the private key. For more information on public and private keys, see Chapter 7 on encryption and Chapter 37 on PKI and certificate authorities in this *Handbook*.

When digital signatures are used to authenticate code, it may be possible to validate production systems routinely, provided that the process is not too arduous to be accomplished as part of the normal production process. For example, it should be possible to validate all digital signatures in no more than a few minutes, before allowing the daily production cycle to start.

47.2.5 Using Externally Supplied Software. Production often uses software from outside the organization; such software may be commercial off-the-shelf (COTS) programs or it may consist of programs modified for, or written especially for, the organization by a software supplier. In any case, external software poses special problems of trust for the production team. There have been documented cases in which production versions of software from reputable software houses have contained viruses

or Easter eggs (undocumented features, such as the well-known flight simulator in MS-Excel 97, which popped up a graphic landscape that included a monitor showing the names of the Excel development team). In addition, some consultants have publicly admitted that they deliberately include Trojan horse code (undocumented malicious programming) that allows them to damage data or inactivate the programs they have installed at client sites if their fees are not paid.

In large data centers, it may be possible to run quality-assurance procedures on externally supplied code (see Chapter 39 in this *Handbook*). Such tests should include coverage monitoring, in which a test suite exercises all the compiled code corresponding to every line of source code. However, it is rare that an operations group has the resources necessary for such testing.

The trustworthiness of proprietary external software written or adapted especially for a client ultimately may depend on the legal contracts between supplier and user. Such legal constraints may not prevent a disgruntled or dishonest employee in the supplier organization from including harmful code, but at least they may offer a basis for compensation should there be trouble.

47.2.5.1 Verify Digital Signatures on Source Code If Possible. If externally supplied code is provided with its source library as well as with compiled modules, operations should try to have the supplier provide digital signatures for all such programs. Digital signatures will permit authentication of the code's origins and may make it harder for malefactors to supply modified code to the user. In addition, the digital signatures can support nonrepudiation of the code (i.e., the supplier will be unable credibly to claim that it did not supply the code) and therefore the signatures may be useful in legal action, if necessary.

47.2.5.2 Compile from Source When Possible. Wherever possible, it is highly desirable to be able to compile executables from source code on the target machine. Compiling from source allows quality assurance processes to check the source for undocumented features that might be security violations and to couple the executables tightly to the verified source. In addition, compiling on the local system ensures that all calls to system routines will be satisfied by linking to executables such as dynamic link libraries (DLLs) supplied in the current version of the operating system.

However, compilation on a local system has additional implications that complicate implementation of new applications: Because the system routines being linked to the compiled code may not be identical to those used during the manufacturer's quality assurance tests, the customer organization must plan for its own quality assurance testing.

Operations staff should express this preference for source code clearly to the person or group controlling acquisition of external software. For more information about writing secure code, see Chapter 38 in this *Handbook*; for information about secure software development and software quality assurance, see Chapter 39.

47.2.6 Quality Control versus Quality Assurance. Throughout this chapter, quality assurance has been mentioned as an essential underpinning for operations security. *Quality assurance* refers to the processes designed to ensure and to verify the validity of production programs. However, another aspect of quality concerns the operations group: the quality of output. The process of verifying and ensuring the quality of output is known as *quality control*.

47.2.6.1 Service-Level Agreements. Unlike mathematical truth, there is no absolute standard of quality for computing operations. Every organization must define the level of quality that is suitable for a particular application. A commonly quoted principle in programming and operations is that there is a complex relationship among quality, cost, and development time: Increasing quality increases both cost and development time; shortening development time increases cost, if quality is to be maintained. It follows that every system should include a definition of acceptable performance; such definitions are known as *service-level agreements* (SLAs).

SLAs typically include minimum and maximum limits for performance, resource utilization, and output quality. The limits should be expressed in statistical terms; for example, “The response time measured as the time between pressing ENTER and seeing the completed response appear on screen shall be less than three seconds in 95 percent of all transactions and shall not exceed four seconds at any time.” SLAs may define different standards for different types of transactions if the business needs of the users so dictate.

47.2.6.2 Monitoring Performance. Computer-system performance depends on five elements:

1. Access time and speed of the central processing unit(s) (CPU)
2. Access time and speed of mass storage (disks)
3. Access time and speed of fast memory (RAM)
4. Application design
5. Available network bandwidth

Operations groups should monitor performance to ensure that the requirements of the SLAs are met. There are two approaches to such monitoring: (1) analysis of log files and (2) real-time data capture and analysis.

Log files that are designed with performance analysis in mind can capture the precise times of any events of interest; for example, one might have a record in the log file to show when a particular user initiated a read request for specific data and another record to show when the data were displayed on the user’s screen. Such level of detail is invaluable for performance analysis because the data permit analysts to look at any kind of transaction and compute statistics about the distribution of response times. In turn, these data may be used for trend analysis that sometimes can highlight problems in program or data structure, design, or maintenance. For example, an excessively long lookup time in a data table may indicate that the system is using serial data access because it had been designed without an appropriate index that would permit rapid random access to the needed records.

Another approach to performance monitoring and analysis is to use real-time monitors that can alert operations staff to abnormal performance. For example, an application program may be designed to calculate response times on the fly; the results may be displayed numerically or graphically on a *dashboard* for the operations staff. Values falling below a specified parameter may signal an abnormal condition, using color or sound to alert the operators to the drop in performance. Such *integrated performance metrics* allow the fastest possible response to performance problems. Extensive sets of real-time measures are sometimes called *situational awareness* tools.

Even if the application programs lack integrated performance metrics, it is sometimes possible to use system-level online performance tools to analyze system activity. In one instance in the experience of one of the authors (Kabay), for example, a software supplier in the mid-1980s had promised a response time of 10 seconds or less for all transactions, but one particular operation was taking 43 minutes. Because the SLA was violated, the client was threatening to sue the supplier for the entire development cost and the three years of maintenance payments—a total of \$3.8 million (about \$12 million in 2013 dollars). Using an online performance tool, it quickly became obvious that the transaction in question was generating an enormous amount of disk I/O (read and write operations): 80,000 random-access reads in a particular data set to filter out a few target records using a nonindex field. Installing and using an appropriate index and compacting the data set on that field as the primary key to provide rapid access to blocks of related records reduced response time to 6 seconds.

47.2.6.3 Monitoring Resources. Consistent monitoring of resource utilization is one of the most valuable roles of the operations staff. Data center operations should include regular analysis of system log files to track changes in the number of files, amount of disk free space available, number of CPU cycles consumed, number of virtual memory swap operations, and less esoteric resource demands, such as numbers of lines or pages printed, number of tape mounts requested, number of backup tapes in use, and so on. These data should be graphed and subjected to trend analysis to project when particular resources will be saturated if the trend continues. Even a simple spreadsheet program such as Excel can produce regression lines in graphs easily. Operations can then reduce demand either by improving aspects of production (e.g., optimizing programs to require fewer resources) or by increasing available resources (e.g., installing a memory upgrade).

Another level of analysis focuses on specific users and groups of users. Each functional group using the production systems should be analyzed separately to see if there are discontinuities in their trends of resource utilization. For example, a specific department might show a relatively slow and stable rise in CPU cycles consumed per month—until the rate of increase suddenly increases tenfold. If such a rate of increase were to continue, it could surpass all the rest of the system demands combined; operations therefore would investigate the situation before it caused problems. The cause of the discontinuity might be a programming error; for example, there might be a logical loop in one of the programs or a repeated computation that ought to have its result stored for reuse. However, the change in slope in CPU utilization might be due to introduction of new programs with a rapidly growing database; in such cases, operations would have to act to meet heavy new demands.

Disk space is often a key resource that can cause problems. If users fail to clean up unwanted files, disk space can disappear at an astounding rate. This problem is exacerbated by poor programming practices that allow temporary work files to remain permanently in place. Systems have been designed with tens of thousands of sequentially numbered temporary work files that had no function whatsoever after a production run was completed but that were accumulated over several years.

One of the methods widely used to reduce resource waste is *chargeback*. Using system and application log files, system administration charges the users of particular systems a fee based on their use of various resources. Sometimes these chargebacks are viewed as *funny money* because they are an accounting fiction—no money actually changes hands. However, requiring managers to budget carefully for computing resources can greatly improve attention to mundane housekeeping matters such as

cleaning up useless files. If the chargeback system extends to aspects of program performance such as number of disk I/Os, it can even influence programmers to optimize their design and their code appropriately. Optimization is appropriate when the total costs of optimization are less than the savings in resources and the increases in productivity that result from optimization efforts, measured over the lifetime of the application.

47.2.6.4 Monitoring Output Quality. The final component of quality control is the meticulous monitoring of everything that is produced in the data center and sent to users or clients. Although much printing is now performed on local printers controlled by users, in many situations the operations group is responsible for documents such as payroll checks, invoices, and account status reports. Every operations group must explicitly assign responsibility for verifying the quality of such output before it leaves the data center. Operators should keep careful logs that record various types of error (e.g., torn paper, misaligned forms, or poor print quality) so that management can identify areas requiring explicit attention or repairs to improve quality.

47.3 PROVIDING A TRUSTED OPERATING SYSTEM. The operating system (OS) is usually the single biggest and most important example of externally supplied software in a data center. Because the OS affects everything that is done in production, it is essential to know that the software is trustworthy. To this effect, operations staff use procedures to ensure that *known-good* software is always available to reinstall on the system. Systems with such software are known as *trustworthy computing platforms*.

47.3.1 Creating Known-Good Boot Medium. The simple principle that underlies known-good operating software is that there shall be an unbroken chain of copies of the OS that have never run any other software. That is, operations will create a boot medium (tape, cartridge, CD-ROM) immediately after installing known-good software.

For example, if boot-medium V1B0 is defined as version 1 of the OS as it is delivered from the manufacturer; its installation would require specific settings and parameters for the particular configuration of the system. Immediately after installing V1B0, but before running any other software, operations would create medium V1B1 and set it aside for later use if V1B0 had to be replaced.

47.3.2 Installing a New Version of the Operating System. Continuing this example of how to maintain known-good operating software, it might become necessary to install a new version of the operating system—say, version 2 on medium V2B0. Before using V2B0, operations would reinstall the current known-good OS, say from V1B1. Only then would V2B0 be installed, and the new boot medium V2B1 would be created immediately.

47.3.3 Patching the Operating System. Often, when it is necessary to modify a small part of the OS, rather than installing a whole new version, manufacturers ask users to *patch* the OS. The patch programs modify the compiled code in place. If checksums or digital signatures are in use to maintain OS integrity, these codes will

47 · 14 OPERATIONS SECURITY AND PRODUCTION CONTROLS

have to be regenerated after the patch is applied. However, to maintain a known-good status, applying a patch should follow a rigid sequence:

1. Load the current known-good software from the appropriate medium (e.g., V2B1).
2. Install the patch.
3. Immediately create a known-good boot medium before running any other software (in our example, this medium would be V2B2).

For extensive discussion of managing patches for production systems, see Chapter 40 in this *Handbook*.

47.4 PROTECTION OF DATA

47.4.1 Access to Production Programs and Control Data. Just as the operations center needs restricted access, so do production programs and data. From a functional point of view, there are three categories of people who might be allowed access to programs and data on which the enterprise depends: users, programmers, and operations staff.

47.4.1.1 Users. The only people who should have read and write access to production *data* are those users assigned to the particular systems who have been granted specific access privileges. For example, normally only the human resources staff would have access to personnel records; only the finance department staff would have full access to all accounts payable and accounts receivable records. Managers and other executive users would have access to particular subsets of data, such as productivity records or budget figures. Of course, *no* user should ever have write access to production *programs*.

47.4.1.2 Programming Staff. Programmers create and maintain production programs; they naturally have to be able to access the versions of those programs on which they currently are working. However, programmers must not be able to modify the programs currently used in *production*. All changes to production programs must be documented, tested, and integrated into the production environment with the supervision of quality assurance, operations, and security personnel.

Programmers need to be able to use realistic data in their development, maintenance, and testing functions; however, programmers should *not* have privileged access to restricted data. For example, programmers should not be allowed to read confidential files from personnel or medical records or to modify production data in the accounts payable system. Programmers can use extracts from the production databases, but particular fields may have to be randomized to prevent breaches of confidentiality. Programmers generally resent such constraints, but usually an effective process of education can convince them that maintaining barriers between production systems and systems under development is a wise policy.

47.4.1.3 Operations Staff. Much as the programmers are responsible for developing and maintaining systems, so the operations staff are responsible for using and controlling these systems. Operations staff perform tasks such as scheduling, error handling, quality control, backups, recovery, and version management. However,

operations staff should not be able to modify production programs or to access sensitive data in production databases.

47.4.2 Separating Production, Development, and Test Data. For obvious reasons, testing with production data and production programs is an unacceptable practice, except in emergency situations. Therefore, programmers who develop new programs or modify existing programs must perform tests using their own libraries. These are frequently referred to as test libraries. Experienced programmers keep copies of the source programs for which they are responsible as well as copies of some of the data files that are used by the programs and subsets of others in their own test libraries. To avoid security violations, such copies and subsets of privileged data should be anonymized to the degree necessary to protect confidentiality. For example, a system using personnel data might substitute random numbers and strings for the employee identifiers, names, and addresses.

It is important to include time stamps on all files and programs, including both production and test versions. This practice serves to resolve problems that arise about program malfunctions. If all programs and files have time stamps, it can be helpful in determining whether the most current version of the load program is in the production library and whether test files and production files have been synchronized.

Final testing prior to production release may entail more formal review by an independent quality assurance section or department; the quality assurance group may also control transfers of programs to the production library.

47.4.3 Controlling User Access to Files and Databases. Access to files has to be controlled for two reasons:

1. There is confidential information in files that is not to be made accessible to everyone.
2. There are other files that are considered auditable.

The information in these files may be confidential, but that is not the reason for controlling access to them. The information in these files must be controlled because changing it is illegal. An example would be an enterprise's general ledger file once the books have been closed. Changing the information in these files gave birth to the pejorative phrase *cooking the books*. The original copies of these files are developed on the computer that handles the day-to-day transactions of an enterprise. Some time after the month-end closing of the books, copies of these files are archived. In this form they are the recorded history of the enterprise and cannot be changed. Storing this chiseled-in-stone historical information, combining details and summaries in database format so as to be accessible for the purpose of analysis is known as data warehousing.

In most large enterprises, these files are created on mainframe and midsize computers, although microcomputer database servers in LANs are increasingly in use today. In any event, controlling user access to files is performed in several ways depending on what types of access are allowed. Remote access to online production databases and files is often done over leased lines—dedicated communication facilities paid for on a monthly basis as opposed to dial-up or switched lines paid for on a when-used basis. Access control may be readily accomplished through the use of front-end security software modules, which in turn feed into database and file handling software and finally into the application software. For example, in an environment using a software product

for handling queries and updates of online databases and files, a number of different security software products could be installed. Such products use what are called rules or schemas to validate user IDs and passwords, to authorize types of transactions, and to allow access to files and databases.

Many information system installations allow remote communications for many kinds of transactions. Various individuals, including sales representatives entering order information and traveling executives wishing to access current information from databases or files, use public networks, such as wired or wireless Internet service providers at hotels, airports, and coffee shops. This type of access increases the potential for security breaches. The usual practice today is to use *virtual private networks* (VPNs), which consist of encrypted channels between the portable equipment and the enterprise networks. Even so, some inadequate implementations of VPNs allow cleartext transmission of the initial logon information, allowing the identification and authentication data to be captured and used for unauthorized access. Poorly secured network access also allows *man-in-the-middle* attacks on the user's traffic.

For more information about encryption, see Chapters 7 and 37 in this *Handbook*; for more about network and communications security, see Chapters 5, 25, 32, 33, and 34.

47.5 DATA VALIDATION. Just as it is essential to have trusted operating systems and application software for production, the operations group must be able to demonstrate that data used for production are valid.

Validation controls normally are carried out dynamically throughout data entry and other processing tasks. Some validity checks are carried out automatically by database software; for example, inconsistencies between header records and details may be reported as errors by the database subsystems. Bad pointers are usually flagged immediately as errors by the database software; examples include:

- Pointers from a particular master record to a detail record with the wrong key value or to a nonexistent location
- Forward or backward pointers from a detail record to records that have the wrong key value for the chain or that do not exist at all

However, many errors cannot be caught by database subsystems because they involve specific constraints particular to the application rather than errors in the database itself. For example, it may be improper to allow two chemical substances to be mixed in a processing vat, yet there is nothing in the data themselves that the database software would recognize as precluding those two values to be recorded in the input variables. The programmers must include such restrictions in edit checks; often these relations among variables can be coded in a data dictionary. If the programming environment does not allow such dependencies, the programmers must incorporate the restrictions in lookup tables or in initialization of variables.

From a production point of view, operations staff must run appropriate validation programs created by the database suppliers and by the application programmers to assure the quality of all production data. The next sections review in more detail what is involved in such validation programs.

47.5.1 Edit Checks. Operations should have access to diagnostic programs that scan entire databases looking for violations of edit criteria. For example, if a field is

designated as requiring only alphanumeric characters but not special characters such as “#” and “@,” then part of the diagnostic sweep should be checking every occurrence of the field for compliance with those rules. Similarly, range checks (greater than, less than, greater than or equal, equal, less than or equal, between) are a normal part of such scans. Lookup tables listing allowed and forbidden data and combinations of data provide further sophistication for more complex relations and restrictions. In any case, the role of operations staff is to run the diagnostics and identify errors; correction of the errors should fall to authorized personnel, such as the database administrators.

Diagnostic programs should provide detailed information about every error located in the production files. Such details include:

- Configurable view of the record or records constituting an error, showing some or all of the fields
- Unique identification of such records by file name or number, record number, and optionally by physical location (cylinder, sector) on disk
- Error code and optional full-text descriptions of the error, including exactly which constraints have been violated

A diagnostic program should, ideally, also allow for repair of the error. Such repair could be automatic, as, for example, insertion of the correct total in an order-header, or manual, by providing for the database administrator to correct a detail record known to be wrong.

47.5.2 Check Digits and Log Files. Another form of verification relies on check digits. Programs can add the numerical or alphanumeric results of data manipulations to each record or to groups of records when transactions are completed properly. Finding records with the wrong check digits will signal inconsistencies and potential errors in the processing. Check digits are particularly useful to identify changes in production databases and other files that have been accomplished through utilities that bypass the constraints of application programs. For example, most databases come with a relatively simple *ad hoc* query tool that permits lookups, serial searches, views, and simple reporting. However, such tools often include the power to modify records in compliance with database subsystem constraints, but completely free of application program constraints.

An even more powerful type of utility bypasses the file system entirely, and works by issuing commands directly to the low-level drivers or to the firmware responsible for memory and disk I/O. In the hands of the wrong people, both database and system utilities can damage data integrity. However, it is usually difficult for the users of these utilities to compute the correct checksums to hide evidence of their modifications. A diagnostic routine that recomputes checksums and compares the new values with the stored values can spot such unauthorized data manipulations immediately.

If possible, checksums in log files should be *chained* from one record to the next so that the checksum for every record is calculated using the checksum from the previous record in addition to the data in the current record. Changing, adding, or deleting any record in the log file then requires the criminal to modify all subsequent checksums, and comparison of the modified log file with the backup of the original log file may easily identify the tampering because there are so many discrepancies in evidence.

A similar technique for validating and repairing data uses database and application log files to record information such as before and after images of modified records.

Such log files also can include special marker records to flag different steps in complex transactions; these flags can allow diagnostic programs to identify precisely when transactions have been interrupted or subjected to other forms of failure. Using these log files, it is often possible to identify which defective transactions need to be removed, repeated, or completed.

Commercial data-integrity software is available for a wide range of platforms and databases. Searching on “data integrity software” in the Google search engine (www.google.com) locates many references to such products.³

For more information on integrating security into application design, see Chapter 52 in this *Handbook*. For more about log files and other monitoring and control systems, see Chapter 53.
